25. **Thyroid and Parathyroid Grafts.**—Von Eiselsberg's experience has been disappointing, like those of others in this line. The implanted gland tissue sooner or later becomes absorbed. But there was unmistakable benefit at first in some cases, and this might tide the patient along until the natural gland had recuperated enough to resume its functioning. The benefit at first may be marked, but then it soon dies out, contrary to what occurs with thyroid treatment; here the benefit develops very slowly and gradually. He describes in detail his 2 cases of repeated thyroid grafting in cretin children, and also 4 cases of repeated grafting of parathyroids in adults for postoperative tetany. Two patients were cured and transient improvement was evident in the others. In connection with the above grafting experiments, he reviews the 22 cases of postoperative tetany that have developed in the last twelve years among his 1,300 operations on the thyroid. In 14 cases the tetany was mild and transient; in 4 it persisted for several years, nine months or six weeks, and in a fifth case it was extremely severe, but subsided after parathyroid grafting. In 3 other cases the patients succumbed to pneumonia not long after the operation, and the severe tetany had persisted during the interval. In 2 cases of long persisting tetany, cataract developed during its course. In some of the cases the postoperative tetany can be explained only on the assumption that the patients did not have the normal number of parathyroids at the time of the operation. Parathyroid grafting is not always feasible, as the donors can seldom spare enough parathyroid tissue for the purpose. Consequently, Eiselsberg advises waiting until parathyroids can be obtained from a child dying at birth or from a fatal accident. His one attempt to use a parathyroid from a monkey proved a failure.

26. **Thyroid Grafts.**—Payr has done seven transplanting operations on the thyroid in the last eight years. In five cases the interval since has been over three years. He thinks that the improvement in the myxedema which followed the grafting is to be ascribed to the implant, and justifies further work in this line even if the implant does finally become absorbed. Certain important conclusions can be drawn from his experience, namely, the necessity for distinguishing between congenital thyroid insufficiency and acquired insufficiency. Children born without a thyroid do not survive puberty, while cretins with a goiter may live to an advanced age. Signs of defective development of all or part of the brain render the outlook for treatment less promising. Zingerle and Scholz found decided pathologic changes in the brains of cretins, asymmetry of the hemispheres, unusually small size of certain lobes, abnormal convolutions or entire absence of convolutions in the frontal lobe, and abnormally large ventricles. These characteristic findings readily explain the inefficacy of any treatment.

Payr is convinced that the thyroid plays an important part in the development of the central nervous system; the earlier the thyroid loses its physiologic balance, the more serious the resulting influence on the development of the nervous system. The clinical forms of imbecility must be studied more closely so as to differentiate those in which thyroid functioning is at fault from the cases of mental impairment from encephalitis, hydrocephalus, syphilis, rachitis, steeple skull, etc. With acquired thyroid insufficiency we can hope for some relics of normal thyroid tissue. Thyroid treatment must be given a thorough trial before any grafting operation of the kind. If there is not the slightest benefit after a thorough parenteral course of thyroid treatment, the thyroid origin of the trouble is open to doubt.

In case of doubt he advises a small exploratory incision to expose the thyroid and show its actual condition. This is a very simple and harmless procedure even for small children, and the incision can be utilized to implant thyroid tissue at the same time. It might be advisable to make an incision at the root of the tongue in case there is suspicion of an aberrant thyroid here. Blood relations seem to be better for donors, and as so much of the graft is promptly absorbed it is wise to make it quite large. When the implant is in a serous cavity or organ, fitting tight and snug against the tissues, the conditions for nourishment may be better than when the reliance is on the sutured vessels. Thrombosis dooms the whole implant in the latter case. The marrow of the tibia, the spleen and the subcutaneous cellular tissue are the best sites for the grafting operations. The latter permits repetition of the grafting with less damage than at other points.

31. **Absorbable Tampons to Arrest Parenchymatous Hemorrhage.**—Jeger and Wohlgemuth make a fibrous, lint-like mass out of a delicate membrane taken from the intestines of sheep or cattle. It is frozen in a solid mass and then cut into very thin slices which break up into extremely fine threads. It is sterilized by keeping for three days in a 5 per cent. solution of phenol and then rinsed well in alcohol. The soft fibrous mass is rinsed in salt solution before using and is applied still dripping to the bleeding surface. The capillary attraction of the fibers is equal to that of strips of gauze, and the broad stream of blood is thus changed into innumerable minute streams, thus multiplying the surface area—a powerful factor in the coagulation of blood. The fibrous mass is also pressed down on the bleeding surface like any tampon, but it is gradually absorbed. Not a trace of it could be seen after four or six weeks in the experiments on dogs' livers, spleens, etc., reported.

33. **The Thymus.**—Nordmann was unable to detect any influence on the growth or development in any way of dogs thymectomized soon after birth. His evidence is all against the assumption that the thymus is a vitally necessary organ. On the other hand, when the thymus is unduly enlarged and probably hyperfunctioning it is liable to set up or aggravate exophthalmic goiter. He operated on the thyroid for exophthalmic goiter in eighteen patients and three died during the operation, and in all of these—a man of 48 and two women of 28 and 23—the thymus was found unusually large for their age. The others were all cured by the operation on the thyroid. In some cases everything seems to incriminate the thymus as the cause of exophthalmic goiter. In any event the thymus should be investigated in every case, and if the thyroid seems practically normal while the symptoms are severe, the thymus is probably at fault. It should be resected if unduly large for the age. If not enlarged, the intervention had better be restricted to simple ligation of the vessels at the poles of the thyroid. If no improvement follows this in the course of months, resection of the thyroid should be advocated. When the exophthalmic goiter is of purely thymic origin, the patients seem to be unable to stand the simplest operative procedures, not even ligation of the vessels of the thyroid under local or general anesthesia. The operation in itself and the resulting shock seem to be the cause of death with persisting thymus, and yet one of the patients in his group with fatal outcome had passed through an operation for ruptured tubal pregnancy without harm two years before. It is possible that the operation on the thyroid causes the production of certain fatally poisonous substances. It is certainly noteworthy that some of these patients had had operations done on the thymus without harm; the thyroid had been left unmolested, however.

39. **War Neurology.**—Oppenheim is in charge of what he calls the Nerven-Lazarett at Berlin with 100 beds, exclusively for soldiers with nervous affections. Neuroses and psychoses are not so frequent among the troops as might be anticipated, and as a rule they develop only in the predisposed, either by previous nervous or mental affections, trauma affecting the head, or abuse of alcohol. The vasomotor sphere seems to be peculiarly affected in these war neuroses. The syndrome of exophthalmic goiter developed in one officer, but disappeared again after a six weeks' rest cure. Oppenheim has been impressed with the remarkable variety of the symptoms that may follow a gunshot wound of the head. The destruction caused by the bullet on its way is responsible for them, not the bullet itself, he thinks.

When a bullet hits the spine and swerves aside, the impact may cause hemorrhage in, softening or acute necrosis of the spinal cord, even with intact vertebrae. What to do in these cases is a problem. He operated in five, but learned nothing definite except possibly that signs of a total lesion of the cord do not contra-indicate operative measures unless of several months' standing.

The sensory nervous system participates to a remarkable extent in gunshot wounds of the peripheral nerves; sometimes the sensory fibers alone seem to be injured. The agonizing pains are relieved only transiently by morphin in large doses. These pains seem to occur only when the nerve is partially injured and not when the injury blocks the entire nerve, as a rule. He has had several cases in which the bullet had injured the sensory fibers and no others in the sciatic nerve. There was anesthesia of the sole, while the motor functioning and electric excitability were normal. These experiences confirm Stoffel's views on treatment of spastic paralysis.

The psychic and remote vasomotor and secretory phenomena in some cases suggest that the impact of the projectile caused a wave of molecular changes in the various parts of the central nervous system. The terrific neuritic pains were sometimes relieved by a hot bath or superheated air or a plaster dressing. The pains usually become attenuated in time, but this may require months.

41. **Freezing Injuries.**—Actual freezing requires rubbing with snow or cold cloths and then wrapping in cotton to allow the limbs to warm up in bed without artificial heat. The same is advisable also when there has not been actual freezing. To emphasize the danger from artificial heat, even when the parts are not actually frozen, Melchior reports the case of a robust young man who had been out with snow shoes in extreme cold and danced in the evening. On the homeward trip he put his cold feet on the stove in the car, and rapid gangrene followed with sloughing of all the toes. When gangrene threatens, the stasis may be arrested by slitting the end of the finger or toe down to the bone, as Noesske has recommended (described in The Journal, 1909, liii, 1605). This measure rendered good service during the recent Balkan wars. When gangrene has developed, the drying up of the tissue can be hastened by peeling off the epidermis. The benefit from this is especially apparent when the epidermis has been partly removed and patches of it left. The mummification and healing of the bare areas proceed much more rapidly than elsewhere, as the epidermis acts like an impermeable membrane damming up the secretions, the sweat glands, etc., having lost their functional capacity in the gangrenous region.

42. **Transfusion of Blood.**—Plehn says that during the seventeenth century attempts were made to tranquilize persons with rabies and insane persons by transfusion of the blood of the gentle lamb. Denis and Tardy used a silver catheter for the purpose, but owing to the disapproval of the Paris medical faculty the procedure was abandoned until revived about 1820. Plehn took it up about six years ago and has applied it in thirty cases, mostly of pernicious anemia. The technic for keeping the blood at body heat until it enters the vein is still far from perfect. He found that it lost several degrees between the donor and the recipient in his cases. The primary symptoms as the blood begins to flow into the vein gradually become attenuated and there seldom are secondary symptoms unless 600 c.c. or more is transfused. With 200 or 250 c.c. he has had no secondary reaction. The symptoms are slight fever, head-

ache and prostration and possibly a chill. The donor's blood must show at least 95 or 80 per cent. hemoglobin. Plehn's results have been incomparably better since he has made a point of selecting persons with polycythemia for the donors.

Four of his patients were practically moribund and soon succumbed notwithstanding transient benefit from the transfusion. One of these was a woman almost exsanguinated from a bleeding myoma. When the blood was allowed to pour into the vein it seemed to meet with some hindrance; the transfusion was then changed to the other arm but the same hindrance to the inflow was encountered. This rendered it evident that the trouble was in the right heart itself, the degenerated muscle not being strong enough to manage with the extra supply of blood. Constriction was then applied to the vein below to retard the inflow, and with this modification the whole amount was infused, 550 c.c. of blood and 500 c.c. isotonic salt solution, the procedure taking nearly an hour. Toward the last there were nausea and chilliness and the temperature ran up to 40 C. but these soon subsided and the woman's condition was improved so much by the transfusion that three days later an attempt to remove the myoma could be made.

In a fifth case a robust man of 49 had had stomach disturbance for six months and then pernicious anemia developed in the course of a few weeks. When the hemoglobin had dropped from 25 to 23 in a week, 400 c.c. of blood from a young woman was infused plus 500 c.c. salt solution. Symptoms of intoxication followed, with death the nineteenth hour. The blood of the donor induced agglutination and hemolysis with blood from other patients, and the dead patient's urine contained hemoglobin. The extra mechanical task imposed on the heart renders extreme caution necessary during the infusion. Attacks of coughing are evidently due to the overfilling of the vessels in the lungs. They cease as the heart adapts itself to its task. The infused fluid must be kept at body temperature or there is liable to be trouble, but aside from this, if there is no tendency to hemolysis—and this can be excluded by preliminary tests—the secondary disturbances need not be feared. His experience with transfusion in cases of secondary anemia has been extremely gratifying, as also preliminary to operations in which considerable loss of blood is feared, with placenta praevia, extra-uterine pregnancy, etc. As there does not seem to be any tendency to anaphylaxis with transfusion of blood, it can be repeated as often as needed. He has found it the best means to arrest subacute hemorrhages, and theorizes to explain the mechanism of its action in this and other respects, emphasizing in conclusion that the transfusion requires trained assistance.

48. **Nosebleed in Children.**—Petry relates the case of a child of 9 who for a year had suffered from recurring epistaxis and was extremely anemic. She had been treated with iron for the anemia but the nosebleed kept returning. Finally two minute ulcers were discovered on the septum, the source of the bleeding, and as soon as these had been cauterized with trichloracetic acid there was no further hemorrhage and the anemia rapidly gave place to normal conditions. During sepsis and acute infectious diseases, the diagnosis of "septic nosebleed" should never be made without inspection of the nose, as an overlooked bleeding ulceration may do great harm as he shows by a number of examples. In one case a child of 7 had pneumonia, fever, headache and vomiting, and by the end of the week he began to vomit large amounts of dark clotted blood and was much agitated. No one, not even the trained nurse, suspected that the blood came from the nose until a small bleeding ulcer was found on the septum and promptly healed under an epinephrin salve. In two other cases pneumonia set in with profuse epistaxis and necropsy in one case showed numerous emboli of diplostaphylococci in the capillaries of the nasal mucosa. The mucosa in the non-fatal case presented the same aspect. In a third case the profuse epistaxis came on likewise late in the course of pneumonia, and the nosebleed was followed by extravasation of blood into the skin at various points. The child had tossed around so much that the ecchymoses at various points were evidently of a traumatic nature, but the hemorrhages were none of them profuse enough to have proved fatal if it had not been for the continuous drain from the bleeding ulcer on both sides of the septum. It is more than probable, Petry adds, that the child might have been saved if the bleeding ulcers in the nose had been discovered earlier. The hemorrhages were ascribed to the sepsis in general and no search was made for a possible local source.

53 *Treatment of Furuncles. A. Schüle.

49. **Acute Injuries of the Esophagus.**—Grober discusses the treatment of caustic corrosion of the esophagus, foreign bodies, etc., and wounds of the esophagus in war. He warns against any attempt to remove foreign bodies by mechanical means except under direct visual inspection with endoscopy. Until this can be done the patient's pain and distress can be alleviated by sipping a solution of cocain, a drop or so at a time, keeping well under the maximal dose, or twenty drops of a 1 per cent. solution of morphine in a tablespoonful of water. The region should be examined with the endoscope also if the slightest disturbance is noted a few days after a foreign body in the esophagus has been expelled by vomiting or has been carried down and off through the stomach and intestines. Gunshot and bayonet wounds of the esophagus display a marked tendency to spontaneous healing. In one such case the man died a week later from a wound in the head received at the same time a bullet had severed about a third of the circumference of the esophagus; necropsy showed that the opening had healed without suppuration. The man had been given nothing by the mouth except ice water. With cancer in the esophagus, the physician's task is to inform the family but keep the patient from suspecting the nature of his trouble. Here more than anywhere else perhaps, he remarks, is the difference more evident between the true physician and the "for revenue only" type. In management of a diverticulum, relief can often be obtained from an emetic; he has one patient who for years has taken an emetic every morning and thus regularly clears out his diverticulum.

53. **Treatment of Furuncles.**—Schüle declares that every furuncle can be aborted in the first forty-eight hours if the center is burnt out under local anesthesia with 2 per cent. novocain injected first to make a blister and then injected perpendicularly into the center of the boil. The actual cautery can then be used to burn out the center or merely a knitting needle can be used, heated red hot in an alcohol flame. The knitting needle can be stuck through a cork for a handle. To prevent further furuncles developing the skin should be cleansed with soap, rubbed with alcohol and any suspicious looking points painted with tincture of iodin, burning out the center if a furuncle does develop. Even with a fully developed furuncle he advocates burning out the center plug in this way rather than to incise. The hyperemia thus induced aids in warding off new infection.

60 Chronic Duodenal Ulcer; Clinical Study of Operative Treatment. F. Kaspar.

54. **Plastic Operation on the Esophagus.**—Jianu has applied in two further cases his method of making a new esophagus out of a strip of tissue cut from the greater curvature of the stomach and brought up under the skin of the chest to form a tube opening into the stomach and serving as the gullet. These two cases show that the operation can be done success-

fully even on much debilitated children, and that the technic is comparatively simple and easy even when the stomach is adherent to the abdominal wall. He answers the various objections that have been made to the method.

55. **Diabetes and Surgery.**—Fischer reviews his experience with various operative measures for surgical affections in 86 diabetic patients. The total mortality was 48.8 per cent., but it was 54.5 per cent. in the 57 requiring operative treatment; and 72.7 per cent. in the 11 amputations for diabetic gangrene. In 8 of his 23 cases of diabetic carbuncle the diabetes was discovered first when the carbuncle developed.

57. **Cystinuria.**—In Frankenthal's two cases the output of cystin was reduced when meat was dropped from the diet but then there was almost constant pain. When meat was allowed, plus sodium bicarbonate, there was little cystin but still great pain, regardless of whether the patient was in bed or up and about. On a meat diet the amount of cystin crystals increased but the pain was less, the patients increased in weight and felt better. The first patient was a woman of 24 and a cystin stone was removed from her kidney pelvis. The other was a boy of 3 and the concrement causing the trouble was in the bladder. It cast a shadow and measured 3x2.3x1.6 cm.

59. **Serodiagnosis of Cancer.**—Trubina obtained a positive response to the Abderhalden test in 95 per cent. of 73 cancer cases, but 50 gave a positive response also with placenta tissue, and 13 of 19 pregnant women gave a positive response with cancer tissue.

64 *Trauma and Pulmonary Tuberculosis. A. Mayer.

61. **Abdominal Syphilitic Affections.**—Hoppe-Seyler expatiates on the variety of clinical pictures which may be presented when syphilis attacks the liver, and the severe impairment of the general health which results. But appropriate treatment in time corrects conditions completely, even serious changes in the liver tissue retrogressing so that full functional capacity is restored. The syphilitic nature of the liver trouble is liable to be overlooked and as long as this is the case suitable treatment is not applied. In some cases early in the second stage of syphilis symptoms develop of what seems to be ordinary catarrhal jaundice; they may subside and return or keep up for a long time. The jaundice is caused sometimes by swelling of the portal lymph glands, thus compressing the outlet for the bile. In other cases the catarrhal affection is restricted to the bile ducts. The liver with syphilitic jaundice is usually enlarged, smooth, often tender, and the spleen may be enlarged likewise without ascites, and there may be fever of a variable type. Symptoms of cirrhosis of the liver may appear and if the tissues around become inflamed there may be violent pains. Sometimes the pain with syphilitic disease in the liver simulates in every respect actual gall-stone colic; this has led to useless operations in numerous instances on record. The cirrhosis sometimes develops without jaundice; the liver is large and smooth but not tender and there may be no congestion in the portal domain. The spleen may be enlarged from the same characteristic tendency to proliferation of connective tissue and there may be anemia, the clinical picture thus simulating splenic anemia or pseudoleukemia. In some cases the liver is found small and hard and knobby, the spleen enlarged, with ascites and anemia—the whole thus deceptively resembling Banti's disease. In other cases the liver is hard and shriveled, with a knobby surface as in typical Laennec's cirrhosis; this form is generally found in connection with abuse of alcohol. Deep grooves may cut the liver into queer shapes, and there may be inflammation around with adhesion to the parietal peritoneum. When this is the case the assumption of cancer seems justified, except that the spleen is usually enlarged also and that the trouble does not progress so rapidly as malignant disease. Particularly in the young, syphilis is liable to entail gummatous growths in the liver; it grows large and tough, protruding at unusual points, with much pain and fever.

Still another clinical picture is that from inflammation of the walls of the portal vein and vicinity, with thrombosis and shriveling, followed later by stasis in the portal domain, ascites, and hemorrhoidal hemorrhages, while the liver keeps small and soft.

When the vicissitudes of a campaign are superposed on these clinical pictures, the outlook is serious unless specific treatment is applied at once. A vigorous course of iodid and mercury can do no harm in any event, and the result may be a complete cure. He warns to be very cautious with salvarsan in cases with fever and jaundice, as acute atrophy threatens; under other conditions an intravenous dose of 0.2 gm. salvarsan once a week is usually borne without harm and may transform the clinical picture. The diet must be restricted as usual with liver affections.

The pancreas and kidneys may likewise be affected with the syphilitic proliferation of connective tissue, and glycosuria up to severe diabetes mellitus may develop in consequence. Cases are comparatively frequent of mild syphilitic interstitial pancreatitis with cirrhosis of the liver, or syphilitic interstitial nephritis leading to secondary contracted kidney.

Syphilitic affections of the aorta and other vessels seldom retrogress so completely under specific treatment as the liver and pancreas affections. Prophylaxis here is the main thing, seeking to stamp out the syphilis in time, and to avoid physical strain and abuse of alcohol or tobacco. Gummas develop by preference where the tissues have been injured or overworked.

64. **Trauma and Tuberculosis.**—Mayer was unable to find in his experimental research any evidence indicating that blood-borne tubercle bacilli located by preference at a point in the lungs previously injured by trauma. But trauma reduces the resisting powers in general and thus favors the development of pulmonary tuberculosis, just as chilling, hunger, fatigue, etc., lower the barriers to infection. It follows from these premises that pulmonary tuberculosis may develop as the result of trauma even when the trauma did not act on the lungs. Peripheral injuries may be responsible for the development of pulmonary tuberculosis; that is, the disease might not have developed if it had not been for the trauma.

65. **Chronic Thyroiditis Explains Death at Operation.**—Brünger's two patients were women of 35. The first required an operation for hernia; the other was operated on to relieve mild exophthalmic goiter. The first died as the general anesthesia was just commenced. In the second case the anesthesia was with scopolamin, an opium preparation and eucain, but the patient never roused, and the fourth hour the respiration became very slow, only twice in thirty-five seconds for a time. As the breathing improved the pulse grew worse, and death ensued sixteen hours after the operation. The thyroid was not much enlarged and only on one side. The first patient had had mild exophthalmic goiter diagnosed years before but it had apparently retrogressed completely long ago. In both cases, however, the thyroid showed changes typical of Basedow's disease and also of chronic inflammation and hyperemia. The findings in these

cases and in a thyroid removed from another patient confirm the analogy between Basedow's disease and Bright's disease. The various phases of the inflammation in the thyroid correspond to the changes in the kidneys which entail Bright's disease. In the above cases there was pronounced lymphocytosis and the ovaries were abnormally large. The first patient was of the type called status lymphaticus, the other status thymicus, as, although the thymus was not palpable yet it was abnormally large for the age.

66. **Serodiagnosis of Cancer.**—Cytronberg urges further study to avoid the present sources of error in Abderhalden's dialysis method of differentiating cancer. Even allowing for the present imperfections in the technic, there can be no question that it is highly specific especially with incipient cancer. Before accepting a reaction as negative, he applied the test with another specimen of cancer tissue and sometimes obtained then a positive response. Tissue from a solid cancer particularly rich in cells gives the most instructive reaction. The work issues from Goldscheider's service (Berlin) and the clinical details are compared with the results of the test in 97 cases including thirty-five certain and five of suspected cancer. The tabulated findings show remarkable unanimity in the different groups, especially the digestion of cancer tissue alone in the cancer group and of pancreas tissue alone in the group of diseases of the blood-producing organs.

68. **Factors in Coagulation of Blood.**—Fonio refers to hemophilic blood in particular as his further research has confirmed that the blood platelets are actively concerned in coagulation and that the red and white corpuscles are only passively enmeshed in the clot. The platelets in the blood of a hemophiliac are not below but are rather above the normal figure. According to his experience, about 350,000 is the average figure in health. The platelets from a hemophiliac seem to be less capable than from a normal person. When added to hemophilic blood they do not hasten clotting, but, strange to say, they do when added to normal blood, hastening the clotting even more rapidly than in normal conditions. These facts and others learned in his research demonstrate, he says, that the blood in hemophiliacs contains thrombogen in normal amounts and power but that the reaction between it and the platelets is insufficient because some element is lacking in the latter, and it is our task now to discover and supply this lacking element. The fact that the platelets were in normal numbers or above in one hemophiliac with 22 per cent. hemoglobin and only 2,036,000 reds, suggests that the production of the reds and of the platelets occurs at different points. The hemophiliac whose case is described in detail was of the fourth generation of a bleeder family. In purpura and similar hemorrhagic affections the number of platelets is abnormally low (149,048 and 0 in two cases cited), but the platelets seem to be normal in themselves. This difference in the platelets content may serve to differentiate such affections from true hemophilia.

69. **Influence of Iodin, Etc., on Myxedema.**—Frey gives the detailed findings in myxedema in a young woman and a girl of 10 given systematic courses in turn of iodin, potassium iodid, iodothyrin and of an iodin-free extract of goiterous thyroids. The metabolism, temperature, pulse and clinical picture of the myxedema were recorded from day to day over long periods. The research was done in Kocher's service and is practically a continuation of work along much the same lines in 1911. Iodin alone transformed the blood picture while thyroid extract free from iodin was entirely ineffectual in this line. Iodothyrin acts more powerfully than iodin alone. The neutrophils increased by 11.8 and 12 per cent. under the iodin and by 29 and 14 per cent. under the iodothyrin. The lymphocytes decreased by 15.8 and 14 per cent. under iodin and by 27 and 12 per cent. under iodothyrin. The effect was most pronounced in the younger patient. It was so striking that it suggests a possible benefit from iodin and iodothyrin in other pathologic conditions accompanied by lymphocytosis, such as the lymphoid form of leukemia.

70. **Ulcerating Colitis.**—Albu has encountered two acute and twenty-one chronic cases of ulcerative colitis, and comments on the remarkable lack of cicatricial changes afterward in the intestinal mucosa. Only when the ulceration had been unusually extensive or had burrowed very deep was there much scarring, but the mucosa showed striking anemia over large areas and it was sometimes hard and thick like leather. Treatment requires much perseverance on the part of both physician and patient; bed-rest, food that spares the bowels as much as possible, and astringents applied to the mucosa are the main features of treatment. A mixed albumin and vegetable diet has proved the best for these cases, the food all fluid or soft mashed, with gelatin in the form of meat, milk and fruit jellies. For local application he prefers a dry astringent powder applied through the rectoscope. When the latter is not available, a suspension of an astringent in ¼ liter tepid water can be injected. The enema is retained for twenty or thirty minutes. The mucosa must be thoroughly cleaned each time before the local procedure, flushing it abundantly through a two-way tube with a warm dilute soda solution. Gradual improvement and sometimes a complete cure was realized by these measures. In a few others the colitis recurred and the patients were finally cured only by making an artificial anus on the right side to leave the diseased gut at rest except for systematic flushing with astringent solutions from above. This required a year in one case; another patient still has his artificial anus after four years as every attempt to close up the opening has brought back the trouble anew. In the two cases in which the appendix fistula or artificial anus was closed after several months, the stools still show traces of blood and pus, and after every error in diet the condition becomes aggravated so the patients have to stay in bed for a time. His experience with surgical treatment has not been very encouraging; it should be restricted, he says, to the desperate cases in which almost any attempt to relieve is justified, especially when there are repeated hemorrhages. In a later series of five cases there is constant constipation and the inflammatory process seems to be limited to the ampulla of the rectum and entrance to the sigmoid flexure. A suspension of bolus alba and animal charcoal by the mouth and by the rectum has proved more effectual in his recent experience than anything previously tried in one of his rebellious cases. On a mixed diet there has been no return of diarrhea for five months to date. A tablespoonful of the bolus and animal charcoal mixture in a glass of water is taken half an hour before breakfast, and before this, after the intestine has been rinsed clean with warm soda solution, an injection is made into the rectum of a tablespoonful of the mixture in ¼ liter of warm water. The number of passages and the tenesmus became reduced at once and there was less pus evident. He gives a colored plate to show the typical rectoscope findings with ulcerative colitis.

73 *Does Menstruation Influence Hemolysis by Vaginal Bacteria? Hellmuth.
74 Serodiagnosis of Pregnancy. (Spezifität der Abderhaldenschen Fermentreaktion.) M. Fetzer.

73. **Influence of Menstruation on Hemolysis of Vaginal Bacteria.**—Some authors hold that hemolysis is a specific characteristic of certain very virulent strains of streptococci. Others consider it only an accidental characteristic dependent on the blood content of the nutrient medium. Hellmuth describes in detail a series of experiments undertaken to show whether hemolysis does occur with vaginal bacteria during menstruation, and he finds that it does not. Even in two cases in which metrorrhagia had persisted for weeks, no hemolytic bacteria could be demonstrated. In the three cases in which hemolytic bacteria were found, he thinks that they did not develop during menstruation from non-hemolytic ones, but reached the vagina through invasion or inoculation. He does not feel that he has proved that the faculty of hemolysis could not develop under long continued hemor-

105. **The Blood in Inherited Syphilis.**—Chiaravalloti analyzed the blood of 150 children with certain inherited syphilis. The blood was of the anemic type in all, whatever the age or manifestations of the syphilis. The hemoglobin ranged from 12 to 75 per cent., averaging about 56.8. The reds were also usually below the normal proportion. The differential leukocyte count is extremely variable but nothing strictly characteristic was observed. Abnormal findings in the leukocyte count in any direction may confirm the assumption of an inherited taint. Very frequently an inherited taint with both syphilis and tuberculosis was apparent.

106. **Fermentation Test Applied to Infants' Stools.**—Luna states that the fermentation test may sometimes reveal in olerance of carbohydrates escaping all other methods of examination when there is intestinal inflammation. The sound infant intestine eliminates only minute amounts of carbohydrates as waste. Infants with flatulent dyspepsia and positive findings with the fermentation test should be fed very little carbohydrate but much albumin. He tabulates the findings in five typical cases showing the prompt improvement under dietetic treatment on these premises.

107. **The Tryptophan Reaction in Children's Cerebrospinal Fluid.**—Segagni reports that in eight cases of tuberculous meningitis, one of cerebral hemorrhage and one of a cerebellar tumor, the tryptophan reaction was constantly negative.

108. **Intravenous Injections in Infants.**—Maggiore confirms the advantages and the convenience of selecting the external jugular vein as the one to puncture in drawing blood or for intravenous infusion. The child lies on his back, the head turned away and held by another person. He uses a needle and rubber tube and bulb rather than a syringe, and says that the large branches of the vein can be utilized in the same way in case it is necessary to repeat the puncture.

114 *Pathogenesis of Peptic Ulcer. R. Crescimone and B. Anglesio.

114. **Anemia a Factor in Peptic Ulcer.**—Crescimone and Anglesio induced anemia in dogs by daily subcutaneous injection of 1 per cent. solution of pyridin. By the tenth day the hemoglobin had dropped to 25 or 30 per cent. and the reds to about two million. The anemia continued a progressive course, the animals dying between the tenth and forty-fourth day with one exception. In fifteen of the sixteen animals lesions were found in the stomach or duodenum or both and nowhere else. These lesions displayed the characteristics of peptic ulcers, and they regard them as analogous to the first stage of chronic ulcer in man. In some of the dogs the vagus had been severed, and this seemed to aggravate the lesions. The experiments reported and the literature reviewed seem to sustain the assumption that an anemic condition is an important factor in gastric or duodenal ulcer, and that treatment of the peptic ulcer should not disregard the underlying anemia.

121 *Salvarsan Alone in Syphilis; Four Years' Experience. R. Krefting.
122 *Etiology of Dementia Praecox. (Aarsaken til dementia præcox.) B. Ebbell.

117. **Action of Digitalis.**—Holst discusses the history of and reviews recent literature on this subject and then relates a number of unusual cases to show the action of digitalis in different conditions. It may have a diuretic action without or before manifesting any influence on the heart. Some patients can stand remarkably large doses; one man of 60 took 7.3 gm. of digitalis in twenty-two days with great benefit and no apparent by-effects. Another patient, a telegrapher of 22, developed symptoms of heart-block with Adams-Stokes phenomenon during the course of acute articular rheumatism, and the symptoms grew worse under a dose of digitalis but subsided entirely an hour after subcutaneous injection of 2 mg. atropin, and complete recovery followed.

118. **Effusions, Etc., Share in Circulation.**—Scheel injected 0.10 gm. of methylene blue into the pleural effusion of a woman with severe valvular disease. The urine voided the next day and for seven more days was highly colored by the stain, showing that the pleural effusion participates in the circulation, even when it is impaired as seriously as in this case. This assumption was further confirmed by the discovery that the edema fluid in the legs was also tinted by the stain. In other patients similar tests were made with 1 gm. hexamethylenamin, by the mouth and with urea, showing that each passes into the edema and pleural effusion in a very few hours. A dropsical accumulation therefore must be regarded as a flowing stream instead of a stagnant pond.

121. **Four Years of Exclusive Salvarsan Treatment of Syphilis.**—Krefting never had any threatening by-effects from the salvarsan in the 718 cases of syphilis in which he has given it, and all but 3 were outpatients, and the drug was given by intravenous infusion. The cure was so complete in 10 cases that the men have acquired syphilis anew since. In the 221 cases of primary syphilis, 3 were given at least three injections and 70 only one or two—all with a two weeks' interval and with doses of 0.5 to 0.6 gm. for men and 0.3 to 0 4 gm. for women. His experience teaches, he says, that salvarsan is just as effectual alone as when combined with mercury, and that there are no actual contra-indications.

122. **Dementia Praecox and the Thymus.**—Ebbell presents evidence which seems to demonstrate a connection between some primary anomaly or acquired disorder of the thymus and the development of clinical symptoms of the dementia praecox type. The pathologic anatomic findings in dementia praecox, he continues, seem to be identical with those found in animals after partial destruction or total removal of the thymus. This assumption of thymus insufficiency as the cause of dementia praecox harmonizes with the observation of its hereditary nature and with the influence of acute infectious diseases and abuse of alcohol. When the dementia praecox develops in childhood there may be some congenital deformity of the thymus. Attempts to treat animals and human beings with thymus extract or in substance have given no results. This is but natural, Ebbell remarks, as an artificial chemical mixture or devitalized tissue is unable to do the work of the living thymus. Transplantation of thymus tissue seems the only encouraging prospect, and progress must be sought along this line, although Klose and Vogt have reported disappointing results in two dogs; scraps of thymus tissue were implanted in the omentum and spleen of two thymectomized dogs but the scraps were all absorbed in time.

INSTITUTIONAL MORTALITY OF THE NEW-BORN

A REPORT ON TEN THOUSAND CONSECUTIVE BIRTHS AT THE SLOANE HOSPITAL FOR WOMEN, NEW YORK *

L. EMMETT HOLT, M.D.
AND
ELLEN C. BABBITT
NEW YORK

Much interest has recently been awakened in a study of infant mortality during the early weeks. The importance of such a study is evident for several reasons. According to the best recent statistics available, one-third of the deaths of the first year occur in the first month of life, and seven-eighths of these come in the first two weeks. Using our own statistics to supplement these, of 100 infant deaths during the first year, approximately

33 occur in the first month
28 occur in the first two weeks
22 occur in the first week
13 occur on the first day

This is a concrete statement of the problem of infant mortality from one point of view. While the campaign for the reduction of infant mortality has greatly lowered the deaths from diarrheal and nutritional diseases and has made some considerable impression on respiratory and contagious diseases, thus far it can hardly be said to have touched at all the causes of the large group of deaths in the first month. Finally, at no time of life is diagnosis so difficult and the records of vital statistics so unreliable in giving the exact causes of death as during the first month.

It was thought, therefore, that an analysis of a group of cases from an obstetric hospital would shed considerable light on several phases of the problem under discussion. The records of the Sloane Hospital for Women in New York have been kindly placed at our disposal by Professor Cragin for this study. These records are especially valuable for such an investigation as they are unusually complete and have been kept with great care.

While the number of cases analyzed is small when compared with the statistics of a large city, the hospital figures have the greatly added value of more accurate diagnosis and are in all respects much more reliable than records available from general vital statistics.

What is an average or normal mortality among 10,000 births? How do the general figures of the city compare with those of a special institution? How much of the general mortality of the first two weeks could be prevented by proper obstetrics? How much of it is due to malformations and unavoidable accidents of delivery — causes which are beyond the reach of usual or even extraordinary preventive measures? Some of these questions we hoped to answer.

Ten thousand consecutive confinements in the Sloane Hospital for Women have been analyzed for this paper. These occurred during a period of about six and one-half years, ending in October, 1913. They were divided as follows:

Abortions (fetus non-viable, less than 37.50 cm. in length)	253
Stillbirths (fetus viable, 37.50 cm. or over in length)....	429
Living births	9,318
	10,000

The hospital receives but few waiting women; nearly all are admitted after labor has begun. Patients are regularly discharged on the fourteenth day, and complete mortality records are therefore possible only for this period. In many cases infants who were ill, not thriving or premature, were kept for a longer time and some interesting facts regarding hospital mortality during a period longer than fourteen days are presented in this report.

In our paper we have first followed the fortunes of the 9,318 infants born alive, and later have analyzed the stillbirths.

The total deaths occurring in the first fourteen days were 291, these being 3.1 per cent. of infants born alive. Of these, 159, or 54.6 per cent., occurred in infants born prematurely; 132, or 45.4 per cent., occurred in infants born at term. Prematurity must, therefore, be recorded as the largest single factor in infant mortality of this period.

The following tabulation gives the exact time of death in premature infants and those born at term:

	Premature	Full Term	Total
Died on first day	102	38	140
Died on second day	8	10	18
Died under one week	135	98	233
Died during second week	22	34	56

Of infants born alive, 1.5 per cent. died on the first day;[1] 2.5 per cent. under one week; 3.1 per cent. during fourteen days. Nearly one-half (48 per cent.) of the deaths of the first fourteen days were on the first day.

Curiously, a report by Kerness[2] from the Universitäts Frauenklinik, Munich, for four years, 1907-1911,

---

* Read before the American Association for the Study and Prevention of Infant Mortality, at the Fifth Annual Meeting, Boston, Nov. 12-14, 1914.

[1] Twenty-seven died during the first two hours. Were these classed as still-births, as is not infrequently done, the total mortality under 14 days would be lowered from 3.1 to 2.8 per cent.

[2] Kerness: Ztschr. f. Kinderh., 1912, Referate, iv, 19.

gives exactly the same mortality, 2.5 per cent. of 9,610 living births during the first eight days. The figures given by him for the other periods are not recorded, so that they cannot be compared.

Infants have been classed as premature if they were born after the beginning of the twenty-seventh week of gestation and before term. As reliable information on this point was not usually possible to obtain, the length, weight and general development of the child were also used as a guide. Infants have been considered premature who measured less than 46 cm. (18½ in.) in length, and also those whose weight was less than 2,275 gm. (5 pounds). Only two cases have been included among the prematures in which these figures for weight and length were both exceeded; these were regarded as premature for other reasons.

The measurements of the premature infants were as follows:

Length	
40 to 44 cm.	90 infants
44 to 47 cm.	64 infants
47 to 48½ cm.	10 infants

Weight	
Under 3 pounds.....	40 infants
3 to 4 pounds	72 infants
4 to 5 pounds	63 infants
5 pounds and over ..	8 infants

Only two of this last group were over 46 cm. in length.

The causes of the premature birth in many of the cases were not recorded, but certain facts were obtainable from the records. The age of the mother, the condition of the baby and the number of the pregnancy were usually noted. The age of the mother seemed to be without influence. In only four instances was the mother under 15½ years of age, and in no case under 14 years. Three others were between 17 and 19 years; 103 between 19 and 30 years; 46 between 30 and 40 years, and only 1 was over 40 years. In 90 cases the mother was a multipara; in 70 cases a primipara; one unknown. The baby's condition was recorded as good in only 13 per cent.; fair in 31 per cent.; but poor in 56 per cent.

The labor was spontaneous in 132 cases and induced in 27 cases; in 20 of the latter the reason was toxemia of pregnancy.

We will now pass to a consideration of the causes of deaths during the first two weeks, taking them up in the order of their frequency. These are shown in the accompanying table.

CAUSES OF DEATH DURING FIRST FOURTEEN DAYS*

	Under One Day		Under 7 Days		Seven to 14 Days		Total Under 14 Days		Grand Totals

* Ten thousand confinements: Abortions, 253, stillbirths, 429; living births, 9,318. (Prematures—heavy type.)

CAUSES OF DEATH DURING FIRST FOURTEEN DAYS

Congenital Weakness.—This was assigned as the cause of death in 134 premature infants, and in 9 full-term infants, making a total of 143, or about one-half (49.4 per cent.) of the total deaths under 14 days. This, then, is one of the very largest and most important factors of infant mortality. Its cause must be sought in the physical condition of the mother during her pregnancy, but not in circumstances connected with delivery.

Accidents of Labor.—Accidents of labor were responsible for but 33 deaths, only one of which was in a premature infant. The most important accidents were intracranial hemorrhage and injuries to the head. The single premature infant died from a meningeal hemorrhage aften ten hours; no forceps were used, and the diagnosis was confirmed by necropsy. Intracranial hemorrhage in infants born at term was given as the cause of death in 18, nine coming to necropsy. Of these 18 cases, forceps were used in 7, and 10 were breech presentations.

Besides the cases classed as intracranial hemorrhages, injuries to the head were put down as the cause of death in 10 cases, necropsies being made in 3. Of the 10 cases, forceps were used in 8, and 2 were breech presentations. The most frequently mentioned causes of these accidents were difficult deliveries, persistent malpresentations and prolonged labor, the latter usually before admission to the hospital. Combining the above we have intracranial hemorrhage or injury to head or upper part of spine as the cause of death in 29 cases; of which 15 were forceps, 12 were breech deliveries and the diagnosis confirmed by necropsy in 13 cases.

Other accidents of labor causing death in rare instances were: Rupture of the liver, 2 cases; rupture of hematoma of the liver and peritoneal hemorrhage, 1 case; rupture of umbilical cord before labor, 1 case.

In 10,000 deliveries, therefore, accidents of labor caused death in but 0.33 per cent. of the cases. Of the 291 deaths, 33, or 8.8 per cent., were due to this cause. Very few of the accidents of labor mentioned here belong to the preventable causes of infant mortality. That death was due to such causes in but 0.33 per cent. is explicable only by the skilled management of complicated cases. Outside of a special hospital the death-rate from causes of this sort would surely be higher; but in such an institution, even when we consider that a much larger proportion of complicated cases are treated than occur in general practice, deaths from accidents of labor form an astonishingly small fraction of the infant mortality.

Malformations and Congenital Diseases Other Than Syphilis.—Of the 12 deaths from these causes, 4 were cardiac malformations; 2, intestinal; 2, of the nervous system, and 4 were recorded as status lymphaticus. Only 2 were in premature infants; of the 10 occurring in infants born at term, 8 were confirmed by necropsy. Monsters have been included among the stillbirths. These figures of course do not represent the number of malformations in 10,000 births, but only those which caused death in the first fourteen days. Four other deaths from malformations occurred in the hospital between the fourteenth and the forty-second day.

Atelectasis.—This was a cause of death in 25 infants during the first fourteen days, 4 of these being in premature and 21 in infants born at term. They form a total of 8.6 per cent. of all deaths. Necropsies were obtained in only 5 cases. Atelectasis is also given as a cause of death in 7 infants in the hospital after the fourteenth day. The causes of atelectasis were not determined. All but 3 were normal deliveries, one of these being a breech, and 2 were cases in which forceps were used.

Asphyxia Neonatorum.—Asphyxia was a cause of death in eight born at term; in none of those born prematurely. It caused 2.7 per cent. of all the deaths in the first fourteen days. Six of the deaths occurred during the first six hours and all of them occurred on the first day of life. Among the causes of asphyxia were mentioned: Laryngeal obstruction; knot in the cord; cord tightly around neck; a loop of cord pulled out alongside the head with the forceps; application of the forceps to the after-coming head and inhalation of liquor amnii. In two cases there was placenta praevia.

Congenital Syphilis. — The records of the Sloane Hospital offer but a limited field of observation on the results of this disease for two reasons. In the first place, cases which are markedly and definitely syphilitic are not, as a rule, received, although in fact a good many are admitted where symptoms are not very marked. In the second place, the Wassermann test was applied in but a small proportion of the cases used in these statistics. The figures for syphilis, therefore, are much smaller than doubtless would have been obtained were the cases taken from an institution of a different character, or from the city records outside of hospitals.

Congenital syphilis was named as a cause of death in 13 infants during the first fourteen days; 12 were premature and one born at term. In addition, there were 6 others, 3 premature and 3 infants born at term that died from this disease during their stay in the hospital later than the fourteenth day. The diagnosis of syphilis, as indicated above, rested in only a small number on the Wassermann test, but on the other symptoms, such as hydrops of the placenta, definite evidence of syphilis in the mother, pathologic evidence in the placenta, a history of other premature births or previous miscarriages, macerated stillbirths, etc.

Hemorrhage of the New-Born.—No deaths in premature infants were recorded from this cause. Ten occurred in infants born at term, forming 3.4 per cent. of the deaths in the first fourteen days. The earliest death occurred on the third day, three each on the fourth and fifth day, one each on the sixth, ninth and eleventh day; there was one also on the sixteenth day. Six received some form of serum treatment. Two had received full doses of human serum without effect; two, single doses of rabbit serum without effect; one, human serum, late and in small doses, without effect; in one other, full doses of rabbit serum, late, without effect.

Sepsis.—No premature infants died from this cause; but of those born at term, 9 died from sepsis, making 3 per cent. of the deaths in the first fourteen days. However, 5 additional deaths occurred in the hospital from sepsis between the fifteenth and twenty-fifth days. Of the infants dying before the fourteenth day, cord infection, phlebitis, and abscess of the liver were present in 3 cases; cellulitis of the scalp and infection of the antrum of Highmore in one each, and 2 were of unknown origin. Deaths from sepsis later than the fourteenth day were 5, from the following causes: meningitis secondary to abscess of the scalp, cellulitis of the neck, suppurative mastitis, multiple abscesses; and one, cause not known. Two were forceps deliveries. The 12 deaths from sepsis were scattered through five years, not more than 2 deaths from this cause occurring in any single year. This is a striking evidence of the efficiency of the asepsis of the institution.

Pneumonia.—Pneumonia was the cause of death in 28 infants, or 9 per cent. of those occurring during the first fourteen days, and of 38 infants who remained in the hospital for a longer time, none, however, more than thirty-two days. Thus the total number of deaths from pneumonia was 66, or 17 per cent. of the total 387 deaths which occurred among infants while in the institution. There were twice as many deaths as those due to accidents of labor. Pneumonia thus ranked next to congenital weakness as a cause of death during this period. So far as season is concerned, no special influence is seen on the occurrence of pneumonia; the largest number (39 per cent.) occurred in the fourth quarter of the year.

Several distinct house epidemics of pneumonia were observed. In March, 1909, four deaths occurred from this cause within two weeks; in October, 1910, there were 5 deaths in four weeks; in September and October, 1912, there were 7 deaths in five weeks; in December, 1912, there were 5 deaths in three weeks. Many of these cases were diagnosticated lobar pneumonia and in a large proportion of those coming to necropsy extensive consolidation of the lung was found. In nearly all of the cases, however, catarrhal symptoms of the upper respiratory tract preceded the pneumonia. Only a small proportion of the pneumonias were seen in the first week of life, nearly two-thirds of the deaths occurring between the fourteenth and seventeenth days.

In obstetric hospitals, as in all institutions where infants are brought together, respiratory infections must therefore be reckoned among the greatest dangers to which these small inmates are exposed. More liberal accommodations for babies must be furnished than those provided in most of our obstetric hospitals and greater care to prevent crowding must be exercised. It is also imperative that those infants who are suffering from even the milder types of infection should be promptly and completely isolated from the healthy, and that nurses also with infectious colds should be temporarily relieved from duty.

STILLBIRTHS

Probably no part of vital statistics is so unreliable as the records of stillbirths. This is due to many causes. The first is that there is no general agreement among the keepers of records as to what should be called a stillbirth. In New York City and State a case is classed as a stillbirth in which a child has never breathed nor shown other signs of life. This is perhaps the best definition that can be given. There is good ground for the belief that for religious reasons death certificates are sometimes written for stillbirths ascribing the death to other conditions. This would tend to raise slightly the figures for infant mortality during the first days of life. But there is not the slightest doubt that a considerable proportion of stillbirths are never registered at all. A convenient and not an uncommon way of reducing the infant mortality rate is to class as stillbirths all the deaths that occur soon after birth. A clerk of the board of health in a middle western city stated to one of us that prior to 1911 death certificates in his city for infants under one week of age were not filed at all. Some registrars of vital statistics have admitted that they were accustomed to class as stillbirths all children dying in two hours; others, all who died in the first two days. In our figures, had we classed as stillbirths all dying in the first two hours, we would have reduced our mortality 10 per cent. Had we excluded the deaths of the first two days, the mortality would have been reduced 50 per cent. From all these considerations it is evident that it is somewhat difficult to determine with even approximate accuracy what is the proportion of stillbirths to living births. The records of New York City may be taken as fairly trustworthy for a large municipality — they are much more reliable than those of most cities — especially since the classification mentioned above is rigidly adhered to. The past records of many cities are entirely unreliable and we cannot compare infant mortality figures until definite knowledge of what is included as stillbirths has been determined.

The percentage of stillbirths in an institution where careful records are kept is therefore of special interest. In the 10,000 confinements at the Sloane Hospital there were 429 stillbirths or 4.29 per cent. It is interesting to see how this compares with the general records of the city. In 1912 the stillbirths were 4.64 per cent. of the 142,280 total reported births; and in 1913 they were 4.65 per cent. of the 141,765 reported births. These figures are sufficiently close to those from the Sloane Hospital to add much to their reliability. While the records of birth registration in New York are not absolutely complete, the Registrar of Vital Statistics estimates that as a result of agitation and penalties enforced during recent years, over 98 per cent. of the births are now recorded.

In comparing hospital with general statistics it should be remembered that difficult and complicated cases form a much larger proportion of those admitted to a special hospital than occur in general practice. This would have the effect of considerably raising the proportion of stillbirths; since in half these the cause of the stillbirth is prolonged, difficult or complicated labor. But it would be expected that more skilful obstetrics and better care would tend to lower the proportion of stillbirths. That the percentage was reduced to 4.29 at Sloane certainly speaks well for the character of the work done there. We have been unable to obtain comparable statistics from other lying-in hospitals in this country. Kerness, however, has given the figures from the *Universitäts Frauenklinik* in Munich. Among 10,297 confinements in four years ending October, 1911, there were 5.22 per cent. stillbirths. What the percentage would be in our different cities were they all reported and honestly registered, one can only conjecture. Taking the Sloane figures as the basis of an opinion they ought not in general practice to be much over 4 per cent.

Period of Gestation.—It was difficult to determine the period of gestation with anything approaching accuracy. This is best estimated by the length of the fetus.

Less than	42.5 cm. (16¾ in.)	56 cases
42.5 to	47.5 cm.	112 cases
Over	47.5 cm. (18¾ in.)	261 cases

More than half these cases were therefore evidently premature infants.

Of the cases, 75 per cent. were admitted during labor and but 25 per cent. were admitted previous to labor. In nearly half the cases (48 per cent.), as the fetal heart could not be heard, the child was presumably dead on admission; while in 250 (57 per cent.), the heart was not heard during labor. Further evidence of the great number of deaths before admission was the fact that in 162 cases (37 per cent.) the fetus was macerated.

The mode of delivery was as follows:

Normal	189 (44 per cent.)
Version with breech extraction	80 (18 per cent.)
Breech	76 (17 per cent.)
Forceps	59 (13 per cent.)
Craniotomy*	20 (4.6 per cent.)
Cesarean section	5 (1.1 per cent.)

*Craniotomy was done on only dead fetuses.

Particular interest attaches to the causes assigned for the death of the fetus.

Prolonged, difficult or complicated labor: (Difficult 75; prolonged, 25; placenta praevia, 29; prolapsed cord, 38; cord around neck, 29; accidental hemorrhage, 18)	196 (45 per cent.)
Toxemia of pregnancy	63 (14 per cent.)
Syphilis	40 (9 per cent.)
Prematurity	18 (4 per cent.)
Monsters	7 (2 per cent.)
Unknown	87 (21 per cent.)

SUMMARY

The deaths in the hospital during the first fourteen days were 3 per cent. of the living births. For half this number prematurity was responsible.

Forty-eight per cent. of the total deaths and 66 per cent. of those due to prematurity occurred on the first day.

Congenital weakness and atelectasis together made up 58 per cent. of the total deaths.

The mortality from conditions intimately connected with delivery — accidents of labor, hemorrhage, sepsis and asphyxia — together made up but 20 per cent. of the deaths of the first fourteen days.

Malformations and congenital diseases other than syphilis caused 4 per cent., and syphilis 4 per cent.

The only important disease developing after birth was pneumonia.

Stillbirths must be reckoned as one of the large problems in infant mortality; they are one and a half times as many as the deaths from all causes during the first two weeks. Except for the larger rôle played by syphilis, the causes of stillbirth in no way differ from those which produce death during the first days of life.

When we come to consider to what degree preventive measures might influence the mortality of the first two weeks of life, two things stand out prominently: The great number of deaths from congenital weakness can be reduced only by care of the mother during her pregnancy; the number of stillbirths and the deaths from causes connected with parturition can be largely reduced by good obstetrics.

Uses Served by Morbidity Reports.—In some diseases morbidity reports make it possible to see that the sick receive proper treatment, as in ophthalmia neonatorum, diphtheria, and, in certain cities, tuberculosis. The reporting of cases of ophthalmia in the new-born makes it possible to save the sight of some infants who would otherwise not receive adequate treatment until after much damage had been done. In diphtheria the health department can be of service in furnishing antitoxin. Some cities furnish hospital or other relief to consumptives who would otherwise be without proper treatment.—John W. Trask, Supplement No. 12, Public Health Reports, April 3, 1914.

SARCOMA OF THE TONGUE

A STUDY OF THE PUBLISHED CASES WITH REPORTS OF TWO NEW CASES

W. T. COUGHLIN, B.S., M.D.
Fellow of the American College of Surgeons; Assistant Professor of Surgery, St. Louis University School of Medicine
ST. LOUIS

A diagnosis of sarcoma in any part of the body seems always to fill the mind of the attending surgeon with a certain foreboding of ill in the prognosis. Rightly or wrongly, there persists for a time at least in the minds of those near the patient the haunting fear that there is far more likelihood of recurrence, or of metastasis, than probability of complete and permanent cure after the first surgical intervention.

The cases here reported aroused an interest, and a study of the condition was undertaken to find out the known and published facts concerning sarcoma of the tongue. The reader will not be wearied with airy speculation, and scant space will be given to any theoretical opinion, no matter how eminent its source.

Search through the literature (English, French and German) has brought to my notice fifty-eight reported cases. From a study of these and the two of my own, the following opinions were formulated.

Of course, one is aware that reports of not all the cases are published. The same is true of sarcomas elsewhere as of other conditions. However, one will conclude that at the present day the disease that can boast of only fifty-eight reported cases must be rare. Most of the cases have been recorded since 1885. Butlin at that time wrote of sarcoma of the tongue, "It would be quite useless to try to write an account of it which shall be useful."

The best article I have found on the subject is that of Fripp and Swan[1] herein frequently referred to.

ETIOLOGY

Age—It is the commonly accepted opinion that all varieties of sarcoma are more common in children. I think this is the usual medical school teaching. Let us see whether it be true with regard to sarcoma of the tongue.

The disease may be prenatal in onset — the congenital type. There are three such cases on record, those of Jacobi,[2] Naegele[3] and Delbanco;[4] that is to say 4.9 per cent. of all reported cases were congenital.

Of the postnatal type the earliest was one appearing in a 7-weeks-old child.[5] The next earliest was in a child of 10 months,[6] and this completes the number of cases of the acquired type found in children under 1 year, 3.2 per cent.

Two more cases, one at 2 and the other at 4 years, make a total of four seen in the first decade, that is, 7.8 per cent. of the acquired type. No cases whatever were reported between the ages of 4 and 14, and all of those occurring in the second decade were seen between the ages of 14 and 19. Three cases at 17, two at 19 and one at 14 make up the total, six cases, between 10 and 20 years, or 11.7 per cent. Adding together those in the first two decades, we find ten cases showing up in patients under 20 years, 19.6 per cent. of all.

I believe that this ought to convince one that the disease is not more common in the early years of life.

After adult life is reached the condition is more frequent. Thus in the twenties there are ten reported cases, 19.6 per cent., or just exactly as many as are found in the first two decades put together. The oldest of these was 28 and the youngest 22 years of age.

In the fourth decade the maximum of frequency is attained — fourteen cases, or 27.4 per cent. of all acquired cases, were found in the thirties.

Between 40 and 50 are only six, 11.7 per cent., and in the sixties only four are recorded, 7.8 per cent., and the oldest of these was 65. The oldest patient of all was 71, and this was the only one found in the eighth decade.

In seven of the cases recorded no mention was made of the age. These were thrown out and the foregoing percentages calculated on a total of fifty-three cases of the acquired type.

Sex.—On looking over the cases one is impressed with the preponderance of males — thirty-three cases. The number of females is twenty. In seven of the cases no mention of the sex was made. The relative known proportion of males to females is 33 : 20, or 62.2 : 37.7 per cent. One cannot conclude that it is more common in either sex at any particular period of life, the foregoing relations being fairly well maintained in all the decades.

Nationality.—In only seven cases was mention made of the nationality of the patient. Five of these were Europeans and the other two (my cases) were American born, the one of Irish and the other of Italian descent.

Occupation.—This was stated in ten cases, one was a pupil in a grammar school and one in high school. Two were medical students, one was a teacher, and the remainder were of the laboring class. One should not be surprised to find most of the cases coming from among the laboring class, nor should one hastily conclude that the disease must be more common in laboring persons. There are probably more persons in this than in any other class, and the percentage of cases may not be higher.

Previous Injury.—In only ten of the cases was any mention made of previous injury. In four the tongue had been bitten some time previously, ranging from eight months[7] to eight years (author's Case 2). Another had a broken tooth, which irritated the side of the tongue, and heavy cigaret smoking was supposed to have increased the irritation.[8] In one a cyst had been removed five years before and the tumor grew in the scar.[9] In one the tongue had been scalded two years previously.[10] In one a beard of wheat penetrating twenty-two years,[11] and in one a fish-bone entering two months before[12] may have been etiologic factors. It is possible then that previous injury may play a part in the etiology in at least 16 per cent. of the cases of sarcoma of the tongue.

PATHOLOGY

Site.—The location of the growth is stated with fair accuracy in forty cases. In fifteen cases it was said to have been located at the tip or within half an inch therefrom. In only three[13] of these was there at first involvement of the under surface, and one is said to have involved the whole thickness of the anterior third.[14] Of these fifteen cases, six were on the right and only one on the left, while the remaining eight were about the middle of the tip. The total number found involving the base of the tongue was nineteen. Five cases were said to have been on the right and two on the left side of the base. In five cases "the right half" and in three "the left half" was said to have been involved.

Altogether then, sarcoma of the tongue seems to have been more common on the right side and toward the base, although no one part of the tongue can be said to be an especially favorite site of the growth.

The sarcoma begins most often in the tongue substance and grows toward the dorsum, soon causing a projection on the upper surface. In one instance, however, in which it sprang from the root or the base of the tongue above the hyoid bone, it grew downward and forward, causing a bulging beneath the chin.[15] Here, as elsewhere, it is the rule for sarcoma to infiltrate the muscles lying in its neighborhood, growing between the fibers, which are soon destroyed. It soon traverses the median septum and invades the other side of the tongue. It spreads to the faucial pillars and to the floor of the mouth, and when either or both of these become involved the organ becomes fixed, thus rendering the patient unable to protrude the tongue, and increasing the difficulty of swallowing.[16]

The rate of growth varies greatly. One case was said to have been growing twenty-two years.[11] It had, however, begun to grow rapidly a short time before operation. In by far the greater number of cases the patient came for relief in less than ten months after the appearance of the growth, in one within six weeks.[17]

Pedicle.—The tumor has been provided with a pedicle or stalk in six instances.[18] In one of these a growth could be traced through the pedicle into the tongue,[19] and in another[12] there was recurrence, so that in these two at least there can be no doubt as to the correctness of the diagnosis; the others are doubtful.

Size.—The size of the tumor is mentioned quite frequently and varies within wide limits. The smallest was only "the size of a large pea."[20] Another was "as large as an orange," while one weighed 400 gm.[21] and the others varied between these limits. The smallest was of the round-cell type while the largest was a "fascicular sarcoma" (spindle-cell sarcoma?). Many were said to have been "walnut-sized," "the size of a hen's egg," etc., while some were diffuse and the size not stated.

Surface.—The color of the mucous membrane covering the tumor as a rule does not vary much from normal. There may be dilated veins over the surface[22] or the mucous membrane may be very thin or there may be abrasions or excoriations which bleed easily when touched. In both my cases the mucosa over the summit of the tumor was paler than normal, as though stretched over an avascular body, while in Foote's case the color was darker than normal. Hutchinson noted that those growing up from the dorsum behind the circumvallate papillae were likely to present a papillary surface. Generally, the mucous membrane covering the tumor is smooth, and when the tumor presents on the dorsum of the tongue, the mucosa is always firmly fixed to the growth. When, however, the sarcoma first appears on the under surface of the tongue, it is not unusual to find the mucosa freely movable over it, and in two cases it was paler than normal.

Ulceration of the surface is commonly seen, the more so of course in advanced cases or large growths. It does not often occur on the under surface, and when it does it is usually because the growth presses on the teeth. Foote noted ulceration on the side of the tumor where it pressed on the teeth. Altogether, note was made as to presence or absence of ulceration twenty-nine times. In eleven of these ulceration had occurred. The time at which ulceration occurs varies within wide limits. The case of Serafini referred to above had been growing twenty-two years; it was said, however, to have rapidly increased in size a short time before operation, and it was ulcerated. No statement is made as to the time at which ulceration first appeared in any of them. One had existed only two months, and was already ulcerated.[23] Seven of those ulcerated were round-cell, three of them were spindle-cell and one was a mixed-cell sarcoma. In one the tumor completely sloughed out,[24] so that "nothing remained to justify the diagnosis of sarcoma." It appeared later in the glands, however.

Glandular Involvement.—In view of the fact that sarcomas found in regions rich in lymphoid tissue often spread through the lymph-stream, and remembering the presence of lymphoid tissue in the tongue, it is important to know the frequency of glandular metastasis in sarcoma of the tongue. Altogether, the question as to gland involvement was answered thirty-seven times. In the others no mention of glands is made. In eighteen of the thirty-seven the glands were enlarged; just what glands we are not told, but presumably the regional glands.

In four of these cases no glandular enlargement was noticed until after operation, and the question arises in the reader's mind as to whether this enlargement was not simple inflammatory hyperplasia following absorption from the operation wound in the mouth. The subsequent history proves, however, that in two of them there was glandular metastasis; the third remains doubtful, while in the fourth the enlargement subsided spontaneously and was most likely not sarcomatous.

Of those enlarged before operation, fourteen in number, one is of doubtful character, inasmuch as the glandular enlargement had existed fifteen years, while the tongue condition had been present only three years. This patient was also designated scrofulous.[25]

There are, therefore, thirteen with glandular involvement before operation, and two in which the glands were found to be involved after operation, a total of fifteen cases out of thirty-seven with undoubted glandular metastasis, or 40.5 per cent.

As to the time at which glandular involvement first appeared we have not sufficient data. In one instance the tumor was said to have been present in the tongue less than two months before the glands became involved.[1]

As to the kind of cell in the parent tumor with glandular metastasis, it is hard to make general deductions from the evidence at hand. In thirteen cases mention was made of the type of cell: of these, seven were round-cell, 53.8 per cent.; four were spindle-cell, 38.4 per cent., and two were of the mixed-cell type, 7.7 per cent.

It will be seen farther on that altogether there were twenty cases of round-cell sarcoma reported, and in these the regional lymphatic glands were involved seven times. Dare one say that round-cell sarcoma of the tongue spreads by way of the lymphatics in seven cases out of twenty — in 35 per cent. of the cases? We shall see also that there were in all sixteen cases of spindle-cell sarcoma. Four of these, or 25 per cent., metastasized by the lymph route. And of the mixed-cell type (round and spindle), there were six cases, two of which showed glandular involvement — 33⅓ per cent.

Cut Section.—The color on cut section varies. In both of mine on cut section the middle of the tumor was whitish and more pink-tinged toward the periphery. "Pinkish gray" is an expression often used to describe the color on section, but some have been red. The color varies with the vascularity of the growth. The spindle-cell growths are as a rule firmer and less vascular than the round-cell type. Pigmentation has not been noticed.

The growth may be firm (my Case 2) or fluctuant,[12] or its consistency may vary anywhere between these two extremes. One finds that both round-cell and spindle-cell growths have been fluctuant, and that tumors of both types have been punctured,[26] or incised[12] (mistaken for abscess or cyst?), so that the type of cell present cannot have much influence on the consistency of the tumor. On puncture or incision no fluid other than blood has escaped. Serious bleeding from the growth has occurred; in fact, one patient bled to death[27] from a recurrent round-cell sarcoma.

Correctly to classify the reported cases is, I am sure, quite impossible. The descriptions are in the main incomplete and the nomenclature used often conveys (to me) little idea of the histologic picture. Such expressions as "medullary cancer" and "plexiform sarcoma" may be quite right, but I do not understand them. In two instances the diagnosis is simply "sarcoma."

Abbe[28] reported a case of angiosarcoma, as did also Santesson.[25] Matrissimone's[29] case was a myxosarcoma, while Godlee's[30] case was a sarcoma of the gland of Nuhn and Blandin and called an adenosarcoma. Murray's[9] was an endothelioma. These I leave unclassified, not knowing whether to place them with sarcomas or not. The term "lymphosarcoma" is used frequently enough; believing that by so doing I simplify matters, I have classed all such with the round-cell sarcomas.

There were forty-nine cases in which the type of cell was noted. Of these twenty-two were round-cell. In only six of them, however, was reference made to the size of the cell, and these were of the small-cell variety. In forty-nine cases therefore of sarcoma of the tongue, 44.8 per cent. were round-cell.

The spindle-cell type was not so often encountered, there being only nineteen cases altogether, or 38.7 per cent.

There were eight cases in which both round and spindle cells were found — mixed-cell 16.3 per cent. In one of these in addition cartilage cells were present (my Case 1), and in the case of Godlee[30] referred to above, but not included in this class, was found "a calcifying nodule as large as a pisiform bone."

The growth is said to have been encapsulated or partly encapsulated in five of the cases. One of these was the case of Abbe, an angiosarcoma (?). Eve's[31] case was a mixed-cell sarcoma. A case of Butlin's[32] (Knight, Mr.) recorded as having a capsule was circumscribed but not encapsulated and consisted of small round cells. Downie's[12] case was a spindle-cell sarcoma, and as well as being encapsulated was pedunculated; that of Wiggin was a spindle-cell sarcoma, which had been growing in the posterior part of the tongue for seven years. It recurred in the scar very soon after operation, so there is no doubt as to the diagnosis.

Symptoms.—Usually the first symptom noticed by the patient is the feeling as though a foreign body were in or on the tongue,[24] and depending on whether the growth is in the anterior or posterior part of the tongue, the next is likely to be interference with speech or deglutition.[33] In two instances the patient first sought relief for "sore throat."[34]

Bleeding on mastication was the first sign in the cases of Marion[19] and Mickulicz.[14] These were both pedunculated growths. Bleeding may occur independently of mastication and may be very severe; in fact, in one case this was the cause of death.[27] Bleeding may occur without ulceration.[22]

Pain or soreness has been observed very often, pain more often. This is usually in the tongue at the site of growth and may occur only at intervals as in my cases. It may occur in the presence or absence of ulceration. In the absence of ulceration it may occur at intervals and be of a sharp, stabbing character. Soreness does not often occur without ulceration, but when this happens both soreness and pain may become constant. The pain may radiate to the ear of the same side.[35]

It may occur only on attempting to protrude the tongue or on taking food. It is sometimes so severe as entirely to prevent chewing or the swallowing of solids.[36] It has been known to disappear as the tumor grew larger.[24] A tickling and burning sensation accompanied the pain in the throat in the case of Schleinzer.[37]

Difficult swallowing is a constant symptom when the tumor is in the base of the tongue, but it has also been noted when the growth was anteriorly situated.[38] The dysphagia is not always due to the pain, but the tumor may mechanically interfere with swallowing. This has been seen in growths beginning in the base or root of the tongue,[39] and in those involving the fauces or pharyngeal wall.[40] It was the first symptom in the case of Fripp and Swan.[1]

An accumulation of mucus in the back of the throat was an early sign in Shambaugh's case.[22] An increased expectoration was noted in the case of Schleinzer.[37] When for any reason swallowing is difficult or painful, drooling of saliva occurs.[35]

Dyspnea is common as a late symptom. It is most often found in those cases in which the tumor is situated far back in the tongue, but in Poncet's case the growth began in the under surface of the tongue; this, however, was a large tumor. A small growth in the tongue just in front of the epiglottis can early interfere with respiration.[22] In the case of Wiggin the patient was obliged to sleep sitting because of pharyngeal obstruction on each attempt at lying down.

Fetor ex ore has been noted twice.[41] In both cases ulceration was present. It will be found more marked in those who do not take trouble to keep the mouth and teeth clean.

Inability to close the mouth properly is seen in the case of large tumors.[21] In the case reported by Perkins the tumor during the past six months was said to have caused a habitual recurrent dislocation of both jaws on attempts at opening the mouth.

Protrusion of the tongue may be interfered with or totally prevented. This occurs when the growth, spreading through the root of the tongue, involves the floor of the mouth or the fauces and pharyngeal wall.[42]

A blister on the tongue where it had been bitten was the first sign in Dunham's case.[7] It persisted for three or four months and then grew hard and tumor-like.

In many of the cases loss of weight and anemia have been remarked. They have been present in cases without as in those with ulceration of the tumor, but I find that all so affected suffered with dysphagia.

Diagnosis.—The condition is a rare one and there is no macroscopic picture on which one may depend. Failure to make a diagnosis, however, will usually be due to failure to remember that there is such a thing as sarcoma of the tongue. It may be confused with inflammatory lesion or with other new growths. Of the inflammations, chronic interstitial glossitis, tuberculosis, lues, actinomycosis or chronic abscess are the most likely to lead to error.

Tuberculosis is generally seen as an ulcer at the side or tip on the dorsum of the tongue, but it may begin as a small lump or tumor, and if so might lead to the diagnosis of sarcoma. It is as a rule found only in those who have well-advanced tuberculosis of the lungs. It ulcerates early. The ulcer shows some tendency in places to heal or granulate, and this a sarcomatous ulcer ordinarily does not do. Still, a case is referred to above in which the whole sarcoma sloughed out, and "left nothing to justify the diagnosis of sarcoma."[24]

The luetic lesions likely to be mistaken for sarcoma are the chancre, the gumma and the diffuse infiltration. The chancre's ulcerated surface, generally raised up on an infiltrated base, reaches its maximum size in a couple of weeks, and ceases to grow. The ulcer precedes the tumor. The glandular enlargement occurs early and is usually very marked. Pain is not common nor is soreness. The appearance of secondary symptoms within six weeks is the rule.

A gumma grows rapidly. It is usually near the middle line and pain is absent. A yellowish or grayish spot soon appears in its center; it breaks and discharges a thick mucoid matter. The resulting ulcer is "punched out" or has undermined edges and its floor is covered with a grayish or yellowish membrane. It soon shows signs of healing.

Diffuse infiltration of lues sometimes attacks the tongue. It usually begins in the deeper parts of the tongue and early impairs the movement of the tongue. There is no tumor to be found and the tongue is only slightly increased in size. Pain is not common or severe and ulceration of the surface does not often occur. If the conditions have existed for long the surface of the tongue is bosselated, and painful fissures may develop in the sulci.

Actinomycosis usually presents signs of inflammation from the beginning; abscess formation with resulting sinus is the rule. Then ensues the diffuse and spreading infiltration with further sinus formation. Later, the granules are seen and the microscope makes the diagnosis easy.

With chronic abscess of the tongue I have had no experience, nor do I find more than a reference to it in the records consulted. Aspiration might be used to clear up the diagnosis.

The condition will hardly be mistaken for benign new growth. It is of far more serious import to the patient to mistake a benign growth for a sarcoma.

Benign growths develop slowly and rarely cause pain. Their outline is usually more clearly defined and they seldom, unless by their size, interfere with the mobility of the tongue. In some of the cases of sarcoma there is a history of the presence of a tumor for many years, but it is to be noticed that shortly previous to consultation the tumor had begun to grow rapidly. A papilloma may appear on the side or tip of the tongue and soon cause the patient to seek relief. Such a growth can be readily removed together with a small portion of the tongue substance, and then a microscopic examination of its point of attachment will reveal its true nature. The sarcomas infiltrate.

Macroglossia is present at birth. The tongue protrudes. Its whole anterior part is enlarged, and it seems edematous though it is often hard. The papillae are hypertrophied. Its rate of growth is slow.

Glandular cysts develop at the tip, along the sides and on the under surface. They may be of slow or rapid growth. They often alternately enlarge and diminish in size. Usually they are grayish and semi-translucent, as their content is most often retained inspissated mucus, which escapes on puncture.

The diagnosis of thyroglossal tumor has been made in a case of sarcoma.[43] The cyst or tumor growing from the remains of a thyroglossal duct is to be found in the median line and in the base of the tongue. It is painless and grows slowly, and until large interferes only slightly with tongue movement. Such tumors are to be removed when found, and at operation the discovery that the tumor is encapsulated will probably lead the surgeon to make a correct diagnosis before mutilation has been done.

Sarcoma of the tongue is not likely to be mistaken for a carcinoma, but if this should occur, the error is not a serious one, as the treatment is the same in either case. In the case of sarcoma a tumor appears which later ulcerates, while in carcinoma the ulcer, as a rule, is first noticed. A painful chronic indurated ulcer appearing at some point of irritation points to carcinoma; but it is well to remember that at least one sarcoma first appeared as an ulcerated spot in the scar of a scald.[10] In both we are likely to meet glandular enlargement, but this is more common in carcinoma.

After all clinical manifestations have been duly weighed, a diagnosis should not be made until one has excluded syphilis by both Wassermann test and antisyphilitic treatment. This causes a delay of from ten days to three weeks, but the benefits overbalance the dangers.

It used to be said that suspicious growths should be carefully watched. It should be urged that suspicious growths be promptly removed.

All efforts to make a diagnosis may fail until a section of the tumor is examined under the microscope. It is necessary to obtain the section from the edge of the growth that one may, if possible, see both sound and diseased tissue in the section. One must bear in mind that the removal of a section may lead to rapid fungation in the growth, as happened in the case of Barling.[44] Therefore no section should be removed until one is ready to do immediately whatever is indicated by the report of a competent pathologist.

Treatment and Prognosis.—The treatment has been operative in forty-six of the certain cases. In four no operation was done. In two no history is available, the specimens having been found in the museum of the Royal College of Surgeons.

Local removal only has been primarily done in twenty-five cases, two of these with division of the jaw (one of which lived four years without recurrence); three were removed with a V-shaped piece of the tongue (one of these was free from recurrence six years after, one two and one-half years after and one has been lost sight of).

Ten of the local excisions are noted as having recurred. In six others less than two years have elapsed since operation. Only three of the twenty-five patients are *known* to be well more than two years. Of the others there is no postoperative history.

The more radical operative treatment comprises (*a*) removal of one-half the tongue and (*b*) total removal of tongue and some adjacent part or parts.

There were twelve grouped in Class A. Of these, one had lived fourteen years,[12] one five years, and one three and one-half years without recurrence. Three others had lived less than one year without recurrence, to wit, two, nine and eleven months, respectively.

There were eleven cases in which removal of the tongue or more was done. Of these, four are free from recurrence after two and one-half, three, four and five years, respectively. One was well one year after operation. One was lost sight of, and three recurred in a year or less.

In the great majority of cases, the knife was used for the removal of the growth. In two instances it was followed by the actual cautery. One of these recurred in eight days; the other patient remained well two and one-half years afterward.

The electrocautery was used three times in excising the growth: one patient was well two years later, one well two weeks after and the other died soon of recurrence.

Coley's fluid was used before operation by Foote[45] without apparent benefit. It is still being used in my second case. Trypsin and holadin were used in Wiggin's case[43] and with seeming benefit for a while. Pyoktanin was also used in the case of Foote, but it seemed to make the condition worse.

The Roentgen ray was used after operation by Fisk,[46] but with what effect we are not told. It, too, is still being used in my second case. For the difficult respiration, tracheotomy may become necessary (Fripp and Swan).[1] The palliative treatment must be symptomatic.

In formulating my ideas of the prognosis I consider only the fifty cases in which the microscopic examination was made.

It may be conceded that left to itself, sarcoma of the tongue is a uniformly fatal disease. The length of time required by the disease to run its course when uninfluenced by treatment will be very difficult to foretell. In one case[23] death occurred about two months after the first appearance of the tumor. Naegele's patient died of pneumonia in a little more than three months.[3] In the other untreated cases recorded the patient was lost sight of or no mention is made of the final outcome.

Fripp and Swan,[1] in personal communication with the surgeons who had reported cases, were able to follow twenty-five cases in which operation had been performed. Eleven of the patients had lived without recurrence from six months to thirteen years. In thirteen of them there had been recurrence. Three of these "recurred in a short time" and four had remained well more than two years. In one of these four, recurrence appeared three, and in another three and one-half years after operation. In nine cases the recurrence was local only, and in one in the regional glands alone, while in four recurrence appeared both *in situ* and in the glands. These thirteen patients died of the recurrence.

Of patients with the round-cell type, only four out of thirteen remained well longer than three years. Of the spindle-cell variety only two out of twelve were free from recurrence after two years. One of these patients had been operated on four and the other eight years previously. Downie[47] informs me that in his case—spindle cell—the patient is well after fourteen years.

One expects the prognosis to be better after a primary operation than after an operation for recurrence, but one finds that this is not necessarily so. Schleinzer[37] reported one well five years after an operation for recurrence *in situ* and in the glands, and this in a round-cell sarcoma ("lymphosarcoma"!).

[45] Foote: Am. Jour. Med. Sc., 1912, i, 198.
[46] Fisk: Ann. Surg., 1903, xxxvii, 273.
[47] Downie: Personal communication to the author.

As to metastasis through the blood-stream, there are three cases in which this seems to have occurred.[48] In one of these,[23] the whole course of the disease was only two months and in another eleven. Murray's[9] patient died in three years of metastasis in the brain. In the case of Beregszaiszy,[23] the peritoneum, mesentery and bowel wall were the seat of metastatic growths; in Keenan's[24] the stomach and peritoneum; while the skin was the site of metastasic deposit in a case of Butlin's.[32]

The direct cause of death may be exhaustion, pneumonia, sepsis or hemorrhage. I find no death occurring during the operation or immediately afterward. It is likely that a death attributed to sepsis, or pneumonia, or hemorrhage, occurring within eight days may be laid to the operation; one does not say so positively.

Recurrence has been noted up to three and a half years after operation.[49] I find no recurrence to have been delayed longer than this. Recurrence has been seen as early as eight days after operation,[40] and several recurred in two weeks.

The probability of recurrence after local excision is impossible to estimate from the case reports. Of eleven undergoing the intermediate operation (half the tongue with or without glands) four had been previously operated on by local excision, and in the nine requiring the most radical treatment only two were secondary operations.

There are certain cases reported in which the tumor was said to have been present for from six to twenty-two years.[50] In several of these the statement is made that the tumor had shortly before operation taken on rapid growth.

A fibroma that takes years for its development may show nearly the same microscopic picture as a spindle-cell sarcoma.[51]

CASE REPORTS

Case 1.—A. H., schoolboy, aged 14, Irish-American, comes because of lump growing in tip of tongue. Lump has been growing five or six months. History of having bitten tongue about two years ago. Has occasional darting pains in tongue and cannot speak as he used to. Has not lost weight, is well nourished and strong.

There is an irregularly oval lump in the tongue at its tip, slightly more on the right side than on the left. The lump is about ¾ inch long and about ½ inch wide at its middle; it projects both on the dorsal and under surfaces. It is whitish below and pinkish above. The papillae can be seen on the posterior but not on the anterior part of its upper surface. There is no ulceration. The mucous membrane above is fixed to the growth; that below is fixed to it anteriorly only. It is firm to the feel, resilient and irregular. One projecting boss in the lower anterior part is hard. No fluctuation. No glands feelable.

The diagnosis hung between new growth and implantation cyst and it was decided to remove it.

Under local anesthesia (novocain 0.5 per cent. infiltration in tongue on each side well back from tumor) a V-shaped portion of the tongue bearing the tumor was excised. The base of the part removed measured 1½ inches and from middle of base to apex measured 1⅜ inches. Through-and-through interrupted silkworm-gut stitches about 1 cm. apart had been placed before the incisions were made and these when tightened controlled the bleeding and closed the wound.

There was very little shock.

Liquid diet was allowed and talking forbidden.

Union was by first intention and the last stitch was removed on the ninth day.

Cut in two, the tumor was solid throughout with a sharply limited edge. In its anterior part was a nodule about 1 cm. in diameter which was semitranslucent, somewhat opalescent, and harder than the adjacent tissue. The scraped surface yielded a whitish mucoid substance.

The specimen was sent for microscopic examination and the report came back that the growth appeared to be sarcomatous and contained round and spindle cells and that a part of it contained cartilage cells.

The patient returned no more after the stitches were removed and inquiry showed that a false address had been given. Nothing further has been heard of him by me.

Case 2.—L. D., 19, male, Italian-American, student. Lump in tongue, began to grow two and one-half or three months ago; has a drawing feeling and occasional sticking pain not very severe. Bit the tongue eight years ago at site of growth. Growth has always been hard. Had not interfered with movement of the tongue, nor with speech up to three weeks ago. It was then removed but is now growing again. The patient now has a slight lisp. Sections were made from growth removed and a diagnosis of sarcoma was made. A glance at the slides (brought along) showed an infiltrating growth made up of spindle and round cells, the former predominating.

The growth in tongue is situated ¾ inch back from the tip and is just to the left of the median line. It is pinkish and the surface is raised rounded above the level of the dorsum about ¼ inch and on its summit is a small puckered scar; the growth is about the size of an ordinary marble. It is fixed in the substance of the tongue, is regular of surface, spherical in form and has a resilient feel. There is slight tenderness. This the patient attributes to the recent operation. There is nothing in the history to arouse suspicion of syphilis, and the Wassermann is negative.

The growth was removed in August, 1913. The cheek was split as far as the masseter on the affected side. The root of the tongue was transfixed and a silver wire carried through and tied (twisting) as far behind the foramen cecum as possible. (I do not think this wire did any good whatever; it was recommended as a preventive of bleeding.) The rest of the technic followed Whitehead's procedure for the removal of half the tongue except that one had to go well to the right of the median line and the lateral incision was directed obliquely backward as I believed by so doing I should secure a better approximation, and I did. There was bleeding from the right lingual (ranine), but the left was caught before being cut. Not more than an ounce or two of blood was lost altogether. Not so much would have been lost but that it was deemed advisable to remove a little more from the right side opposite where the growth had been, necessitating a third cut. When the silkworm-gut stiches were drawn tight all the bleeding was well controlled. Healing was by first intention.

Microscopic examinations showed an infiltrating growth, composed of round (small) and spindle cells.

The use of Coley's fluid was begun in the first week and is still continued. Massive dosage of the Roentgen ray was advised and the patient still receives one treatment per month. He writes me that he speaks with a lisp only when he gets excited. He has recently gained 11 pounds in weight and says he feels perfectly well.

THE EXPERIMENTAL EFFECT OF THE COLON BACILLUS ON THE KIDNEY *

IRVIN S. KOLL, B.S., M.D.
Instructor in Genito-Urinary Diseases, University of Illinois Medical College; Associate Genito-Urinary Surgeon, Michael Reese Hospital; Director Genito-Urinary Department, West Side Jewish Dispensary
CHICAGO

The following experiments were undertaken without any preformulated theories and with no attempt to prove anything. My previous work on the colon bacillus stimulated a desire to know more about this organism in its pathogenic rôle within the kidney.

This work is represented by one hundred animal experiments wherein a comparative action between the colon bacillus, the typhoid bacillus and the staphylococcus is shown under different conditions, and these bacterial invasions compared with the effect of a soluble toxin made from each.

In the first series 1 c.c. of a twenty-four-hour bouillon culture of various strains of colon bacilli was injected into one ureter just below the pelvis. These infected kidneys were removed at varying intervals along with the opposite kidneys. Most of the injections were made without producing any obstruction in the ureter, and some with obstruction by either narrowing with a ligature or a small pebble placed within the lumen.

As has been so often shown, the obstructed ureters produced the typical pathology of a pyonephrosis, varying in extent in direct proportion to the extent of the obstruction. The picture produced by the simple injection was consistent in each case, showing a glomerular nephritis. The cellular infiltration was of the polynuclear type in the infected organ, and mononuclear in the opposite one. In some areas there were interstitial hemorrhages, but no extensive involvement of the tubules was found in any instance. No focal necrosis or miliary abscesses, and in no instance in which the kidney remained for longer than twenty-four hours could bacteria be demonstrated in the tissue or by culture from the urine. No specimen showed a limitation of the pathologic condition to the pelvis even as soon as twenty-four hours after the injection, but each picture was that of a pyelonephritis, with the glomeruli the seat of the inflammation. The opposite kidney in every instance showed a similar change, but much less pronounced. In those cases in which the opposite kidney remained *in situ* for some time after the removal of the infected one, a complete restoration to normal is shown. This fact is borne out clinically very frequently. A surgical kidney on one side will produce a toxic nephritis in the opposite organ, which recovers spontaneously on removal of the seat of the infection. That it is a toxic condition is shown in some of the subsequent experiments.

The typhoid bacillus produced a more generalized parenchymatous nephritis, which was emphasized by obstructing the lumen of the ureter, but did not produce a pyonephrotic change. The opposite kidney showed similar changes. Blood-cultures and urine-cultures were positive in each instance.

The staphylococcus produced either focal necrosis or a complete pyonephrosis. Cultures from the urine were positive; from the blood negative.

The next step was the injection of cultures of these three organisms, singly, into the sheath of the ureter, extraperitoneally, at about its middle third; and in another group of animals subcapsularly at the cortex. The histologic pictures were practically the same as when the organisms were introduced through the ureter. The typhoid bacillus produced a general parenchymatous nephritis; the staphylococcus focal necrosis, with inflammatory processes throughout the kidney. The colon bacillus still showed the glomerulitis predominating, and, in addition, when the injection was made at the cortex, a pyelitis secondary to a nephritis. Blood-culture was positive for typhoid, urine-cultures positive for staphylococcus and typhoid.

In the next series of experiments soluble toxins in varying strengths were made from the three organisms and injected at the locations just described. The histologic picture changed somewhat. The typhoid toxin showed an intense parenchymatous involvement, with areas of granular degeneration. The opposite kidney was involved to about as great an extent. The staphylococcus toxin gave a similar picture, but not nearly so marked. The colon toxin gave a very pronounced picture of a generalized parenchymatous nephritis. The type of cellular infiltration with each toxin changed from the polymorphonuclear to the lymphocytic, a rather significant change. The opposite kidneys were involved equally as much, and all became normal from three to four weeks following the injection of the toxin. When too great a concentration of the toxin was used, the animals died very promptly. No attempt was made to ascertain very accurately the minimum lethal dose.

If any conclusions are to be drawn from this work, three facts stand out prominently:

1. A non-traumatized kidney in the absence of ureteral obstruction will overcome spontaneously the invasion of virulent micro-organisms.
2. It appears that our recently slighted blood-stream is the means of extension of these infections from the pelvis to the cortex, from the cortex to the pelvis, and in all probability from the periureteral tissue to the renal parenchyma. This is based on the fact that the glomeruli are the structures mostly involved. Though, in the face of the recent very interesting work of Hess,[1] later verified by Eisendrath, whose specimen showed a predilection for the lymph-tract as the route for ascending infections, my renal specimens show only the glomeruli involved.
3. The pathologic changes are due to a direct toxic action and the soluble toxins of the organisms are carried to the opposite kidney, where a similar picture is seen.

In no instance does any specimen show the changes found by Hess, who asserts that cultures of colon injected into the pelvis will produce pus foci and areas of necrosis within from thirty-six to forty-eight hours, and if the bacteria act longer the changes become more marked. The very convincing work of Francke[2] leads one to believe that the colon bacilli pass from the mesenteric lymphatics into the right kidney, seldom into the left, yet left-sided pyelitis is almost as frequent as right, and if we are to ascribe to gastrointestinal disturbances the rôle for the production of colon bacillus pyelitis, then the blood-stream must be at least as important as the lymph-stream in carrying the bacteria to the kidney.

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* From the Department of Experimental Surgery of the Morris Institute of Medical Research, Michael Reese Hospital.

[1] Hess: Deutsch. med. Wchnschr., 1912, No. 30; Mitt. a. d. Grenzgeb. Med. u. Chir., 1912, No. 26, p. 135.

[2] Francke: Arch. f. Anat. u. Physiol., 1910, p. 191; Mitt. a. d. Grenzgeb. d. Med. u. Chir., 1911, xxii, 623; Berl. klin. Wchnschr., 1911, p. 1973.

Most of the experimental work done along this line has been with narrowed or completely obstructed ureters, which, of course, gives an exaggerated pathologic picture. My object was not to imitate a clinical state, but to ascertain how far the kidney could overcome a simple bacterial invasion, since we see so often a bacteriuria without any clinical manifestation.

Mueller[3] concludes that a pelvic infection spreads to the cortex along the lymphatic channels upward, but all of his experiments were performed after first obstructing the ureter. Kumita[4] has traced the lymphatic capillaries in the cortex, where he says they communicate with the lymphatics of the capsule and surround in a most intimate manner all the convoluted tubules. The meshes of this network are circular and surround in a parallel manner the blood capillaries. From the capillaries, lymphatic vessels arise which surround Bowman's capsule and penetrate the glomeruli. This finding confirms the work of Mueller, although it does not prove that infections in non-obstructed ureters extend along the lymph-channels. All of my specimens show the glomeruli the seat of the cellular infiltration, rarely any interstitial or tubular involvement. This, of course, speaks for a blood-stream extension. One would expect to find thrombi or emboli in hematogenous infections, yet none could be demonstrated. If the extension were urogenous, that is, along the secretory current, the entire epithelial lining of the corresponding tubules, from the papillae to the point to which the inflammatory process has ascended, would show a corresponding damage, which certainly has not been seen in any of the specimens.

In justification of my conclusions, so widely differing from such reliable observers, whose work has been quoted, it must be remembered that this piece of work was not begun to prove any clinical picture or trace the origin of any pathologic process. The technic employed, therefore, differs markedly from that of other experimenters along this line, and the results necessarily are different.

My sincere appreciations are due Dr. James W. Jobling and Dr. Edwin Kirk for their many valuable suggestions.[5]

TECHNIC

Preparation of Bacterial Cultures.—Pure cultures of colon bacilli isolated from the human and rabbit feces. Also stock cultures used. Quantity injected, 1 c.c. of twenty-four, forty-eight and seventy-two-hour bouillon cultures. *Staphylococcus pyogenes albus* and typhoid bacillus obtained from stock culture. Same quantity used.

Preparation of Toxins.—The toxins were made by washing off in normal salt solution a twenty-four-hour agar-slant. This was allowed to stand twenty-four hours. Toluene added to kill the bacteria, which required from twenty-four to forty-eight hours; this toluene then pipetted off. They were then centrifuged and the supernatant solution (the soluble toxin) pipetted off and stored in the ice-box until used.

Preparation of Tissues.—Cut tissues immediately fixed in Zenker's solution and in 10 per cent. liquor formaldehydi. All embedded in paraffin.

Stains Used.—Hematoxylin eosin; Unna's eosin methylene blue; Loeffler's methylene blue and Gram stain for bacteria in the tissue; carmin for fibrin.

Urine cultures made from bladder. Blood-cultures made from renal vein or heart, if at necropsy. Cultures from urine and blood made in bouillon.

Operative Technic.—Twenty-five rabbits and seventy-five dogs used. Anesthetic, ether. Typical lumbar incision. Great care was taken not to traumatize either the kidney or surrounding structures. Whenever possible, the injections were made without tearing the organ from its fascial and fatty bed. Injections into the periureteral tissue were all made extraperitoneally. The kidneys were removed from one to thirty days following injections.

ABSTRACT OF DISCUSSION

Dr. Louis E. Schmidt, Chicago: Work of this kind brings out a great many clinical observations. When we know work of this kind to be true, naturally our clinical point of view may differ from what it was from the former facts at our command. When a disease condition, obstruction and infection, exist on one side it is well worth our while to study the opposite kidney; there can be no question that the toxemic action on the opposite kidney is just as important as in the kidney in which the disease really exists. In the experimental work which Dr. Koll has done, of which the details are not given, how long after the beginning of obstruction and infection were the kidneys removed? From the clinical point of view when we have a renal stone possibly obstructing the lower end of the ureter, how long are we permitted to wait before we consider operative interference on that side and before the so-called sound side becomes involved? That is a matter of great importance. There is no question that all of us see patients with ureteral stone that we do not operate on because the stone is at apparent rest and there is practically no infection present, but we must take into consideration the condition that exists on the other side. Naturally, from the circumstance that there are more infections on the right side, we could wait longer on the left side than on the right. Furthermore, the question of bacteriuria exists. That question is still under discussion. It is often stated that bacteriuria arising from the kidney cannot exist unless there are changes in the renal epithelium; that in individuals suffering from tuberculosis there are tubercle bacilli found in the urine without any renal changes. That is doubted more and more at present. It is believed that the intoxication has caused changes in the kidney which permit this condition to exist. I am under the impression that the colon bacillus, which is the one we most frequently deal with in bacteriuria, produces some changes which permit this condition to exist. I have yet to see cases of renal bacteriuria which clear up without any treatment. I have seen prostatic cases clear up from time to time. They would be macroscopically clear one week and the next week they would show the typical characteristics of bacteriuria. Another important point, clinically, is that we should always take notes of cases, for instance, of chronic appendicitis that exist for long periods of time, in which the condition is not acute but the patient has pains in the right lower quadrant. This condition undoubtedly produces some obstructive condition, and naturally infection can easily occur, and in that way may produce renal conditions similar to those described in the paper.

Dr. H. W. Plaggemeyer, Detroit: One case has bothered me a great deal of late, and I want to ask Dr. Koll what he thinks about it. This patient gives no history of pain, but the phthalein on the right side was merely a trace at the end of thirty minutes. On the left side there was 16 per cent. in the first fifteen minutes and 7 per cent. in the second fifteen minutes, making a total of 22 per cent. The blood urea was 0.2 per cent., the urinary urea on the right side was 0.7 per cent., and on the left side 0.8 per cent. by the Marshall test. On the right side there was a profuse colon infection in the urine and also on the left side. What would Dr. Koll think about operating in a case like that with a distinctly low phthalein on the opposite side?

Dr. A. J. Crowell, Charlotte, N. C.: Some five or six years ago I prepared a paper on the rationale of traumatic nephritis. I had no proof except clinical proof that such was the case but this was really positive of a right-side nephritis following severe traumatism to the left kidney. In Dr. Koll's experimental work I think I see further proof that such a condition can occur. He speaks of the removal of an injured or diseased kidney preventing a diseased condition of the opposite kidney. Dr. Squires and I have lately been doing some experimental work on traumatizing the kidney and injecting the various fresh bacteria, but we are not yet ready to make any report further than the macroscopic appearance. We have operated on about fifty rabbits up to the present, traumatizing the kidney with and without injecting various bacteria into the veins thereafter. I hope, later, to make a report of this work. Macroscopically, the traumatized kidney followed with intravenous bacterial injections, with the exception of a few cases, showed but little of interest.

Dr. I. S. Koll, Chicago: One big mistake that experimenters frequently make is to lay down the laboratory findings as a dogmatic control of clinical findings. There is a long range between the test-tube and the patient, and I am convinced that while our experimental work may pave the way for our clinical deductions, nevertheless we must be careful in applying laboratory findings to clinical manifestations. Now, as to the length of time that it is safe to allow a stone or an infection to remain before urging operative interference, the point is an arbitrary one, because if a calculus is obstructing either the pelvis or the ureter, in the absence of infection, of course, the kidney is not going to be destroyed as rapidly as if there was an infection. How long before the kidney will be infected when there is obstruction to the ureter also cannot be foretold. The infection in the kidneys removed in my experimental work varied from twenty-four hours to four weeks. I found that within twenty-four hours after the injection of colon bacilli into an obstructed ureter there were very marked changes in that kidney. In some instances in which there was a high degree of virulence of the organism there was a marked tendency to total destruction of the kidney in twenty-four hours. In the absence of obstruction—and by obstruction we must consider that due to edema or inflammation of the ureter, because that certainly is an obstruction—I was not able in twenty-four hours to recover the organism in the urine taken from the bladder. This widely differs from the work of other experimenters, but I tried it over and over. I was careful not to bring the kidney up out of its bed. I went into the ureter and injected my organism extraperitoneally, and thereby produced less traumatism. In those cases I could not recover the organism after twenty-four hours. I do not believe there is a bacteriuria without renal changes. Within twenty-four hours there is a distinct nephritis. I do not believe that a pyelitis exists as a pathologic entity. In twenty-four hours the glomeruli show changes, but of course the changes are more marked in the pelvis. Answering Dr. Plaggemeyer's question concerning the involvement of both kidneys, if he found involvement indicated by the low phthalein output, the question is, What is the type? By a toxic condition in the opposite kidney I mean that there is no infection, but the toxins are producing an irritation of the parenchyma that is manifested, not by pus-cells in the urine, but by casts, albumin and red corpuscles in more or less abundance. So I should say that if in one kidney he found practically no pus cells present and that great quantities of pus were in the opposite side, that is certainly a case for operation. The toxic condition is manifested not by leukocytes but by hyaline and granular casts, by albumin and by erythrocytes.

EXPOSURE OF APPENDIX BY CULLEN'S METHOD

A SIMPLE WAY OF REMOVING AN ADHERENT RETROCECAL APPENDIX THROUGH THE ORDINARY GRIDIRON INCISION

WILLIAM NEILL, Jr., M.D.
Resident Surgeon, Church Home and Infirmary
BALTIMORE

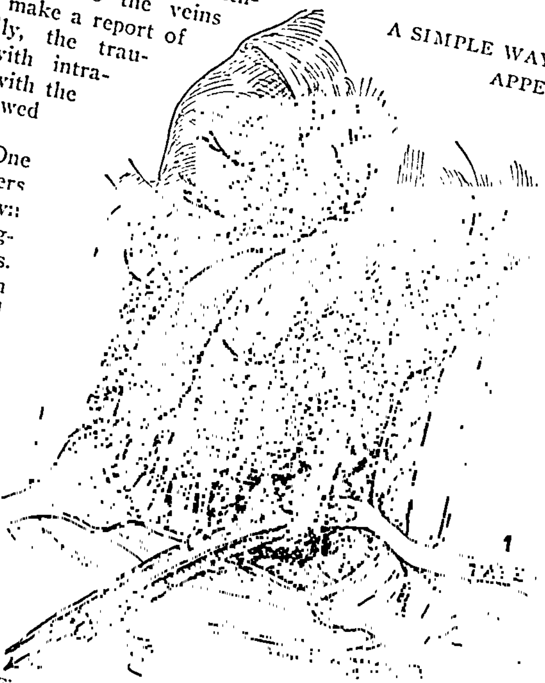

Fig. 1.—Pushing a blunt Kelly forceps through the meso-appendix at the cecum.

For at least seven or eight years Dr. Thomas Cullen, one of the attending surgeons at the Church Home and Infirmary, has been employing such a simple and easy device for exposing retrocecal and densely adherent appendices that I feel its general adoption would not only shorten the time taken in these operations, but also render the surgeon's work much easier.

One of the most important points for the operator to decide when commencing an appendix operation is what kind of an incision to make. In those cases in which the abdominal pains are rather vague, it is usually wiser to make a right rectus incision, as either the gall-bladder or appendix or both may be diseased. With the right rectus incision it is possible to lengthen the wound upward or downward as may be desired. In this manner the entire field can be most satisfactorily exposed.

Again, when a gangrenous appendix is suspected, a right rectus incision may be made and if drainage be necessary then a small gridiron incision can be made near the anterior superior spine just where the drain is to be inserted directly down to the cecum.

It is not my desire to discuss the general subject of appendix incisions but to refer to the method Cullen and those associated with him have found eminently satisfactory in those cases in which the diagnosis of appendicitis was relatively certain and the pain localized to the appendix region—those cases in which one would naturally make a gridiron incision. Not infrequently in these cases after the incision has been made it is next to impossible to expose the appendix, as it is retrocecal and often adherent. In such cases partial exposure may finally be obtained after placing and replacing the retractors several times, but in other cases it will be necessary to cut across some of the abdominal muscles to obtain adequate exposure.

In nearly every case the base of the appendix can be located by following the longitudinal band on the cecum. When once this is located a Kelly blunt forceps is pushed through the meso-appendix at this point and grasps a piece of tape as indicated in Figure 1. The two ends of the tape are then grasped in the tip of the forceps and used as a tractor. Strong traction is exerted without any injury either to the cecum or to the appendix. The traction invariably brings up from three-fourths to an inch of the appendix. Another Kelly forceps is passed through the meso-appendix and grasps a second piece of tape, as shown in Figure 2. The second tape is now used as a tractor and a further portion of the appendix exposed. A third forceps is pushed through the meso-appendix and a loop of tape passed around the appendix, as indicated in Figure 3. Traction on this third loop will usually expose the tip of the appendix. The meso-appendix is now clamped off from tip to base, as indicated by the arrows in Figure 4. Sometimes only two tapes are necessary. As the meso-appendix is cut, the tapes are loosened and removed. They lie outside of the abdomen and with care there is no danger of their being lost. We have never experienced any trouble from this source.

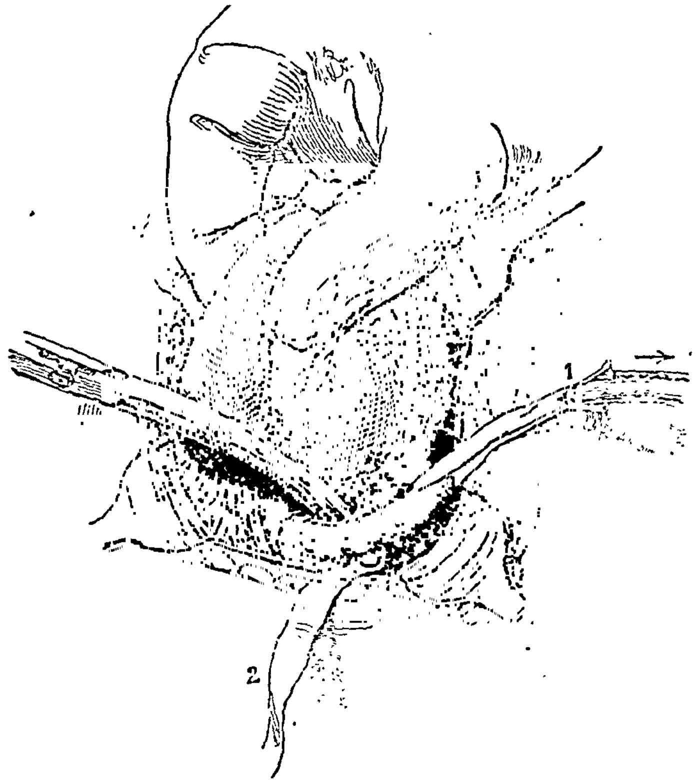

Fig. 2.—Traction on the base of the appendix, bringing more of the appendix into view.

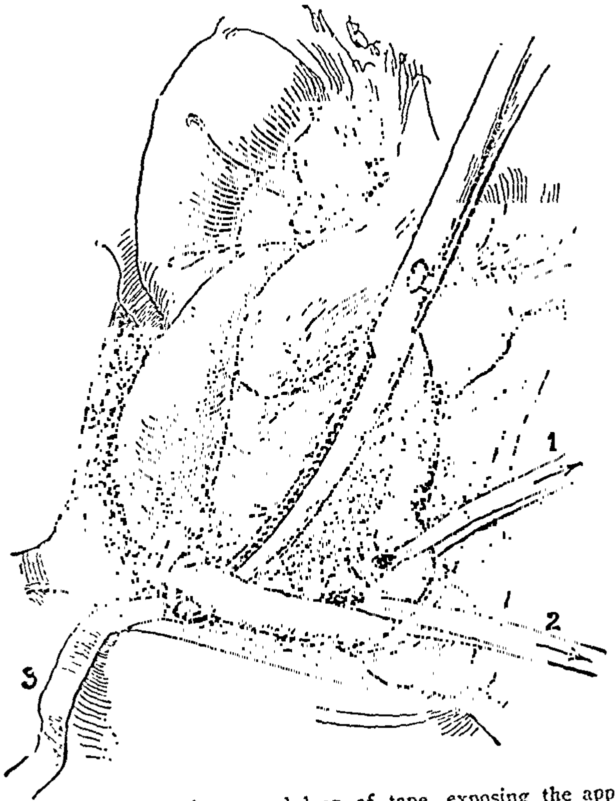

Fig. 3.—Traction on the second loop of tape, exposing the appendix near its tip.

By using this method almost any subacute or chronic retrocecal and adherent appendix can be delivered with ease, and an otherwise difficult and tedious operation rendered a simple one. Various members of the resident staff of the hospital have employed this method of exposure of the appendix with much satisfaction and in no instance have we seen the cecum or appendix injured by the traction with the tape.

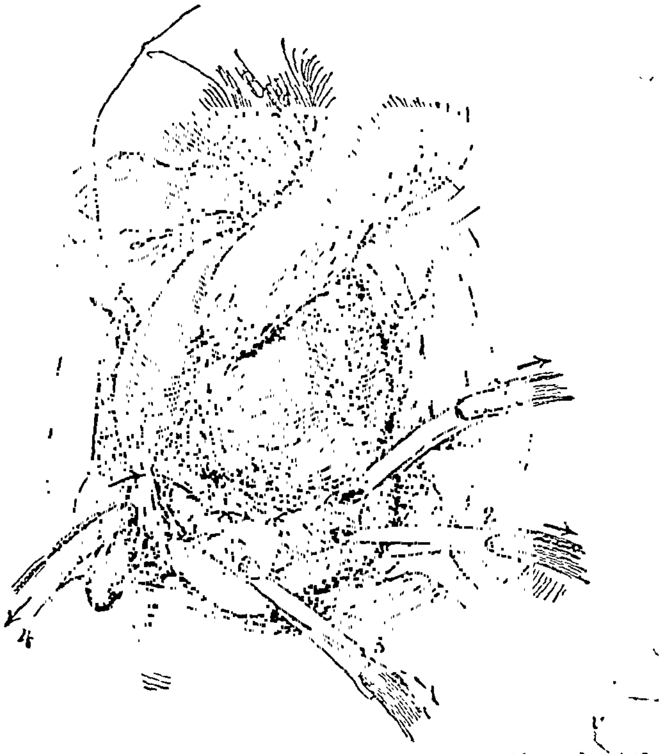

Fig. 4.—The meso-appendix is clamped on its cecal side and cut as indicated by the arrows. Note that the tapes produce an equable and broad traction and that they do not injure the appendix. By this method a long, adherent retrocecal appendix can be removed readily through an ordinary gridiron incision.

The subsequent steps in the removal of the appendix have naturally varied, depending on the method best suited to the individual case.

I wish to express my sincere thanks to Mr. Max Brödel, director of the Department of Art in Medicine of the Johns Hopkins Medical School, for the graphic illustrations portraying the various steps in the procedure herein described.

Sleep as a Habit.—From the psychological point of view, remember that sleep is, above all, a habit. Sleep is one of the rhythms of our existence, and in the lower animals these are more accurately observed than with us; it is only civilized and thinking man who interferes with this the most sacred of the rhythms of Nature.—H. Crichton Miller, *Medical Press and Circular.*

THE USE OF PITUITARY EXTRACT AS A COAGULANT IN THE SURGERY OF THE NOSE AND THROAT

HARRY KAHN, M.D.

AND

L. E. GORDON, M.D.

CHICAGO

The rhinologist has long sought a harmless, efficient drug that will control the hemorrhage during and following operations on the nose and throat. Calcium salts have been used with indifferent success. Blood-serums have given reliable results, but have the disadvantage that anaphylaxis may be produced. Epinephrin only produces its results on the mucous membranes, and then only when directly applied.

Citelli[1] reported to the Seventeenth International Medical Congress in London, August, 1913, on the use of pituitary extract for the control of hemorrhage following turbinectomy, sinus operations and tonsillectomy. Following his suggestion, we have used the drug with universally good results. The blood loss during and after turbinectomies was slight; in fact, the operation itself was almost bloodless. The hemorrhage following curettements of the ethmoids was also much reduced. The blood loss following the tonsil operation was greatly lessened. The snare, Sluder and Beck methods were used for the tonsil enucleation. Not a single untoward result have we had in over one hundred patients operated on which could be attributed to the drug.

The action of this drug as a blood-stilling agent did not seem to us to be wholly explained by the action on the walls of the blood-vessels, as is assumed by most writers, hence we were constrained to look further, and found that the coagulation time was reduced to from one-third to one-half or more after the hypodermatic administration of pituitary extract.

We also made a study of the blood-pressure before and after the administration of the drug. This was done in the hope that we might add something to the knowledge of the blood-pressure of children in normal health, and also to study the effect of the drug on the blood-pressure. The systolic and the diastolic pressures were taken before and after the administration by the auscultation method, a mercury sphygmomanometer of Stanton, with the modified cuff for children, as suggested by Gerstley. A brief summary of our results follows:

Our cases, with the exception of three, were children aged from 4 to 12 years, to whom 12 minims of the drug were given hypodermatically. The influence on the coagulability of the blood was profound. It was reduced from one-third to one-half. In some cases a greater reduction was noted. For instance, in one case the coagulation time was four minutes before the drug was given, and after its administration, only one minute was required for the clot to form. Another was reduced from three and one-half minutes to forty-five seconds, and still another from two minutes and twenty seconds to thirty seconds, etc.

The results of our observations of the blood-pressures are noted below under conclusions.

TECHNIC OF ADMINISTRATION

Pituitary extract (Parke, Davis and Company) was administered hypodermatically in the dose of 12 minims to children and 15 minims to adults, not less than fifteen minutes before the intended anesthetic. The coagulation time was taken before and again after the fifteen-minute interval. The blood-pressures were taken at the same intervals. The coagulation time was determined in the early cases with the Brodie and Russell[2] coagulometer, and the remainder of the cases by the drop-on-the-slide method.

CONCLUSIONS

1. The coagulation time of the blood is materially reduced by the hypodermic administration of pituitary extract.

2. The hemorrhage following nasal and throat operations is much reduced, especially operations on the turbinals.

3. The effect on the blood-pressure of children i variable, as follows: Systolic pressure was increased in 55.31 per cent. of the cases, reduced in 36 per cent. and unchanged in 8.5 per cent. Diastolic pressure was increased in 35.5 per cent. of the cases; reduced in 35.5 per cent., and there was no change in 29 per cent. Pulse-pressure was increased in 61 per cent. and decreased in 39 per cent. of the cases.

OPERATIONS FOR CLEFTS OF THE HARD AND SOFT PALATE *

LINN EMERSON, M.D.

ORANGE, N. J.

A large percentage of these patients are not seen in early infancy by the operator, as the parents do not appreciate the importance of early operation. The parents of a child with cleft palate should be told by the family physician that, if not operated on before the fifth year, the child will never have clear speech no matter how good the cosmetic result, as the child will not be able to enunciate clearly if the operation is performed at a later date.

The Brophy operation should be performed before the end of the third month and Brophy himself operates as early as the second or third week. The technic, as described by Carmody in a recent paper is the following:

The patient having been anesthetized, preferably on the operating table, is placed in a semi-Trendelenburg position thus avoiding aspiration of blood. The lip is raised and with the special, heavy, curved needle a heavy silk suture is carried through the lower part of the maxillary bone behind the malar process, so that the end will show above the palate process, when it appears at the inner border. Care should be exercised to avoid injury to the teeth by working the needle between them if possible. The silk is caught with the tenaculum hook and the needle withdrawn. A needle with the curve in the opposite direction is used in the same manner from the opposite side, leaving silk with closed loops facing each other. The needle is then carried through in the same manner in front of the malar process from both sides, and on the longer side an extra loop farther forward. By looping one loop through the other, as first used by

[2] Brodie and Russell: Jour. Physiol., 1897, xxi, 403.

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Mason, and withdrawing the surrounding loop, we have one double silk strand from one buccal surface to the other. These are replaced by drawing through, by means of this silk, a double silver wire.

On these wires are threaded lead plates, and it is important that the holes should be the right distance apart, so as not to cause buckling of the plates if at too great a distance, and so that the wires will not cut the tissue if too close together. Personally it seems that not enough care is taken in making the holes in these plates, as portions of lead if left, although soft, will irritate the tissues. For this purpose, the ordinary rubber-dam punch of the dentist is used, which leaves a clean-cut hole with smooth surface on the side placed next to the tissues.

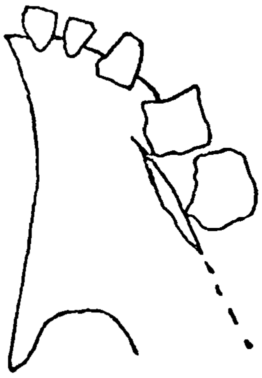

Fig. 1.—(From Owen) showing lateral incision.

The wires are then twisted together, one of the posterior with one of the anterior, care being taken that the same wires are twisted on each side. This will bring the parts together with comparative ease if the patient is not too old, or the cleft is not too wide. If the patient is over 3 months old, this operation should not be performed unless the cleft is very narrow. If the cleft is wide in the younger child, I have at times found it necessary to sever the malar process from the maxilla, as recommended by Brophy. This will allow easier approximation.

The palatal process of the maxilla, and horizontal portions of the palate approach each other so that they are almost in contact. The edges should be freshened, being careful to cut completely through the mucous membrane and periosteum; the wires should be tightened, thus bringing the parts in close contact, and completely stopping hemorrhage.

If the premaxilla is protruding, it is best to force it backward into normal position at the same time, not by simply drawing it back, thus causing a bending of the septum which produces obstruction of one nasal passage, or, as is the habit of some operators, simply to make an incision in the septum, and slip one part of the cartilage past the other, which will produce a thick septum, partially or completely blocking one or both nasal passages.

My method, while not entirely original, is to remove a wedge-shaped piece, base down, subperiosteally from the septum, thus avoiding injury to the nerves and blood-vessels; the space from which this is removed is obliterated by forcing back the premaxilla, leaving a septum smooth on both sides. It is necessary to freshen the edges of the premaxilla, and also the maxilla, in the same way as in the case of a single cleft.

The mortality in the early months of life in the hands of the occasional operator, has caused me to give up the early operation altogether. If complicated by harelip, I usually repair the lip during the first few months, and close the palate some time during the second year.

Of all the literature I have consulted, the monograph of Owen is the most valuable. His ideas have been followed mainly in my work. I desire to give full credit for quotations and illustrations.

The operation considered and here described will be that for uncomplicated cleft of the hard and soft palate: the instruments recommended by Owen were used, with one or two exceptions. The Whitehead mouth gag is very satisfactory. The extension piece to the tongue depressor, should be removed for use with children, as it is too long, and crowds the base of the tongue over the laryngeal opening. The two curved steel raspatories, angular scissors, wire-twisting forceps, long mouse-toothed forceps, scalpel, artery forceps (for sponges), Sim's hollow needle, tenaculum, and Graefe cataract knife, complete the list of instruments required.

The patient should be liberally fed during the week preceding operation, and should have the rectum and lower bowel well cleared out by enemas just before operation. This permits withholding everything, even water, by mouth, for seventy-two hours following the operation.

The chloroform can best be given with a Junker inhaler, but this is not absolutely necessary as a skilful anesthetist can keep the case well in hand with a gauze sponge on a convenient carrier.

As the operation is a tedious and back-breaking procedure, the position of the patient is of considerable importance. Owen recommends the head hanging over the end of the table, conceding, however, its interference with the respiration. The Trendelenburg position is more satisfactory, but the legs, when flexed over the end of the table, should be protected by having the table covered with several thicknesses of blanket to prevent injury from pressure during the necessarily long operation. This position will bring the head of the child of 5 at about the middle of the table, waist high, thus enabling the operator to vary his position from time to time. If he becomes wearied by standing, he can work with equal ease and comfort sitting on a moderately high stool.

The blood accumulates in the vault of the pharynx and is easily removed by stick sponges. While an ordinary portable electric light affords a suitable illumination, it multiplies the number of assistants and interferes with the operator's view of the small field of operation; therefore, the electric photophore is much to be preferred.

Before the introduction of the mouth gag a heavy silk suture is passed through the tongue. This is tied tightly across the lower bar of the gag after its introduction and serves to prevent the tongue from falling back into the throat.

The first step is the denudation of the margins of the cleft, and epinephrin is first used for the purpose of reducing the hemorrhage to a minimum.

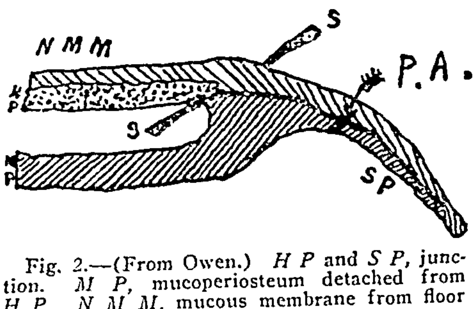

Fig. 2.—(From Owen.) *H P* and *S P*, junction. *M P*, mucoperiosteum detached from *H P*. *N M M*, mucous membrane from floor of nares. *S S*, blades of scissors to cut through aponeurosis of membrane.

Instead of denuding deeply and cutting the periosteum from the margins of the bony cleft, thus removing a part of the tissue which should be left to form the flaps, only a *thin shaving* of the mucous membrane should be removed from the edge, but great care should be observed that the margins are denuded through their entire extent. Owen recommends the use of a blunt bistoury, but in my experience there is nothing that equals a Graefe cataract knife. Its keen, narrow blade ensures rapid and perfect denudation and, under suitable illumination, there is no danger of doing damage with its sharp point.

The next step is a radical departure from Brophy's procedure. While in his skilled hands the dissection of the periosteum from the hard palate with his curved periostomes working outward beneath the denuded margins, is no doubt possible, I feel sure that in most inexperienced hands it would result, as it did in mine, in the tearing of the mucoperiosteal flaps.

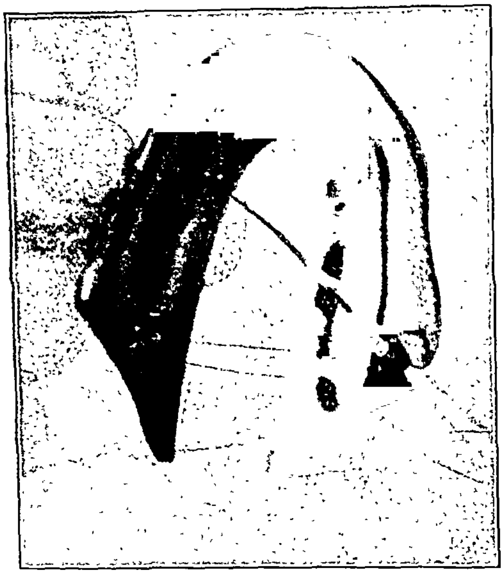

Fig. 3.—Showing manner of passing suture with hollow needle.

Figure 1 (from Owen) shows the location of the lateral incisions and they can be made longer than is shown in the figure if necessary.

The closer these incisions are made to the teeth the less the chances of wounding the larger branches of the descending palatine arteries, the broader will be the flaps, and the less likelihood of their blood-supply becoming impaired.

The incisions pass through the mucoperiosteum down to the bone.

With a raspatory of moderate curve introduced through these lateral incisions the mucoperiosteum is readily detached from the hard palate until the end of the instrument appears at the margin of the cleft. An instrument whose curve is more nearly a right angle is then introduced in an outward direction, and by their alternate use the mucoperiosteum is completely detached.

At this time considerable hemorrhage is encountered which is controlled by pressure and the use of epinephrin. The blood is removed from the pharynx by small absorbent cotton sponges carried on Halsted artery clamps or suitable sponge holders.

Figure 2, from Owen, shows the operation up to this point, and the firm connection between the posterior margin of the hard palate and the velum. This is severed by the introduction of a pair of scissors curved on the flat and on the complete severance of this attachment will depend the success of the operation.

When properly severed the mucoperiosteum and the velum hang loose and are easily approximated to the corresponding flap of the opposite side.

Even when this has been done the most difficult part of the operation is yet to follow, namely, the introduction of the sutures. Undue stretching and laceration of the flaps are liable to occur when the old-fashioned curved needle is used and the flaps necessarily held by a pair of forceps.

The introduction of the tubular mechanical needle by Owen was a great saving of time, but its use, even as he describes it, makes it necessary to grasp the flaps with forceps and considerable traction ensues when the needle is withdrawn. In its use, as I shall describe it, the time required to introduce the sutures is reduced by more than one-half and the flaps do not have to be grasped by forceps. Thus bruising and laceration of them is obviated. Owen lays great stress on having an assistant to look after the needle to see that the end of the wire is just inside the tip of the needle ready for emergence when the wheel is turned after the needle has been passed.

It has not been my good fortune to secure such an assistant, and the rapidity with which the sutures can be introduced by the method I am about to describe leads me to keep the needle in my own hand and manipulate it myself. It goes without saying that a mechanical needle of this sort, to be of value, must be a perfect instrument. After having had three instruments submitted to me by various instrument makers, all of which were unsatisfactory, I induced Meyrowitz to send to Weiss, of London, for the needle here shown. I have found it almost a marvel of perfection. The mechanism is very simple and I have never known it to balk or fail. Meyrowitz has since made such a needle using mine as a model.

The advantage of putting the stitches in from before backward is that the posterior ones being put in last leaves the operator free to sponge the blood from the pharynx at frequent intervals without pulling on the stitches or palate.

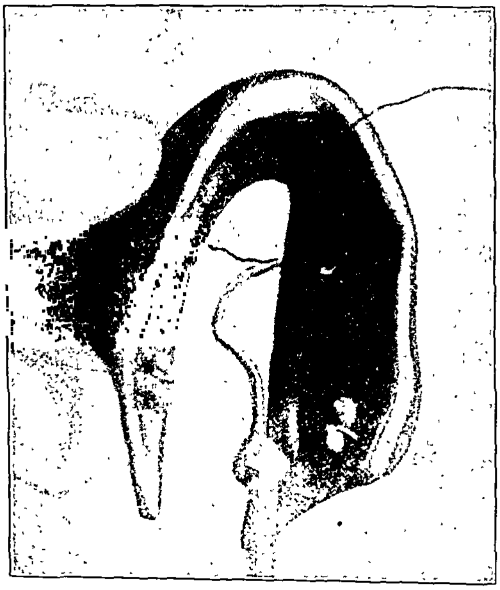

Fig. 4.—Also showing manner of passing sutures with hollow needle.

If the posterior stitches are put in first they are liable to become caught and torn out by the frequent sponging.

In introducing the needle from the oral side of the flap, as is usually done, it is necessary to pull the flaps downward, and even when held by forceps considerable difficulty is encountered on account of the small space in which one must work. The procedure recommended is the following:

The needle is entered between the flaps into the nasal cavity, rotated to one side and the point pushed through the flap from above downward, the point entering the flap on its upper surface and emerging on the inferior or oral surface.

(Fig. 3 indicates its position.) As soon as the point emerges, the milled wheel is turned and about 12 inches of the silver wire extruded from its point. The reason for extrusion of such a long piece will be noted as the description proceeds.

If difficulty is experienced in forcing the needle through the flap a pair of forceps, or, better still, the long curved scissors can be pressed against the oral surface of the flap.

The blades of the scissors are slightly separated at their points and through the separation, the point of the needle emerges. The needle is now withdrawn and the point rotated through 150 degrees in the nasal cavity and passed through the opposite flap in exactly the same manner. (Fig. 4 indicates its position.)

It will be noticed that the wire which projects from the end of the needle is folded back on the outer side of the needle in its passage through the second flap and forms an angular loop at the tip of the needle. This loop is increased in size by the extrusion of two or three inches of wire. The wire is then cut off and the needle removed.

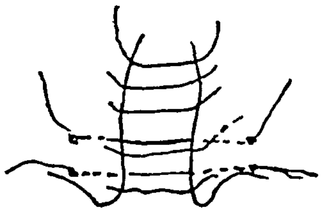

Fig. 5.—Showing sutures inserted.

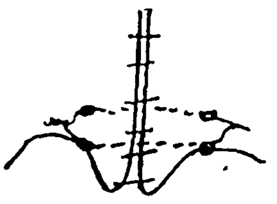

Fig. 6.—Showing sutures tied.

The reason for the long end on the opposite side now becomes manifest. Close to the under surface of the second flap is the kink in the wire made by its being folded back. If this kink is left near the flap, the wire is almost sure to break when it is twisted to tighten the suture. The short end of the wire is now seized and gently pulled out until each projecting end is about 8 inches long. This fine wire pulls through the flaps with perfect ease and no traction or cutting out ensues. The two ends of the wire are grasped by an artery clamp and passed to the anesthetist or an assistant. Thus from seven to ten sutures are inserted, passing from before backward.

Before putting in the last two sutures which hold the uvula, two sutures are passed far out from the median line to prevent the tensor palati from pulling and tearing out the stitches in the soft palate and uvula.

These are shown in Figures 5 and 6. (Also in Figs. 3 and 4.) Instead of being united across the roof of the mouth, as are the other sutures, to prevent their tearing out, they are shotted and their short ends twisted together, as shown in Figure 6. Thus, even should the shot come off, there would still be a loop over the bridge of tissue and little probability of their cutting out.

The after-care of a case requires a nurse of considerable tact and skill. In children, if struggling and crying follows attempts to use the antiseptic spray, it is best to omit it. If possible, absolutely nothing should be given by mouth for seventy-two hours, conversation should be inhibited as much as possible, and children entertained in every conceivable way. Nutritive enemas alternating with large amounts of saline solution passed high into the bowel will maintain the strength and allay thirst.

ABSTRACT OF DISCUSSION

Dr. G. Hudson Makuen, Philadelphia: Dr. Emerson has given a good description of a well-known operation for cleft palate. It has its limitations, as all operations on the palate have. Its chief limitation is that it leaves a velum that is too small and tense to perform what has been called its valvular function in respiration, phonation and articulation. Every operation on the palate fails in this respect, because even though a full quota of tissue may be present there must always be some cicatricial contraction in the line of union between the lateral halves. The Brophy operation, however, although a more extensive and serious one, does give us a more useful soft palate. I have seen some of his cases in which the soft palate very nearly fulfilled its normal valvular function. Dr. Brophy has recently made an addition to his operation. In those cases in which tissue seems to be lacking, he enlarges the velum by means of flaps from the posterior pillars, thus making a longer soft palate. As Dr. Emerson says, the operation should be done before the habits of speech have been formed. No operation on the adult palate can change or improve the speech to any great extent; it can only make it possible for the patient to learn how to speak better. It is a difficult proposition to change the habits of one's speech. We all have our speech habits and we cannot change them offhand. The patient with a cleft palate has characteristic habits of speech, which have become, in adult life, a fixed part of his psychical as well as his physical equipment, and they cannot be changed by merely changing the physical properties of the peripheral mechanisms of speech, but only by careful speech training, in which not only new muscles are brought into action but changes are made also in the auditory and other speech centers of the brain. This is an important matter in connection with cleft-palate operations in adults and even in children of 6 or 8 years of age. As I have said elsewhere, I think I can take a patient with a cleft palate and do more for his speech by psychophysical training than can be done by an operation without training. This, however, is not an argument against the operation, but only a plea for the training which must follow it, and I may add that the necessity for the training increases with the increase in the age of the patient at the time of operation.

Dr. T. E. Carmody, Denver: In speaking of the operation for cleft palate, I will take issue with Dr. Makuen, because I have had some cases in which operation late in life has been satisfactory and the patients have obtained a very satisfactory enunciation. However, my practice is to do all the operating I possibly can, and usually it is possible before the fifteenth month—before the child begins to talk—and better habits of speech are then formed. I reported in a recent article a patient operated on, a young woman of 19 years, who had been associated with a nurse for some time, and who left the city and on coming back four months later and calling the nurse up on the telephone asked her to guess who was talking and she could not. So her habits of speech could not have been bad. I have tried Dr. Emerson's lateral incision with good results, but generally it is not necessary, as we usually have enough tissue. I have seen something like 400 cases of my own and with Dr. Brophy and others, and have only seen one case in which there was lack of development. There is only lack of union. Very frequently a flap of nasal mucosa can be used either from the nasal side of the palatal plate or from the septum, and in one case I have used a flap from the inferior turbinate. I think the lateral incisions interfere with the action of the soft palate, because a flap is obtained that is not pliable, and the velum will not act as it should. Dr. Emerson has given some good methods for the after-care of these patients.

Dr. Oscar Wilkinson, Washington, D. C.: I have used some aluminum plates which are left in for two or three weeks.

Dr. Linn Emerson, Orange, N. J.: As to Dr. Carmody's remarks regarding the lateral incisions not being necessary, that I concede, but the operation which I have reported is done with a view of shortening the procedure. While it used to take me two hours, I can now frequently do it in forty-five minutes. With the use of the Graefe knife and the elevator one can strip it up in two or three minutes, whereas by the other procedure it takes a long time and one is much more liable to tear the flap. As to taking tissue from the turbinate, that can be done, but the disadvantage is that this tissue is so thin that the stitches pull out, and the blood-supply is so poor that necrosis or non-union ensues. As Dr. Carmody has shown, if the flap is loosened enough this tissue is not needed. Another point is to put the sutures in far back instead of too close to the edge. In my first operation I operated four times before I got closure; now it is rare that I have to operate more than once. There is no question of the merit of the Brophy operation, but most of my cases are in older patients. As to the mortality of the early operations: of course the younger the child the higher the mortality. These patients have a low index and since this paper was written I have lost two—one thirteen months old and one eighteen months old. Necropsy failed to show the cause of death. Both died the next day after operation with high fever, 105-6. It is possible that the anesthesia had something to do with it. In the next operation I do I shall use gas and oxygen. Relative to the improvement of speech, I have one patient on whom I operated at 11 years. He came daily for several months for training and Dr. Makuen well lays stress on the importance of that. He now has almost no noticeable impairment of speech.

SO-CALLED CONGENITAL SCOLIOSIS

WITH SPECIMEN, INCLUDING THE THORAX *

HENRY BASCOM THOMAS, B.S., M.D.
Attending Orthopedic Surgeon, St. Luke's Hospital; Chief, Department of Orthopedic Surgery, Cook County Hospital
CHICAGO

Mery in 1700 published the first case report of congenital scoliosis. Fleischman in 1810 and Meckel in 1816 were the first to assert that this deformity could exist without other defects; this was established by Mührig in 1829, Rokitansky in 1844, Hohl in 1850, and Förster in 1854.

Recently cases of congenital scoliosis are much more frequently seen and reported by orthopedists. The obstetrician of extensive practice may say he has never seen a case. If so, it is very likely that cases have gone unnoticed because regular or careful examination of the back was neglected. The pediatrician sees children at a period when this deformity is more readily discovered, and is in a position to call attention to it even before the child is sitting. However, many cases are overlooked, or if seen we neglect to attach sufficient importance to the condition, and in this way the number of reported congenital scolioses are less than they should be.

On the other hand, the number of so-called congenital scolioses, which Dr. Lovett[1] has so properly called scoliosis due to a congenital bony defect, are being described frequently, since the congenital defect, even in the adult, and the dried skeleton, tells the story and shows the etiology.

Thus, in considering the etiology of congenital scoliosis we should discard those cases which are the direct result of bony congenital defects. It is well known that such anomalies as numerical variation of the vertebrae, insertion of a wedge of bone in the column, cervical rib, bifurcated rib, absence of a rib, extra rib, Sprengel's deformity, etc., lead to scoliosis. Should we not regard as rightly belonging in the category of congenital scoliosis those cases having another origin than arrested or perverted *bony* development? If so, we have left for consideration the following theories:

1. Heredity.
2. Intra-uterine pressure.
3. Intra-uterine injury.
4. Intra-uterine paralysis.
5. Intra-uterine rickets.
6. Intra-uterine anomalies of muscles.

In considering the hereditary factor, we should be careful to distinguish between congenital and acquired characters. Histories of cases of scoliosis show that frequently other members of the family on the father's or mother's side also suffered this type of deformity. Hereditary congenital lateral curvature, however, should not be confounded with a scoliosis appearing after birth and following, for instance, congenital rickets, which easily could have prevailed in the family of the patient and that of the patient's forefathers because of innutrition and insanitary conditions existing through generations. It seems that such cases are fairly to be regarded as products of the environment, and not congenital in the true sense. The theory of intra-uterine injury calls for no comment, and "intra-uterine pressure" is at best a vague term which seems to be used at present to cover those cases for which no other explanation is at hand. Paralysis *in utero*, if combined with faulty position and uneven muscle pull which would favor scoliosis, is granted to produce it just as in paralysis after birth.

Following a suggestion of Prof. Basil C. H. Harvey, I have been impressed with the fact that the length, insertion and uneven attachment of muscles probably gives a key to the etiology of many of those cases which have no recognized cause.

Professor Harvey kindly permitted me to take the following data from his manuscript notes:

> In 1906 he has noted that in one cadaver the "left trapezius muscle extended from the occipital bone and the spinous processes of the cervical vertebrae to the clavicle and the spine of the scapula. The lower fibers extended from the spines of the fifth and sixth cervical vertebrae and corresponding supraspinous ligaments to the vertebral margin of the scapula above the spine. This muscle on the left side was absent in the thoracic region."

The following cadavers, representing a small series noted consecutively, indicated that the attachment of the trapezius is eccentric in half of this small number; it extended down to:

The twelfth dorsal vertebra on the right and twelfth on left (Case 10).

The twelfth dorsal vertebra on the right and twelfth on left (Case 11).

The twelfth dorsal vertebra on the right and twelfth on left (Case 12).

The eleventh dorsal vertebra on the right and eleventh on left (Case 13).

[1] Lovett: Lateral Curvature of the Spine and Round Shoulder, Ed. 2, p. 94.

The tenth dorsal vertebra on the right and eleventh on left (Case 14).

The tenth dorsal vertebra on the right and twelfth on left (Case 15).

That is, the tabulation shows that the trapezius in Cadaver 14 is attached to the tenth dorsal vertebra on the right and to the eleventh dorsal vertebra on the left side, and in the fifteenth cadaver to the tenth on the right and the twelfth on the left. In the cadaver noted in 1906 there is no attachment whatever in the thoracic region on the left side. I have also found in the literature one case of congenital scoliosis showing the entire absence of the trapezius on one side.

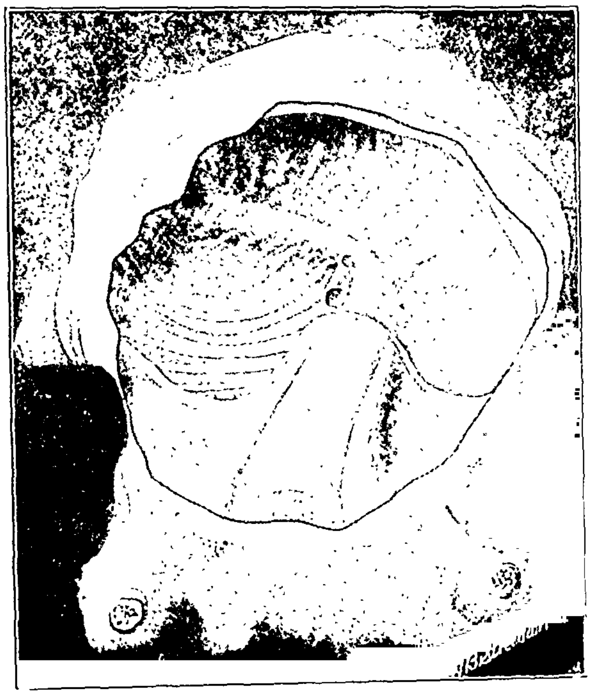

Fig. 1.—The enlarged left thorax and the contracted right thorax are well shown in the drawing.

In another small series among the same notes there is shown some variation in the length of the latissimus dorsi on the right and left side. This muscle extends up to:

The fourth dorsal vertebra on the right and fifth on left (Case 10).

The seventh dorsal vertera on the right and seventh on left (Case 11).

The seventh dorsal vertebra on the right and seventh on left (Case 12).

The sixth dorsal vertebra on the right and fifth on left (Case 13).

The sixth dorsal vertebra on the right and sixth on left (Case 14).

The sixth dorsal vertebra on the right and sixth on left (Case 15).

The question of the frequent occurrence of uneven muscle attachment because of inequality in length of two opposing muscles is borne out by the majority of dissections, making the asymmetry of muscle groups almost the rule.[2]

Such anomalies must be considered as cause for beginning asymmetry, congenital and acquired, whose exaggeration by position would produce scoliosis. On the other hand, there are cases of scoliosis whose dissected back muscles show no anomalies; one case found on the dissecting table later revealed tuberculosis as the cause. However, it cannot be contended that all subjects with anomalies of muscle length or attachment necessarily have scoliosis.

Yet it is reasonable to allow that such facts as the tabulations presented show should justify a theory based on such anomalies of muscle group as is here mentioned. These considerations indeed raise the question whether there are any cases of congenital scoliosis in any other sense than that the deformity is induced by some organic anomaly giving rise to an inclination to deformity.

So far as I know, the theory that scoliosis may originate from an asymmetrical attachment of muscles has not been advanced. I have presented it at some detail here because I think it ought to have a place in the consideration of the general etiology of cases of this class. As a matter of fact, the case which I am to present is not of this class, but one due to bony defect of the vertebrae and of the ribs.

REPORT OF CASE

History.—M. G., a girl, aged 5 weeks, entered the Cook County Hospital in 1913. The parents complained of inability on the part of the child to nurse because of a deformity of the lips. The labor was normal at nine months. The father, mother and her three sisters are all living and normal in every respect; the only other child in the family is normal. The young, healthy-looking mother never had a miscarriage. Venereal history negative. Examination showed a child poorly nourished and badly deformed by congenital defects. There was double harelip and cleft palate; absence of the globes of the eyes, and right lumbar, left dorsal scoliosis, rigid and with rotation. Several operations for harelip and cleft palate were performed. The child was in the hospital for about fifty days and died of pneumonia.

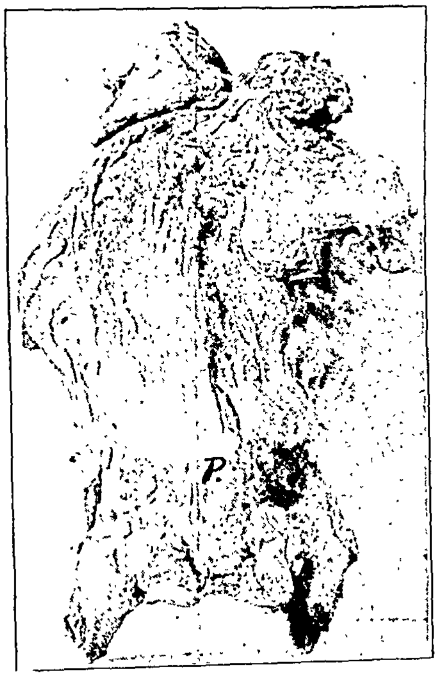

Fig. 2.—Back of specimen, showing the left rotation and bulging, the low right and high twisted left scapula.

The Scoliosis.—The deformity of the spinal column was marked not only when the child lay in the crib, but also when she was held up by the arms and head with stretching of the back which would have straightened a flexible curve (Fig. 1). Palpation of the ends of the spinous processes in the living child revealed a long curve in the dorsal-lumbar region, which was to the left. Rotation bulging of the left posterior ribs was markedly evident even when the shoulders and the head were on the stretch, and this rotation increased when the body was flexed. The left anterior chest wall was prominent, the right side concave. The crests of the ilia were uneven; the left shoulder was much higher than the right, and the scapula on the left side was elevated in a way to suggest Sprengel's deformity, having its position in regard to the right scapula, thorax and clavicle, raised, and its inner border turned toward the spine.

The Specimen: The Back: When the skin was removed and the muscles exposed, the rotation on the left side of the thorax and the extreme elevation of the left scapula attracted attention by their deforming effect. The spaces between the ribs on the left side are much larger than on the right side, and the angles formed with the vertebra and sternum are unlike on the left and right side. Taking a common point on the spine as *P* (Fig. 2), and measuring to the inferior angle of the left scapula, gives a distance of 5 inches, while the distance from the same point to the inferior angle of the right scapula is only 3 inches. Measuring from the same point to the left, to the most distant point on the eighth rib is 4 12/16 inches, while to the right, to the eighth rib it is only 3 8/16 inches.

---

[2] Poirier and Charpy: Traité d'anatomie humaine, ii, 496: "Asymmetry is almost the rule; usually one of the trapezius muscles descends lower than the other" (L'asymetrie est presque la règle; ordinairement, l'un des deux trapèzes descend plus bas que l'autre.)

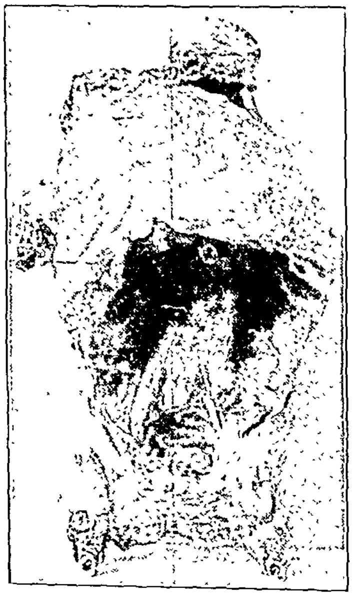

Fig. 3.—Anterior view of specimen, showing the slanting direction of the sternum; the twisted, leaning thorax; dipping of lower line of thorax on right side as compared with the lower edge of the left thorax. Note that the left shoulder girdle is nearer a line drawn to the pelvis parallel to the table than are the cervical vertebrae.

The Anterior View of the Body.—The anterior-superior spines of the ilia are not parallel to the surface of the table on which the specimen was placed (Fig. 3), the right trochanter and ilium are higher than the left, and the spinal column is seen to incline to the left, beginning at the pelvis and extending to the eleventh dorsal vertebra before it bends to the right. The thorax is inclined to the right, slightly rotated in the same direction. The wide spaces between the ribs on the left side and the narrow spaces on the right side are plainly seen from this view. The left shoulder is much higher than the sternoclavicular joint.

The Roentgenogram.—This was taken from the specimen by Drs. Harting and Hubney. It shows the entire pelvis tilted to the left; even the heads and necks of the femur show this tilting. The curve is seen to be a long total curve to the left beginning with the last lumbar and including the entire column, having its apex at a point represented by the tenth, eleventh and twelfth dorsal vertebrae.

The Vertebrae.—There are six lumbar vertebrae apparently normal in all respects, judged from information obtained from the roentgenogram. The dorsal vertebrae are shot to pieces, not one of them appearing to be entirely normal. The right halves of most of them seem defective and show the mechanical cause for the scoliosis. The eleventh and tenth present only the left half of the vertebrae, as do the eighth and second, while the remaining show all grades of incomplete bifurcated portions of the right side of the vertebrae.

The Ribs.—The ribs on the left side are twelve in number and appear fairly normal in shape and size. The various angles they make with the vertebrae vary considerably and the attachments are irregular and not normal, in most instances on account of partial absence or changed inclination of the vertebrae. On the right side of the thorax there are eleven ribs only, the twelfth being fused with the eleventh, both of which are attached to the tenth. Each is narrow and irregular, with faulty attachment ends, and all are crowded together, diminishing markedly the capacity of the chest.

Clavicle.—The right clavicle shows a marked twist.

Dimensions.—The following measurements will give an idea of the comparative dimensions of the left and right sides of the thorax:

Measurement from the sternoclavicular notch to the junction of the fourth rib with its cartilage (Fig. 3): left, 5 6/16 inches; right, 2 15/16. Measurement on the circumference between a point on the sternum at the junction of the fourth rib and a given spinous process: left, 5 5/16 inches; right, 4 13/16 inches. Measurement to determine depth of thorax was taken by pushing a probe through the anterior chest at a point between the fourth and fifth ribs at the junction of the rib and its cartilage and pushing the probe through on the left side to the convexity of the curve and on the right side to the concavity of the curve (Fig. 3): left, 2 8/16 inches; right, 2 10/16 inches.

Further description of the bony framework will be given when the specimen is dissected and the skeleton cleaned up, which is deferred in order to allow those who are interested in the case to examine the thorax closely before farther mutilation.

31 North State Street.

ABSTRACT OF DISCUSSION

Dr. Roland Meisenbach, Buffalo, N. Y.: Those of us who are constantly working with scoliotic cases in children and seeing the roentgenograms of the cases must be impressed with the fact that the anomalies in the bones are not so great as one would generally suppose, as compared with the musculature of the child and the curve of the spine. As the child grows older, the bones, especially the bodies of the vertebrae, become malformed. The irregular muscular development, I believe, occurs very early in some cases, and is induced in others, and is a very important factor in the etiology of scoliosis.

Dr. Reginald H. Sayre, New York: These congenital cases of scoliosis must be more frequent than we have generally been led to believe. I have seen, I am certain, half a dozen that I can remember at present, and in those that have occurred since the days of the Roentgen rays, it happens that all had skeletal abnormalities. I know that these are congenital cases, because I saw them within a few weeks of birth, and the deformity was very marked at that time. Some have fused ribs; some, absence of ribs; some, extra vertebrae, or V-shaped vertebrae; and one, a marked distortion of the pelvis, which was very much warped and twisted. The deformities of the pelvis do not attract our attention so much as they should in connection with the prognosis whether these patients should or should not get married. I have at present under my care a girl whose father is a doctor. He is really worried, not so much about the shape of her thorax as about that of her pelvis; and he wants to know whether treatment will correct that, so that she can get married. That is the point that the obstetricians think of, but that the orthopedists do not think of so much in looking after these cases.

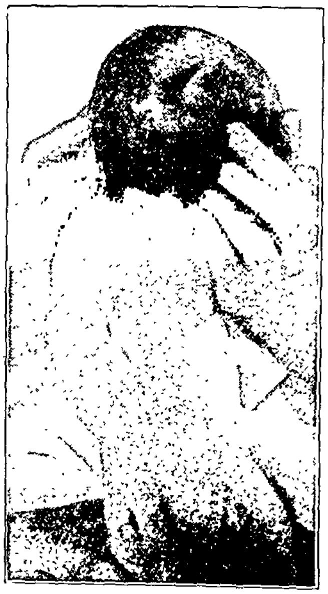

Fig. 4.—A photograph taken at about 3 weeks of age. The child died of pneumonia when 3 months old. Traction is being made above by the nurse as she holds the shoulders and head, and below by the doctor who is stretching the left leg. The left dorsal curve and the rotation deformity are well shown.

On Style.—Every man will read a book with more pleasure or even with more ease, if it is written in fairer characters. Therefore every man will also listen more readily to what is spoken, if it is signified by appropriate and becoming words. —*Epictetus.*

FRACTURES OF BOTH BONES OF THE LEG*

FRANK E. PECKHAM, M.D.
PROVIDENCE, R. I.

Since writing a paper last year which included this fracture, but without going into the details very much, I have had a number of inquiries regarding them which gave the incentive to elaborate the subject somewhat.

In the first place, just as in cutting operations, as these fractures keep coming, a proper technic should be developed, and the Roentgen-ray part should be the same in practically all of them. Each fracture is a definite mechanical problem and the only way to get exact knowledge of the problem is to have roentgenograms in at least two, and sometimes more, views. Then it is possible in a fracture of both bones of the leg to know how the fragments are placed, how much riding by, etc., and from this knowledge to map out exactly what moves are necessary, not only to reduce but also to get an end-to-end position, if it can possibly be done. If at first there is some swelling, the leg may be placed in a pillow splint with elevation, when it hould rapidly disappear. This splint also prevents undue motion which might irritate the tissues as well as cause some pain. For the setting, the patient should be under an anesthetic for complete muscular relaxation. The mechanics for the reduction must be precise, must really accomplish what is desired and must hold the bones accurately end to end while (in my own cases) plaster of Paris is properly applied and set.

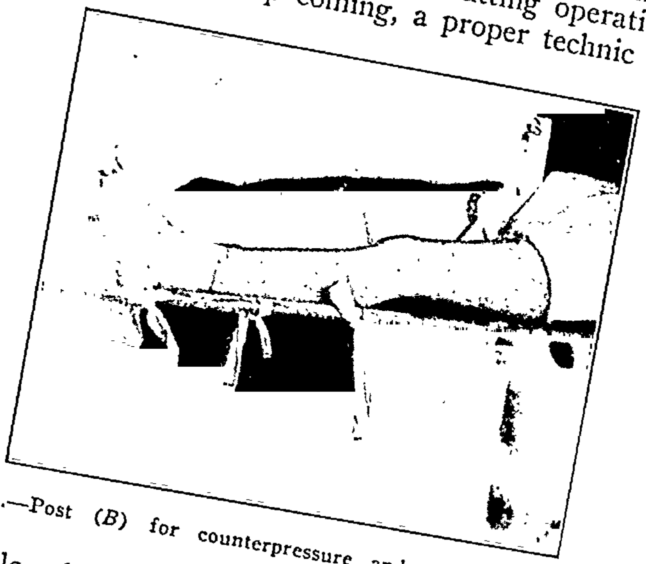

Fig. 1.—Post (*B*) for counterpressure and the foot and ankle bandaged.

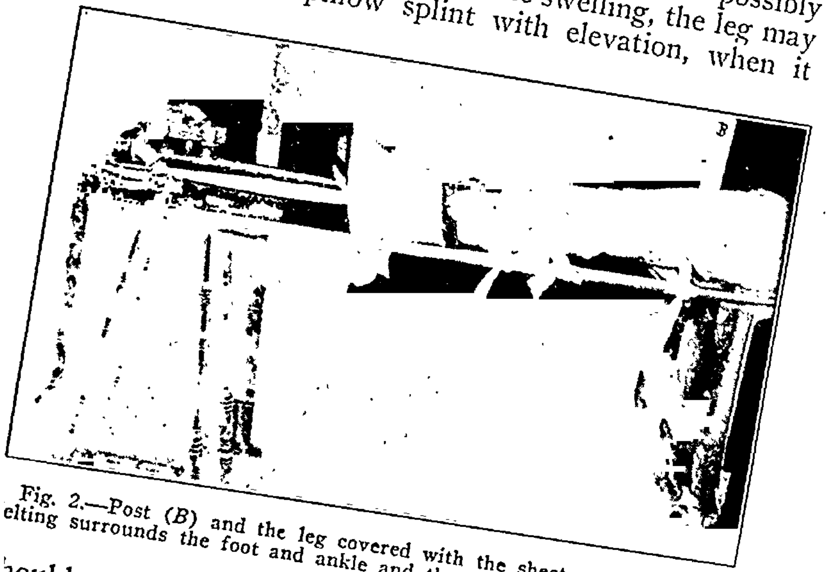

Fig. 2.—Post (*B*) and the leg covered with the sheet wadding. The elting surrounds the foot and ankle and the traction is applied.

The mechanism which thus far has served me well consists of a Bradford frame with an upright or bar for counterpressure against the perineum (Fig. 1), and a windlass arrangement at the opposite end to make traction on the leg (Fig. 2). After the patient is in position, the foot and ankle are bandaged with a cotton bandage to prevent swelling (Fig. 1), and then the foot and leg are covered with sheet wadding, preparatory for the plaster of Paris (Fig. 2). About the foot and ankle is placed full thickness gray felting, and over this the webbing is arranged and attached to the windlass for traction (Fig. 2). The windlass is made in two sections so that the foot on the well leg may be attached and pulled on separately, thus preventing the pulling around of the pelvis and interfering with firm traction on the affected side. Cross-bands of cotton bandages are put in two or three places, one of them being directly under the fracture, thus supporting the leg (Figs. 1, 2 and 3).

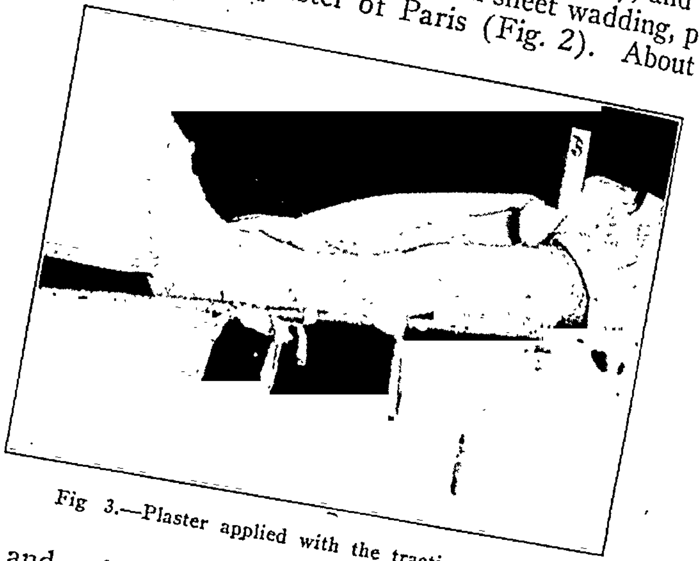

Fig 3.—Plaster applied with the traction still on.

A careful study of the roentgenograms has shown just what is to be accomplished. A sufficient amount of traction is now applied to simply straighten the leg when the operator, who is grasping the leg at the point of fracture, with both hands, gently elevates, thus slightly angulating the fragments. Experience teaches when, in this way, the bones, especially the tibia, are end to end. Then as traction is increased, the leg is gently lowered until it is perfectly straight on the supporting cross-bands. The strong traction necessary also prevents the leg from sagging. If the fracture, particularly of the tibia, is transverse and the frag-

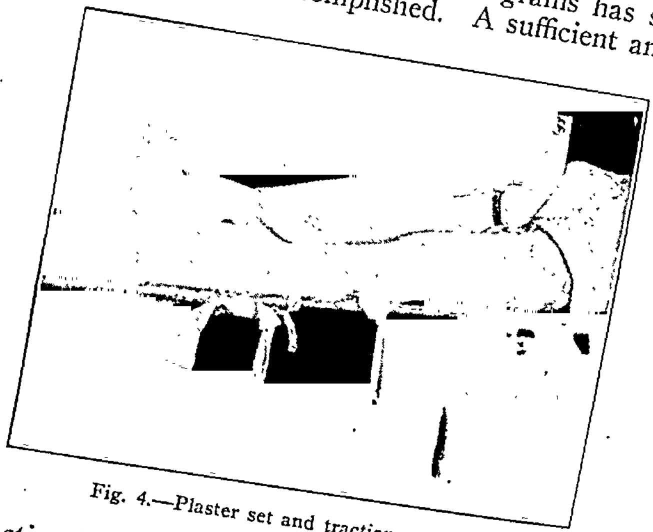

Fig. 4.—Plaster set and traction removed.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

ments are end to end, such strong traction is not necessary; but if the fracture is oblique, full and strong traction is necessary all the time and until the end of the application of plaster. If the fracture is at the lower end, the webbing for the traction should go downward over the outer malleolus; in this way, not only the tibia, but also the fibula can be gotten into apposition, if the fracture is higher up, the traction webbing should go down over the inner malleolus, and in some cases it must go down over both malleoli, in order to pull equally on both bones. Usually in simple fractures, both bones can be arranged, but if perchance the fibula is not quite controllable, the tibia can be gotten into perfect position and the fibula ends in contact, if not in apposition, in which case the fibula should take care of itself as far as union is concerned.

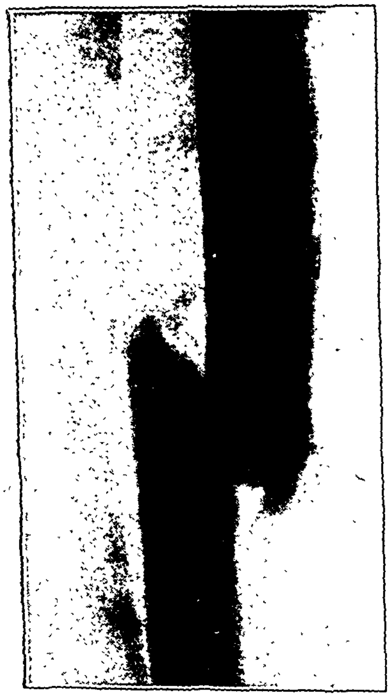

Fig. 5.—A comminuted fracture of the tibia with a simple fracture of the fibula (Case 1).

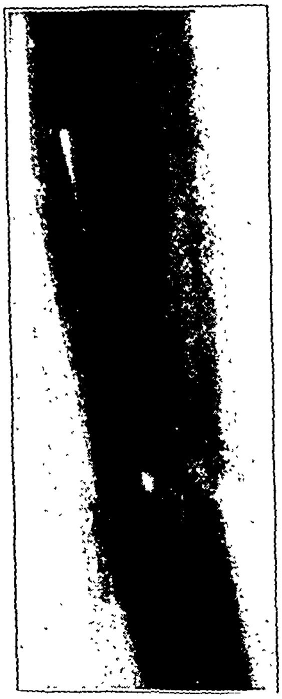

Fig. 6.—The lateral view after setting (Case 1).

When it is thought that the ends are in apposition on the frame and traction applied, a roentgenogram must be taken in at least two views, to be sure of such fact. If it is not all right, a glance at the plate shows just what further work is to be done, and it must be done then and there. When it is all right and actually demonstrated (by Roentgen ray), the mechanics as described will hold while plaster of Paris is applied and allowed to set. Then still another picture must be taken through the plaster, to see if the fragments have remained in position. The plaster is applied to the whole leg, up to the groin and including the foot.

This work, in private practice, is usually done at the office, and as the time is not long, the patient quickly recovers from the anesthetic and may be taken home easily in a machine. If an automobile is not obtainable, the ambulance may be utilized. It is always urged to bring the patient to the office, because the powerful Roentgen-ray machines are there, and the facilities for developing the plates are better. If, however, for some reason the patient insists on having it done at home, a portable Roentgen-ray coil is set up at the bedside and the plates developed in a darkened bathroom or even in a clothes closet.

If now, the last roentgenogram taken through the plaster shows that the bones have not been quite perfectly held, or if the picture, which is again taken at the end of the second week, shows that the position is not satisfactory and any change has to be made, this is the time to make it, because it is at about this time that material begins to be thrown out which is later to become calcified, and thus make a solid and bony union. This particular time is selected because when this material begins to be thrown out, the fragments may be readjusted and this callus material is of some assistance in sticking the ends of the bones together. This readjustment may be so slight that an anesthetic is unnecessary, or if much is to be done, an anesthetic is necessary. If readjustment is made, it means also that another plaster cast should be applied. At the end of a month from the fracture, this cast may be bivalved, so that the posterior half may serve as a splint for two or three weeks longer, depending on the case.

If the mechanics have been carefully applied at the first setting, there is nothing to be done until this bivalving of the plaster.

Instead of showing any number of cases, I shall present only four.

CASE 1.—This was a comminuted fracture of the tibia, and a simple fracture of the fibula (Fig. 5). Figures 6 and 7 show the bones pulled down into position.

CASE 2.—This was a comminuted fracture of both bones just above the ankle joint. Figure 8 is the worst view, and Figure 9 (also the worst view) shows the bones after being pulled down into position and quite some time being spent in manipulation while the traction was applied.

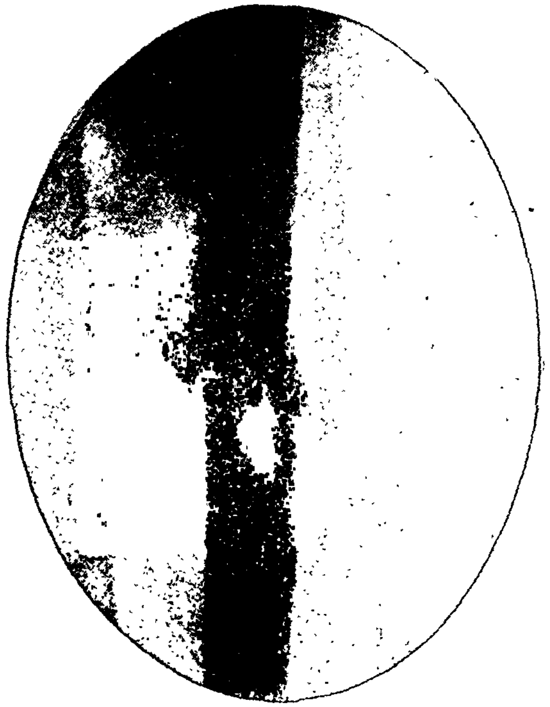

Fig. 7.—The anteroposterior view of tibia after setting (Case 1).

CASE 3.—This was a compound comminuted fracture of both bones which suppurated (Fig. 10). This case was reported at the 1913 meeting of the American Orthopedic

Case 4.—This laboring man presented himself fifteen months after the accident still unable to stand on his feet for very long intervals of time without pain and consequently still unable to work. The roentgenogram shows the bones sagging backward and inward, representing, to my mind, a necessarily weak union and hence a sufficient excuse for his disability (Fig. 13).

The treatment of fractures offers a very fascinating field for men of mechanical ability, and the class of fractures here treated, and indeed all fractures should be studied carefully not only to evolve methods whereby the (open) operative treatment may be obviated, but also that the mechanical treatment may give better results without the risks.

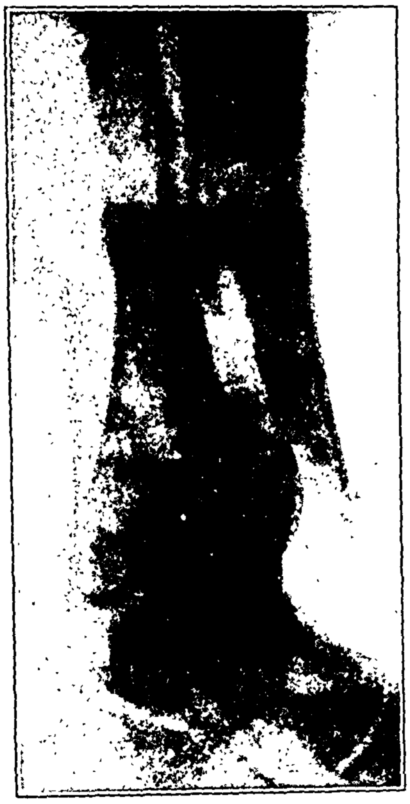

Fig. 8.—Comminuted fracture of tibia and fibula just above the ankle (Case 2).

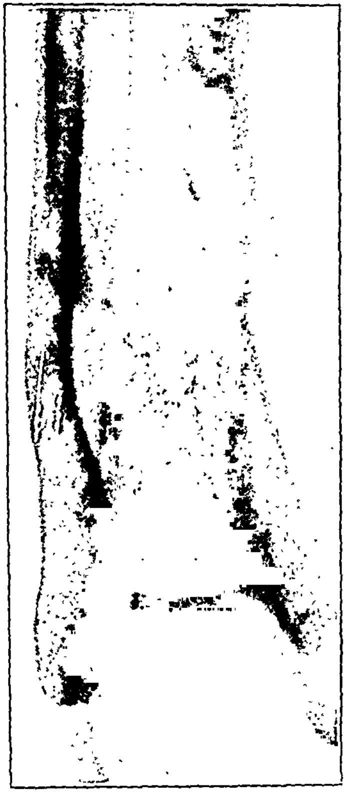

Fig. 9.—The bones pulled down into position (Case 2).

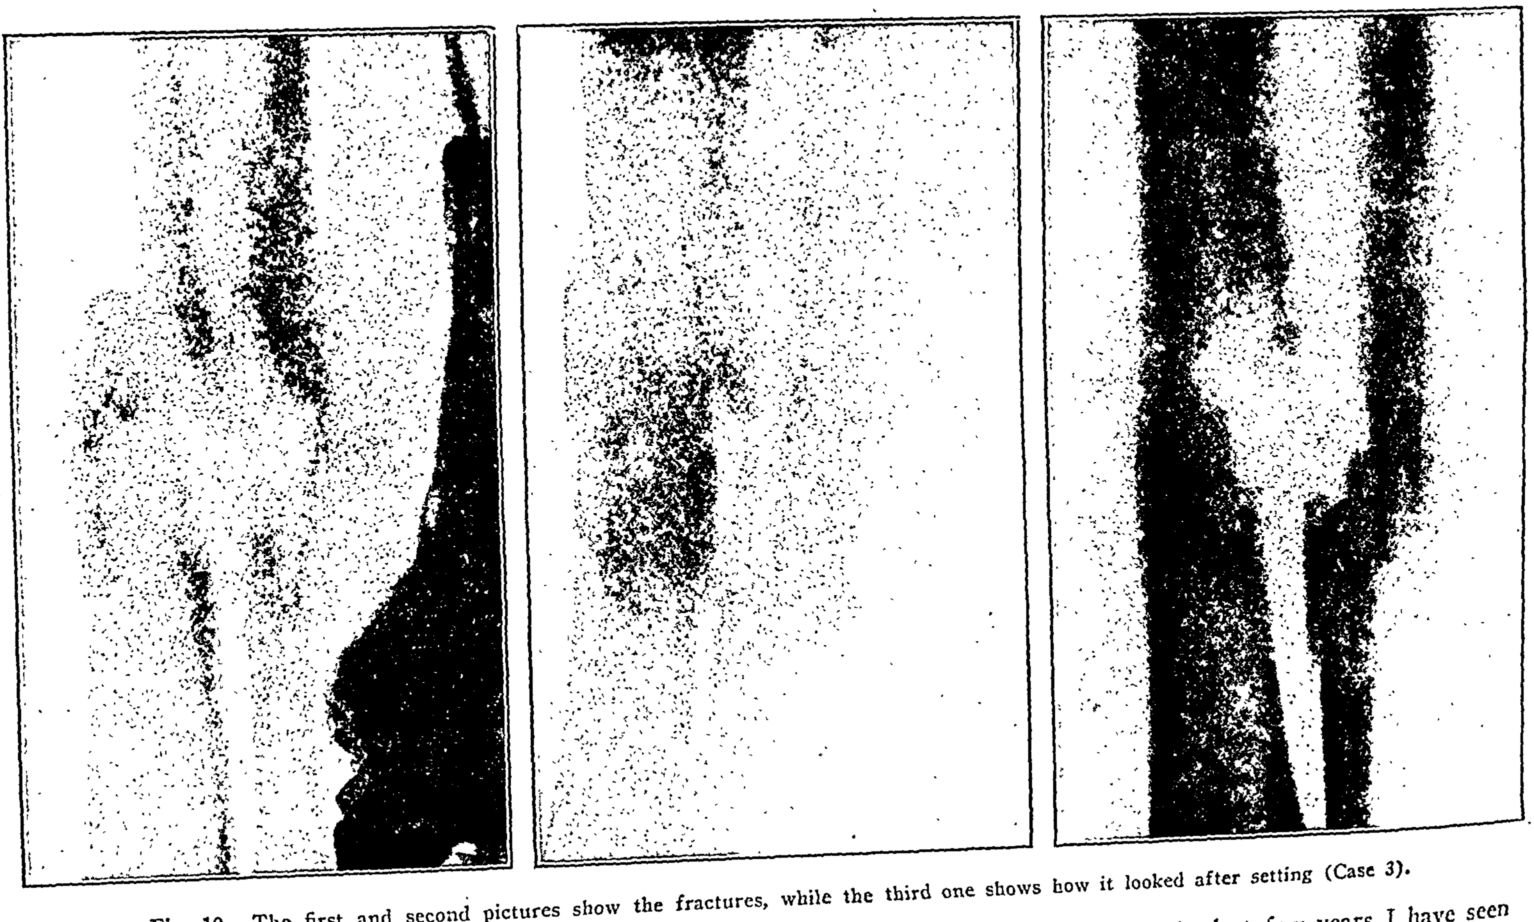

Fig. 10.—The first and second pictures show the fractures, while the third one shows how it looked after setting (Case 3).

ABSTRACT OF DISCUSSION

Dr. H. W. Orr, Lincoln, Neb.: Some years ago, having to treat such a fracture as Dr. Peckham has described, I had occasion to use a method that I have since used with great success, namely, having first applied, as carefully as possible, a perfectly fitting cast on the foot to within a few inches of the point of fracture, I then apply plaster above the fracture, including the knee, which is flexed; so that I can make traction against the fracture and the knee. Then I manipulate the fragments of the tibia and fibula to as perfect a position as possible, and apply plaster over the point of the fracture. Thus, the plaster at both ends having set, and the fracture being under control with traction on the two completed portions, the final instalment of plaster is put on over the point of fracture, with sheet wadding beneath it. The patient referred to was in the country, and could not then be moved; but he was brought to town a week later, to have a roentgenogram taken. It was found that the position was perfect. No change was made, and I got a good result. I have done this in other cases of fracture of the leg and have always secured equally good results, without pressure necrosis. I have tried it occasionally in fracture of the femur and arm, and have generally obtained as good results; but in fracture of the leg, I have had a splendid result in every case.

Dr. Fred H. Albee, New York: It is important to treat these cases mechanically, if possible, without operation; and especially to avoid the use of the metal or Lane plate. Within the last few years I have seen a large number of ununited fractures of the tibia in cases in which the Lane plates had been used. How much these plates had to do with influencing non-union, I do not know; but it seems probable that they had something to do with it. For instance, I cite a case in which there was a fracture of the tibia and two of the fibula. The tibia was plated, and both fractures in the fibula were untouched. The one on which the Lane plate was used, failed to unite, while both of the others united perfectly. I believe that a large percentage of these cases can be controlled by the mechanical methods mentioned by Dr. Orr, Dr. Peckman, myself and others. The Lane plate, even if there is no suppuration, may effect non-union. In a case of fracture of the tibia the Lane plate was used and a large sequestrum came out. There were 2½ inches of the shaft of the tibia removed on account of infection. It was the entire lower end of the upper fragment of the tibia included in the upper end of the Lane plate. As the patient was most anxious to get back to work, we put in a graft ten weeks after removal of the sequestrum, although there was still a sinus. The graft held in, spanning this 2½ inches of space; and to-day the patient has a very firm leg, which he uses constantly in his work. In the presence of a sinus and a loss of 2½ inches of the tibia, union with the preservation of the full length of the leg, could, I believe, have been accomplished in no other way except by the inlay bone graft.

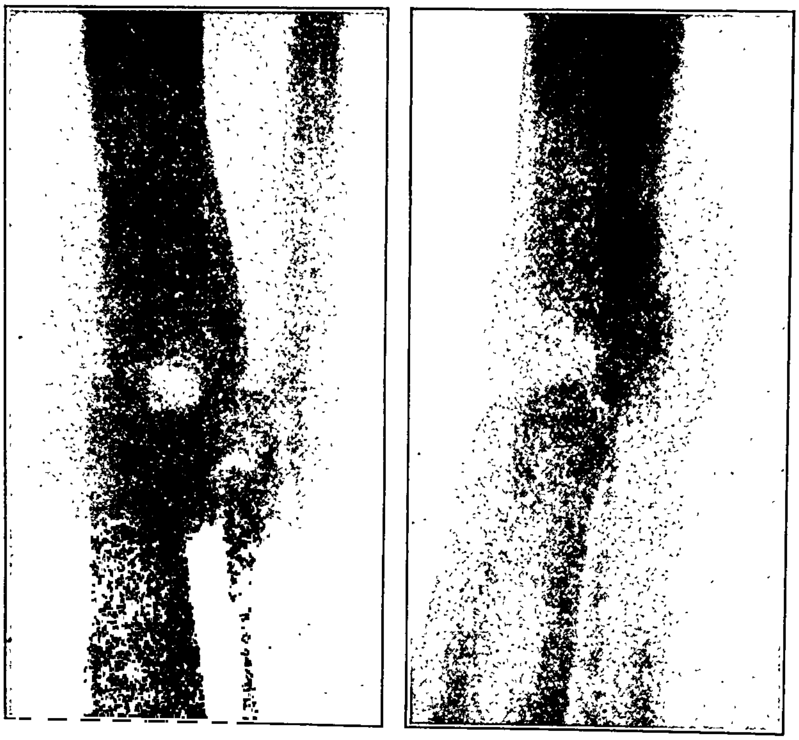

Fig. 11.—About four months after the injury (Case 3).

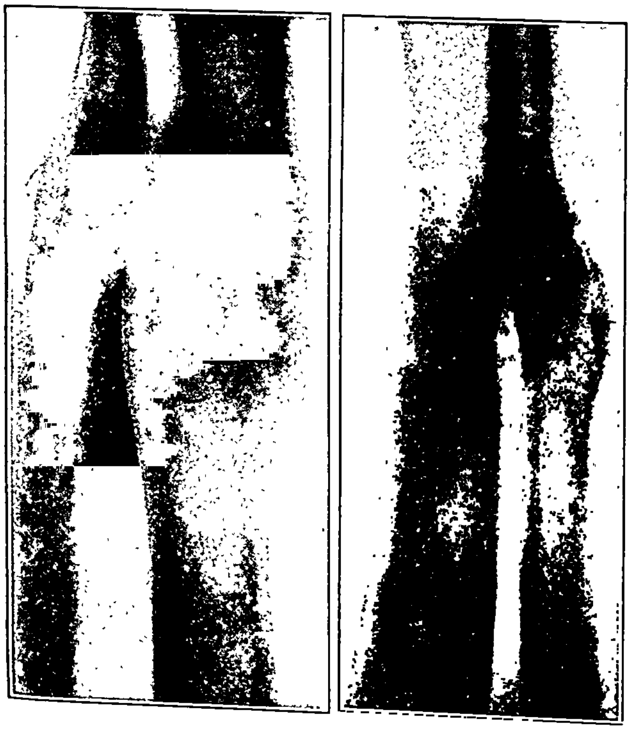

Fig. 12.—About seventeen months after the injury (Case 3).

DR. S. C. BALDWIN, Salt Lake City: I am afraid that Dr. Peckham has overlooked, to some extent, the future use of the limb after the healing of the fracture has taken place. One of his roentgenograms shows twisting of the lower fragment on the upper fragment, and several of the plates show that the lower fragment of the fibula was overriding the upper fragment. If these cases are watched afterward, it will be found that many come back for the relief of pain in the feet, as the result of a present or an approaching flat-foot, because of the weight-bearing being on the wrong part of the ankle. As I have before remarked, I suppose that none of you has ever seen a painful foot on which the patient walked in the position of varus. It is only in the position of valgus that I have seen painful feet. If the fracture is placed in a position in which the lower fragment of the fibula overrides the upper fragment, there will be, in all probability, a condition of valgus later on. Also, when the fracture is put up in such a position that the lower fragment of the tibia is twisted outward, a condition of valgus will come on later, due to this position. It is important to put up all fractures of either the fibula or both bones of the leg in a position of varus. Dr. Orr's suggestion with regard to making traction through the plaster dressing is an important one. I have found in a number of

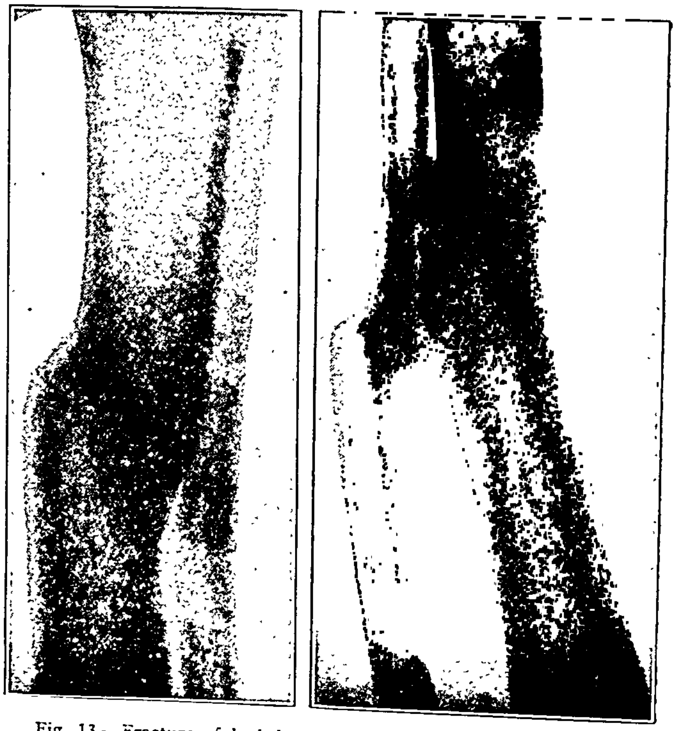

Fig. 13.—Fracture of both bones of the leg fifteen months after accident (Case 4). The bones are sagging backward and inward. (How not to do it.)

cases that extension made with the cast on is very much more comfortable to the patient than traction made on the foot without the plaster cast.

Dr. John Ridlon, Chicago: I wish to utter a word of caution against putting on a plaster boot and making traction on it. The heel very easily becomes sore from the constant pressure used in making traction on the plaster boot and maintaining it by the plaster boot and a fixed point of the bone. When a patient complains of the heel or the dorsum of the foot, the matter should be at once investigated. I had the misfortune in one case to have a necrotic spot produced on the heel as big as a silver dollar, which took four months to heal. It is a beautiful way to make traction; but the padding must be very thick, and great care exercised lest necrotic spots appear.

Dr. J. D. Griffith, Kansas City, Mo.: We must be, and are, exceedingly interested in all this fracture work. We must remember that the public to-day expects 500 per cent. more than it did thirty-five or forty years ago. We are now not only more liable to complaint from the public, but also to be cautioned by the attorney for the patient that we shall be brought up before a judge to decide whether or not the fracture was properly treated. Nowhere in the body do we get into more trouble than in fractures between the foot and the knee, with the exception of the ordinary common Colles's fracture; and this is the place where the individual feels the pain. He will then hunt up a shyster attorney to bring suit on account of the pain in the foot after a fracture of the tibia or fibula. The roentgenogram, which he has succeeded in getting in plate or picture from the other man, shows that he has not a perfect line in one position or the other. If he gets hold of the wrong one, or the worst one, this will raise a row. Every now and then, in making this forced traction that Dr. Peckham speaks of, on the Bradford frame or in any other way, we do not always know the condition of the patient's musculature and ligamentous structures as we should. I was unfortunate in one case, in which, while making this traction, the following day — or shortly afterward, within two or three hours — there was a sharp, acute, synovitis of the knee-joint. I made up my mind that in this case, although the fracture was at the juncture of the lower and middle third, I had made traction enough to frazzle or nearly tear in two the lateral ligaments of the knee; and it was six or eight months before the patient could put weight on the knee without pain. I came near getting into a lawsuit over this case, hence, this word of caution. This is an exceedingly interesting phase of the subject; because we are continuously advancing, and our education of the people is now such that they quickly learn every thing that we should do.

Dr. F. J. Cotton, Boston: I agree entirely with Dr. Albee. Dr. Peckham's work is interesting, not only in general, but also because it is the way by which we can avoid non-union in the lower half of the leg, which has been annoying us for so long. Frequently cases of non-union have been observed after the use of Lane plates, and a good many cases have occurred without previous plating. It seems to me that it depends on poor reduction; and that our way out of the difficulty depends on careful mechanical work, so as to get an exactly true position and to obtain primary healing, even in this poorly nourished region of the body. This is the only way to avoid the cases that come to us in such large numbers later on.

Dr. F. E. Peckham, Providence, R. I.: So far as Dr. Orr's method of treatment is concerned, I distinctly stated in my paper that while this is my method, the other may be equally good. I cannot use Dr. Orr's method so well as my own because I am not sure of my alignment after the foot is encased in plaster. This statement that these cases must be clinically in alignment also answers Dr. Baldwin. I think that he must have misread the roentgenogram, because these fractures are in alignment clinically, and the weight-bearing of the patients is all right. Dr. Ridlon's caution is well given. I have sorrowed for the same reason that he has. I had a case of a bad slough on a heel; but I have found that with the thickness of the felt that I am now using, I have, so far, been able to avoid such accidents. Nevertheless, that is an important point. The heavy gray felt seems to overcome this difficulty.

ANKYLOSIS OF THE ELBOW

WITH REPORT OF FOUR CASES TREATED BY ARTHROPLASTY*

W. RUSSELL MacAUSLAND, M.D.
Surgeon-in-Chief to the Orthopedic Department of the Carney Hospital
BOSTON

Ankylosis of the elbow is probably more objectionable than ankylosis in any other joint in the body. Elsewhere, while stiffness is objectionable, there is, nevertheless, an advantage gained in obtaining stiffness in a good position, more particularly in the hip and knee joints. In the hip, for example, we try to get extension and abduction, realizing that flexion and adduction are deformities interfering with function. In these joints, the end-results of arthroplasties are not so certain. In the elbow, however, there is no position in which ankylosis will not interfere with function.

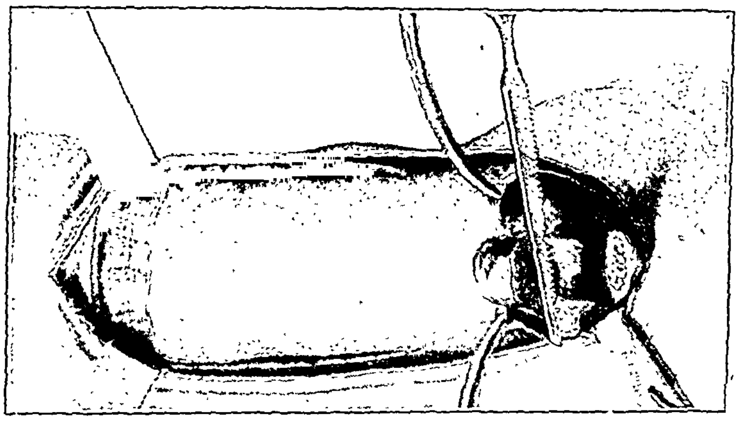

Fig. 1.—Arthroplasty (Murphy). Skin and fat dissected to either side. Fat flap below skin to triceps elevated. Ulnar nerve dissected out and retracted by gauze. Olecranon tip sawed through and pushed up. End of humerus being sawed off.

Ankylosis is in the main the result either of infection or of trauma. The former may be caused by various organisms. When the onset is sudden and the course severe, the causative agent is usually the pneumococcus, gonococcus or streptococcus. Ankylosis may, however, result from a polyarticular arthritis, of insidious onset and progressive course. In the former, the resulting ankylosis is usually bony; in the latter, at least at first, it is fibrous.

Following trauma the ankylosis is commonly the result of a dislocation fracture with wide displacement. The ankylosis result is in this case due to mechanical interference. The hematoma formed at the time of the trauma organizes, forming considerable exuberant tissue; ankylosis finally resulting is fibrous.

Various methods have been tried to remedy this ankylosis. Wolff attempted to correct the deformity by removing all the exuberant tissue. This method has usually been attended by poor results, owing largely to the inaccessibility of the part and difficulty of approach.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

Various foreign substances have been used by different men to separate the parts. Gluck used ivory pegs, Pupovac magnesium sheets, Baer[1] chromicized animal membrane. These have been found unsuccessful and have been largely abandoned. The inabsorbable material acts as a sequestrum and later gives rise to irritation. The Baer membrane has not been successful in my hands because of reankylosis after the rapid absorption of the membrane.

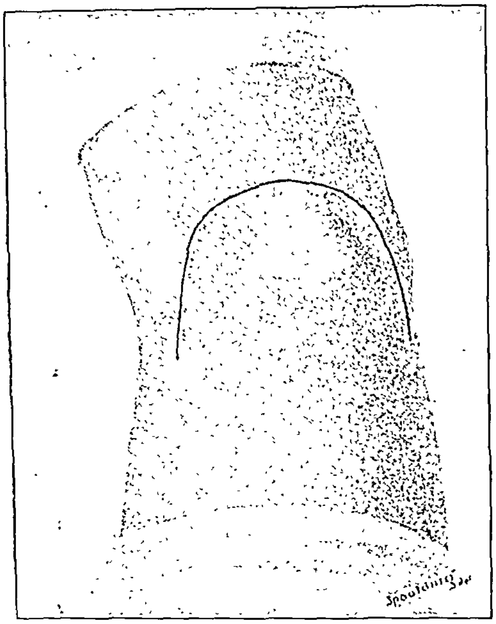

Fig. 2.—Line of incision.

The interposition of soft tissues was first used in a case of temporomaxillary ankylosis in 1893 by Helferich,[2] who interposed part of the temporal muscles.

In the elbow the first operation on record is that of Quenu[3] in 1902, who resected extensively the inferior end of the humerus and the superior end of the forearm, and detaching the anterior ligament and doubling it with a few fibers from the brachialis anticus, fixed it against the bony surface of the humerus with three sutures to the fibrous posterior parts, keeping the parts in plaster fifteen days. He reported a good functional result.

Murphy[10] first used his fascia method in October, 1901, on a knee joint. A large layer of fascia lata with a thin layer of muscle tissue attached was dissected from the outer surface of the vastus externus, with its base below and anterior. A small flap of fascia covering the vastus internus was dissected free and placed between the patella and the femur. He first mobilized the elbow by this method in 1904 in a case of ankylosing arthritis. A pyriform flap of deep fascia was dissected from the posterior surface of the triceps. The flap was 4½ inches long by 2 inches wide at its upper end and received its blood supply from a broad pedicle which remained attached to the muscle and fascia just below the level of the olecranon. After the bony parts had been remodeled, the fascia was drawn down and turned onto the joint around the inner margin of the olecranon. The proximal portion of the flap covered the trochlea and lined the olecranon depression and the lesser sigmoid cavity, while the distal portion covered the external condyle. Subsequent events showed that the flap was not carried sufficiently high on the anterior surface of the humerus to permit adequate flexion of the joint. Five months later, the patient could pass his hand through an arc of 5 inches. Pronation and supination were about one-half normal. His second case was reported two months after operation. The hand could be moved actively through an arc of 3 inches and the elbow forcibly flexed to an acute angle and extended to 160 degrees. Pronation and supination were approaching normal.

I believe from my experience thus far that there are certain objections in dealing with the fatty tissue used by Murphy, such as embolus, fatty necrosis from poor circulation and as happened in Cases 1 and 2, skin necrosis due to the use in the flap of the tissue holding its blood-supply. I, nevertheless, report these cases, citing my fat and fascia method in the first two and the transplantation of fascia lata in the third and fourth, a procedure much more surgical in appearance and with development in technic I am sure more satisfactory in final results.

Case 1.—M. R., woman, aged 34, referred by Dr. Hussey of Holyoke. Family history negative. She has had attacks of rheumatism for the last thirteen years, affecting ankles, elbows and knees. These were affected nine years ago, and were operated on one year later. The right wrist was attacked five years ago, the left wrist and knee six months ago. Examination revealed a well-developed and nourished woman. Heart and lungs negative. Right knee ankylosed with scars on either side. Both knees slightly flexed. Right ankle, contractures. Ankylosis with some contracture of the Achilles tendon. Right elbow ankylosed in about 125 degrees. Left elbow, motion good with exception of 10 degrees limitation in extension. Patient was admitted to the orthopedic service of the Carney Hospital, Sept. 6, 1910, and received rest, compression strapping for the knees, and spiral strapping for the feet, together with aspirin and flannel bandages. Under this treatment very slight improvement took place in

the knees and feet. In October, on account of the swelling and bogginess of the left knee, an arthrotomy was advised.

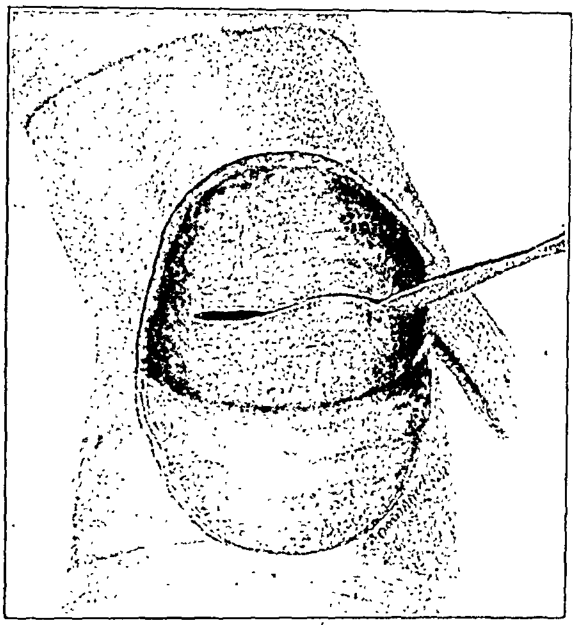

Fig. 4.—Cutting through muscle and fascia to joint.

October 19, ether operation, Dr. MacAusland. Incision about 4 inches long, on the inner side of the left knee, extending through the fascia and capsule into the joint. The synovial fluid was thickened and viscid, and a large lipoma present in the anterior part of the joint which was removed as well as many of the small fringes, and the joint washed out with salt solution. The incision was closed in the usual manner. Daily manipulations followed this operation, beginning on the fifth day, and an uneventful recovery took place as regards the knee.

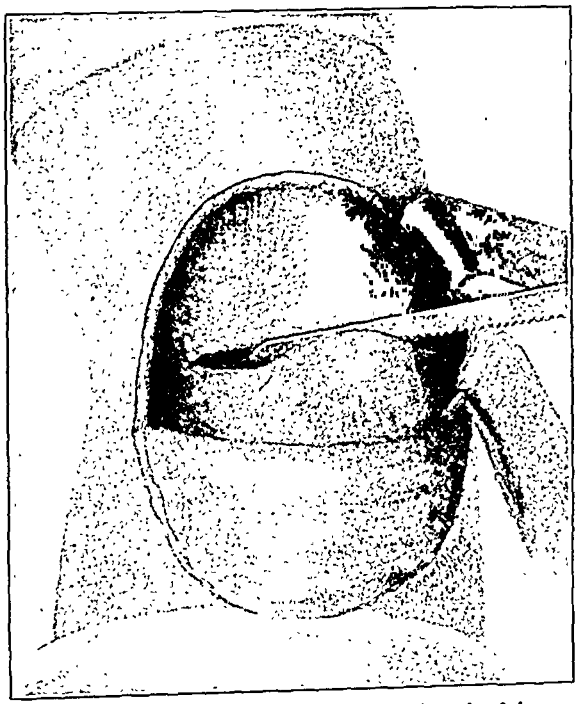

Fig. 5.—Sawing through olecranon tip and end of humerus.

As the right elbow was stiff and in a very ungainly position, an arthroplasty was advised. Nov. 9, 1910, ether operation, Dr. MacAusland. An incision was made extending from just below the right shoulder down the back of the arm to about 3 inches below the elbow joint (Fig. 1). The skin was dissected off at each side, and a large flap of fat and fascia just above the olecranon process freed. The right elbow joint was then opened by a transverse incision across the olecranon and through the capsule. The end of the humerus was excised and the radius and ulna rounded off with a file, making an artificial joint. The flap was then turned from the back of the arm to the inside of the joint and sutured there by heavy catgut, and the olecranon process with the triceps tendon was put through a slit in this fascia and united to the ulna by heavy chromic catgut sutures. The skin was closed with interrupted catgut, and silkworm-gut.

Nov. 10, 1910, the right hand was considerably swollen and painful, for which pressure and hot fomentations were applied. The skin on the upper part of the arm became somewhat necrotic from poor circulation and later sloughed.

November 21, the stitches were removed.

November 23, dry dressing, wound cleaned.

November 30, passive motions started daily. First attempt was made at motion, when 30 degrees were attained.

December 7, doing well; gaining motion gradually.

Dec. 24, 1910, massage to hand, forearm and shoulder.

Jan. 11, 1911, about 30 to 40 degrees motion in flexion and extension obtained. Heavy granulation tissue.

January 18, discharged from the house. Dressings to be done at home.

Feb. 28, readmitted to the house for manipulation. Normal motion was obtained.

March 13, 1911, discharged to continue with massage, manipulations at home. Since this time patient has been seen in the out-patient department. There is practically no lateral mobility, and the end-result is perfect function.

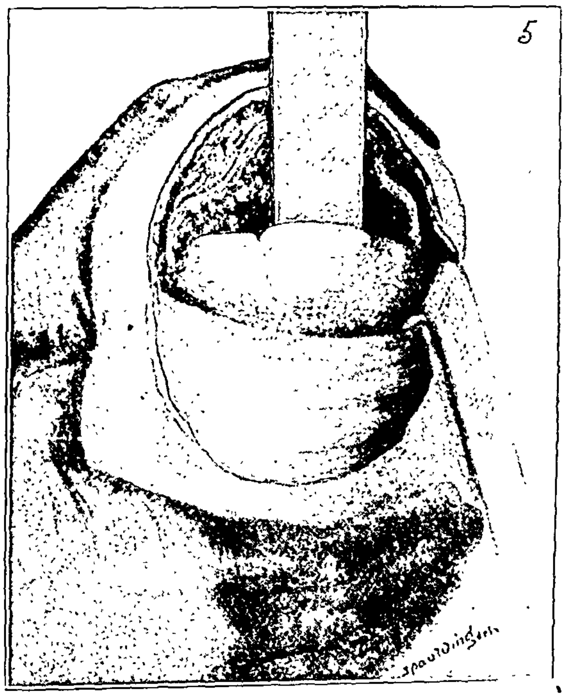

Fig. 6.—Splitting off tip of olecranon with chisel.

Case 2.—F. P., woman, fell and injured elbow, March, 1908. The injury was treated as a sprain and put in splints for about a week. The elbow was discolored and swollen. Liniments were prescribed for the stiffness with no effect. She was able to go back to work in the course of a few weeks, having only slight pain and stiffness, but as time went on, the motion shut down. She received osteopathic treatments for a month without any result. In 1908 she attended the hospital clinic, where roentgenograms were taken, and the arm kept under observation for six weeks. During this time the elbow seemed to be stiffening more and more. Patient entered the orthopedic department of the Carney Hospital, Nov. 17, 1908, and at that time had about 30 degrees motion, but was unable to flex the arm beyond a right angle.

Nov. 18, 1908, a 4-inch incision was made between the external condyle and the olecranon, and posterior displacement of the epiphysis of the humerus was found which, with the callus present, prevented extension. The projection of the humerus forward prevented the flexion beyond a right angle; as much as possible of the exuberant bone was removed.

Nov. 20, 1908, the second day after operation, she had a great deal of swelling and pain in the fingers. The plaster cast was therefore removed. Patient had lost all motion of the fingers owing probably to the forcible manipulation and the large amount of swelling. The plaster was unfortunately allowed to remain on for three days and a paralysis developed.

Dec. 2, 1908, patient was seen in consultation with Dr. Bullard, who considered the case one of Volkmann's paralysis.

Dec. 3, 1908, received daily massage and baking.

Feb. 9, 1909, entered the orthopedic service of the Carney Hospital and was recommended to have a manipulation under ether.

Feb. 10, 1909, ether manipulation, Dr. MacAusland. The right forearm was forcibly flexed and extended through an arc of about 60 degrees, during which the adhesions were felt to break up.

Feb. 14, 1909, the patient has gained about 15 degrees of motion but complains of some pain in the elbow and shoulder. From the time of the first operation, Nov. 17, 1908, until April, 1909, she could not move any of the fingers and there was no rotation. The first sensation of life came in the arm with a slight twiching of the fingers, April 2 and 3, 1909. She received daily baking and massage and passive movements from this time on. Gradually, through the summer months, she gained entire control of all the muscles of the forearm and fingers, although she had only a few degrees of motion in the elbow. This illustrates a splendid recovery from the Volkmann's paralysis, due, probably, to the efficient baking and massage, but, unfortunately, on account of sensitiveness of the elbow, there was not so much motion as before operation, so that an arthroplasty was thought advisable.

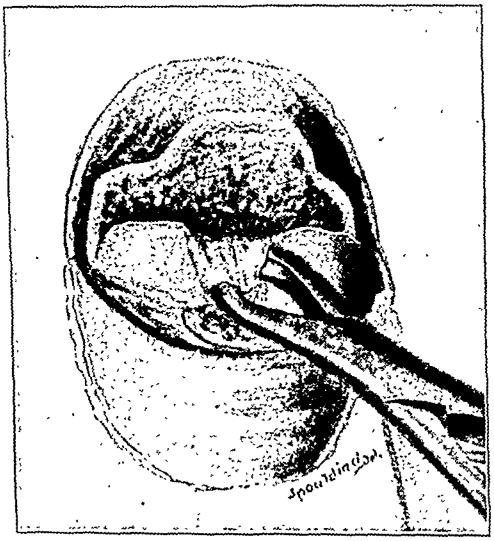

Fig. 7.—Cutting out with rongeur forceps bit of olecranon tip left in humerus.

In December, 1909, the patient entered the orthopedic service of the Carney Hospital, and at this time an arthroplasty of the elbow was done according to method described in Case 1.

The circulation of the skin above the original site of the flaps became somewhat diminished and there was a small amount of sloughing. Wound was dressed each day, and about the fifth day daily movements were attempted. In the course of a month, massage and baking were again taken up, and continued until May, 1910. The result is that the patient has full motion of the arm in flexion, and extension to within 15 degrees of straight, and has a perfect functional hand, in spite of the slight limitation in extension, and uses the arm daily, being employed as a stenographer.

Case 3.—D. W., man, aged 42, referred by Dr. Shea. Case operated before New Hampshire State Surgical Club. March 25, 1911, he received a contused wound of left thumb, which became septic, requiring, one week later, his entrance to hospital as the sepsis had become general. Five incisions were made in the left hand, two in the left wrist, one close to the left elbow joint, and one in the left hip. All had drains put in. A student in the hospital opened a swelling near the right elbow and cut into the joint. At the end of twenty-one weeks the patient was discharged from the hospital with bony ankylosis of the right elbow and with but a few degrees of motion in the left elbow. Both joints were slightly flexed. The left wrist had a sinus which still drained a little and he had little motion in the fingers, being unable to flex them to a right angle with the palm of the hand. He was unable to feed himself or to touch his head with either hand. He entered St. Joseph's Hospital a few weeks later and was operated on in March, 1912.

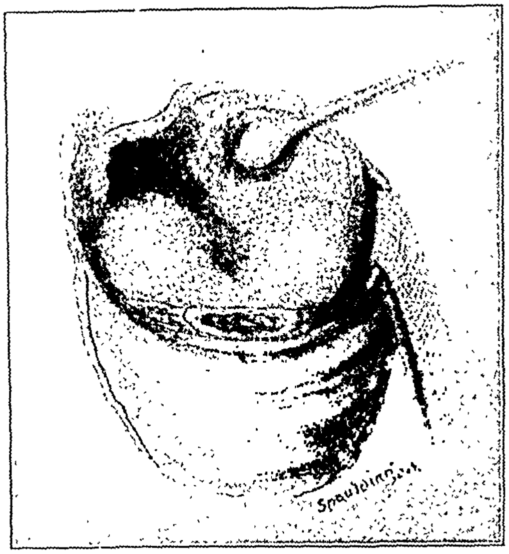

Fig. 8.—Scooping out ulna and radius with curet.

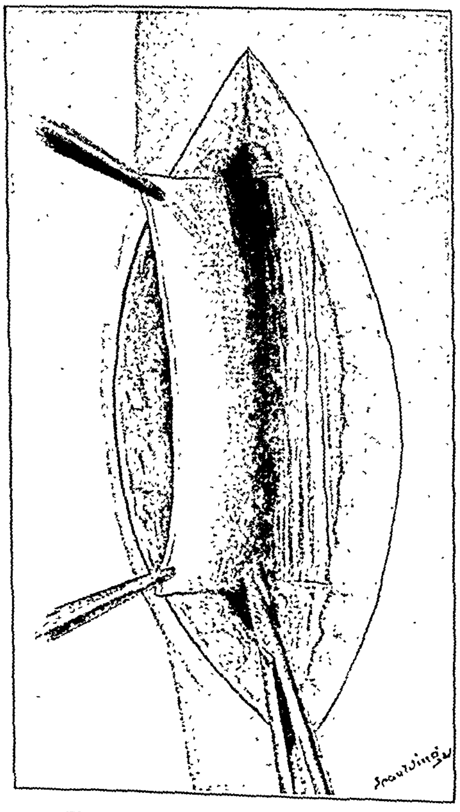

Fig. 9.—Cutting fascia lata from thigh.

Operation was performed by Drs. MacAusland, Shea and Wallace. After the usual preparation and the application of a tourniquet, a U-shaped incision was made, beginning on the lateral aspect about 3 inches above the elbow joint, and passing over the middle of the olecranon to a corresponding position on the opposite side (Fig. 2). The skin and superficial fascia was dissected up to a base line at the end of the incision and then retracted. The skin and fascia were then dissected a little on both sides and on the forearm end of incision. The ulnar nerve was dissected out of its sheath, and gently retracted with gauze (Fig. 3). A straight incision was made extending from one lateral aspect of the condyle to the opposite, crossing midway on the olecranon (Fig. 4). As the capsule and fascia were adherent the incision was made down to the bone over the condyle so as to elevate *en masse* the tissue which would serve as a new capsule. The olecranon was then sawed across and separated (Fig. 5). Owing to the extensive bony ankylosis, even with extreme force the joint could not then be broken open so that it was necessary to saw directly across the line of the old joint. When about three-fourths through the joint, it was possible to fracture the remainder (Fig. 6). There was no doubt of its being a bony ankylosis.

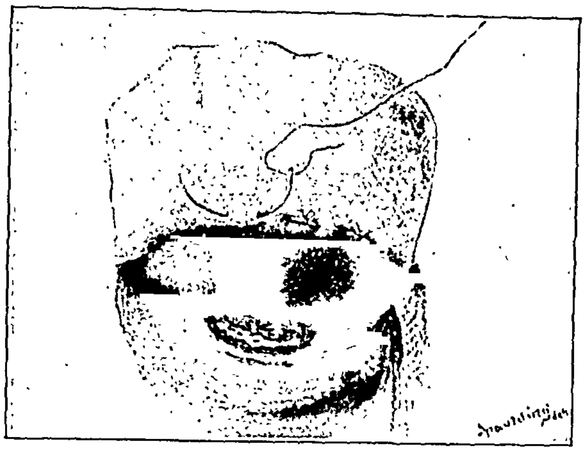

Fig. 10.—Sewing fascia lata to elbow joint anteriorly.

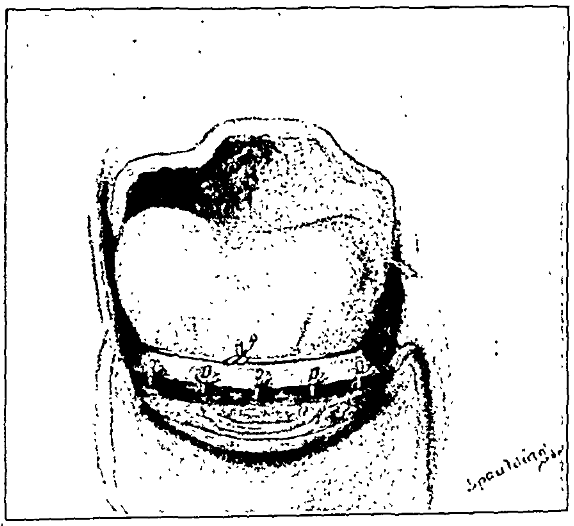

Fig. 11.—Fascia sewed over humerus; tied with kangaroo suture.

The capsule and fascia and ligaments were dissected back so as to allow the lower end of the humerus to protrude out of the wound when its square edges were snipped off with a rongeur forceps and a new trochlear or intercondylar surface formed (Fig. 7). A shoemaker's rasp was used to file this extremity as near like a normal humeral end as possible. A piece was then removed corresponding to the olecranon fossa in the normal humerus (Fig. 8). After this was cleaned, the corresponding surface of the olecranon was curetted so as to take the new humeral head. This modeling of the joint I do largely with a saw and file. To insure good function, the joint surfaces should fit accurately before the fascia is applied, but the joint should not be too loose. Only sufficient bone must be removed to give free motion. If too much of the ends of the bones is removed, a flail joint will result, giving the operation no advantage over an excision. When this mortising was completed, the fascia flap was dissected out of the right leg.

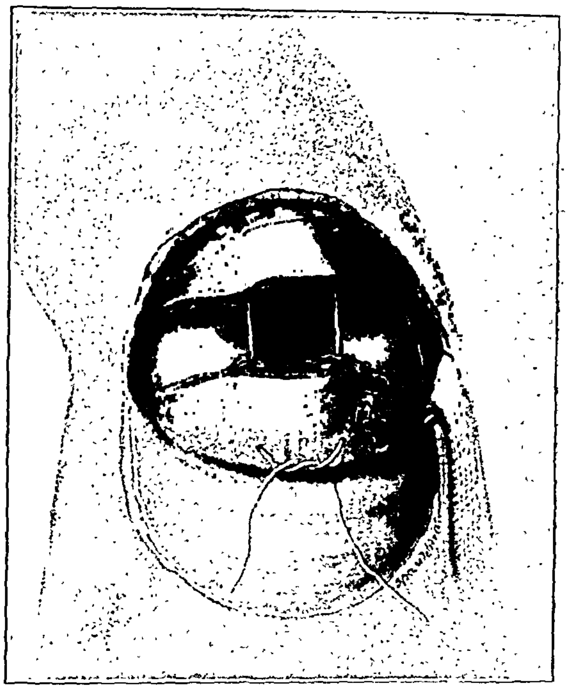

Fig. 12.—Kangaroo suture through ulna and olecranon tip.

A 5- to 6-inch incision was made on the outer side of the right thigh a little below the middle, extending down to the fascia lata. A piece was dissected out (Fig. 9) about 5 by 4 inches and the wound closed. This fascia, free from all fat, was placed about the new humeral condyles by attaching it first to the anterior capsule of joint (Fig. 10) and then tying it about the condyles so that all rough surfaces were covered and a purse-string suture was applied (Fig. 11).

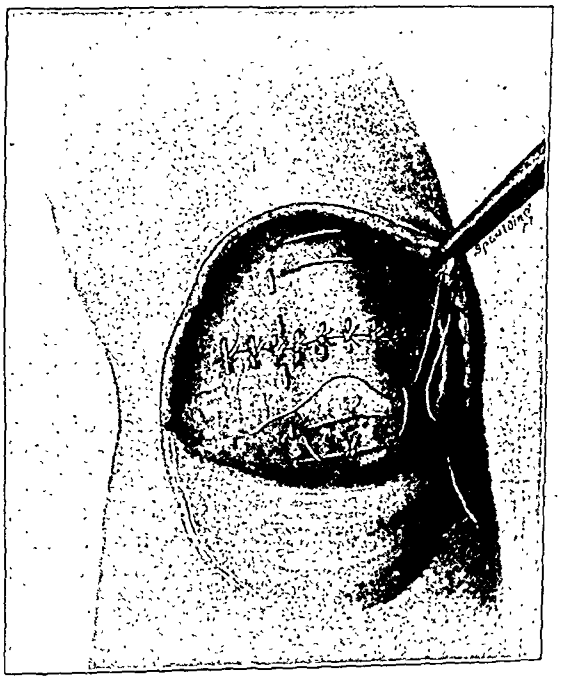

Fig. 13.—Stay sutures.

The fascia ligaments and old capsule were then sutured with chromic catgut. The olecranon was sutured with double chromic catgut (Figs. 12 and 13). The skin was closed with silkworm-gut, and a voluminous dressing applied with the arm at a right angle. Arm and forearm were placed on pillows with heavy dressings but no splint. Passive motion was begun on fifth day. Primary union took place of the wounds of the elbow and thigh. Passive motions were continued and increased, but at the end of six weeks it was found that the patient could not use either biceps or triceps muscles and he had lost all power from long disuse. However, after several weeks he educated the muscles by counting and attempting contraction at the same time and finally was able to flex the forearm himself, since when improvement has continued.

Result: He has full motion in flexion, extension and rotation now, and is able to feed himself and to do chores about the house, and put on his own clothes.

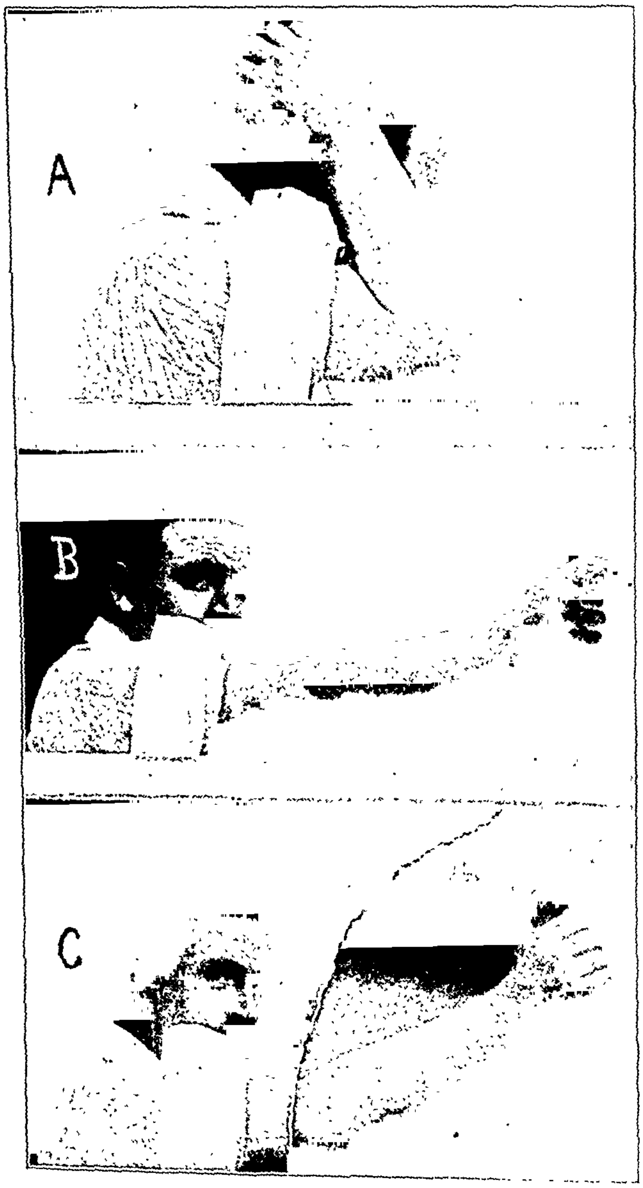

Fig. 14.—Ankylosis of the elbow: *A*, volutary flexion following arthroplasty; *B*, volutary extension following arthroplasty; *C*, voluntary flexion and extension following arthroplasty.

Previous to operation, May, 1912, he was entirely helpless, unable to care for himself in any way. The first duty for every probationer in the hospital was to "feed D."

For the foregoing detailed report, I am indebted to Dr. A. W. Shea, Nashua, N. H.

Case 4.—E. S., woman, admitted to the Carney Hospital, Aug. 11, 1913, for immobility of the right elbow and right knee, of six years' duration. The patient states that while on a vacation she went in bathing while menstruating. Within twenty-four hours she was taken ill with a fever, accompanied by pain and swelling in all the joints. She was placed under treatment in her home without relief. At the end of eight months, the pain and swelling disappeared from the left shoulder and elbow so that she was able to feed herself. She remained in bed for twelve months. The symptoms continued to subside on the left side until at the end of the third year she was able to get about with a cane. As the fever continued to subside and the pain and swelling disappeared, the patient had pretty good motion in all the joints except the right elbow and right knee, in which pain and stiffness continued at the end of the fourth year and motion was out of the question. This condition remained up to the date of admission.

Aug. 14, 1913, roentgenoscopy revealed ankylosis of elbow joint and of patella to femur. Urine examination revealed specific gravity 1.015, acid; albumin 0, sugar 0.

Aug. 20, 1913, operation on right elbow by Dr. MacAusland, as in Case 3. Light plaster cast applied.

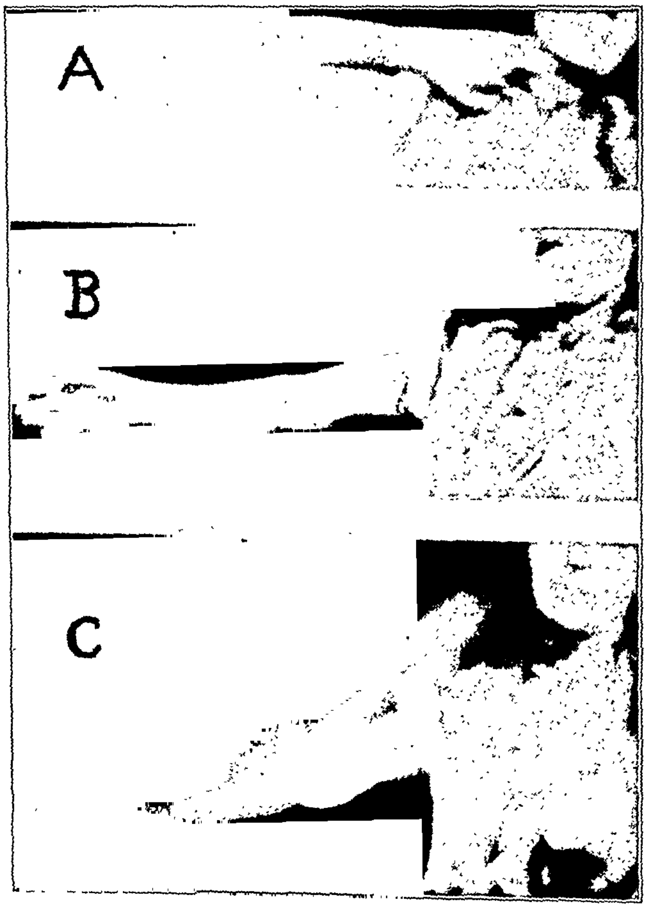

Fig. 15.—Ankylosis of elbow, six months after arthroplasty; *A*, voluntary flexion; *B*, extension and use of arm; *C*, voluntary flexion and extension and power of biceps.

August 22, good recovery; slight pain.

August 27, cast split for dressing.

September 1, wound healed by first intention, except for slight discharge from upper border.

September 4, manipulations daily; motion good.

September 10, arm can be extended completely, and flexed 15 degrees beyond a right angle.

September 15, traction for extending and flexing the arm.

September 20, massage and motion continued.

October 1, active motion possible.

October 15, manipulation of elbow under ethyl chlorid by Dr. MacAusland.

Patient now has perfect flexion and extension and no pain. Excellent functional result.

240 Newbury Street.

ABSTRACT OF DISCUSSION

Dr. Gwilym G. Davis, Philadelphia: Dr. MacAusland has done these operations by means of posterior incision. Dr. John B. Murphy advocates lateral incisions, and I have done it by means of two lateral incisions. It is perfectly feasible to do it with flaps. With the two lateral incisions we do not get great exposure of the parts; and it is extremely difficult to work. If it can be shown that no trouble occurs, for instance, in obtaining the union of the olecranon, which has been incised and detached, so to speak, the greater accessibility afforded by this operation renders it more desirable than the one by means of lateral flaps.

Dr. Charles A. Parker, Chicago: Will Dr. MacAusland state his opinion with regard to rotation in these cases?

Dr. W. R. MacAusland, Boston: First, answering Dr. Davis' question with reference to the non-union of the olecranon, I would say that this problem has arisen in one case. In Case 3, I did not think I was getting motion quickly enough so I gave an anesthetic and manipulated the joint. I suddenly felt the olecranon tear and could distinctly feel a separation. I paid no attention to it, however, but put on a voluminous dressing. Patient now has good motion in the elbow. I think a fibrous union resulted which is just as serviceable as a bony union. With reference to rotation, in two of these cases there was bony ankylosis between the ulna and radius, to which I paid no attention. The ankylosis still remains. I question whether in future procedure I should not go down and make a space in that joint, placing a piece of fascia between the surfaces. The patients, however, have perfect use of the arms in this present procedure, and none of them have the deformity of extreme pronation. The arm is supinated one-half, and, so far as I can see, has perfect function, with no motion between the radius and ulna. Had I found the type of extreme pronation existing, I might have considered an attempt to get motion between the radius and ulna or excise the head of the radius.

A NEW TYPE OF ANKLE FRACTURE *

FREDERIC J. COTTON, M.D.
Visiting Surgeon, Boston City Hospital
BOSTON

It seems a bit late to come forward with a new fracture, but in fact the lesion here in question has never been adequately described in print,[1] and has apparently escaped the notice even of those who deal with fractures habitually.[2]

It is in fact one of the common and typical lesions at the ankle, and its best claim to interest is because it is a lesion that every one must have seen, interesting not from its rarity, but from the very fact that it is common, that it is usually overlooked, and that unless reduced it results in serious disability in many instances.

I have been talking about the lesion for years, until some of my house-officers at the City Hospital, wearied by long insistence, have come to refer to it as "Cotton's fracture."

The characteristic point of the fracture under consideration is backward dislocation with the *splitting away of a wedge*, large or small, *from the back surface of the tibia at the joint*—a *wedge* that is *displaced backward* with *backward dislocation of the foot.*

This wedge carries the posterior tibio-astragaloid ligaments; foot and tibial fragment move together, up and backward.

Fracture of the malleoli is associated with this luxation; usually the malleolar fracture is not unlike that of Pott's, though sometimes the internal malleolus and the posterior tibial edge of the joint are included in one piece that is split away in a spiral line.

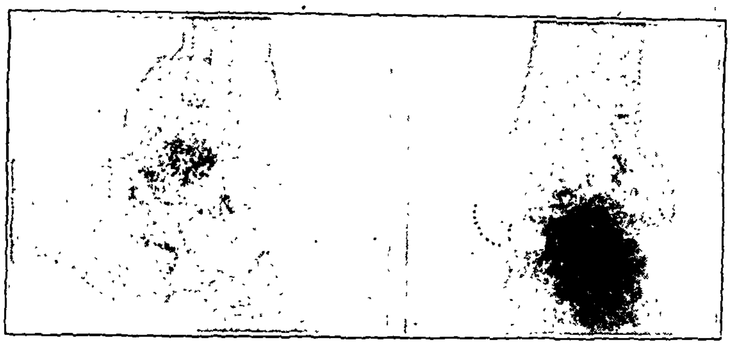

Fig. 1.—Type lesion, more than average total displacement of the foot backward, and in this case outward as well. This is a case that would have resulted in hopeless disability had reduction not been done.

As a rule, however, the posterior tibial fragment is separate, though associated with fracture of both malleoli.

There are no autopsy specimens, I believe, and no operative results on record, of cases opened up in the early days after the injury.

As a rule both malleoli are broken; hence the confusion with Pott's fracture!

It has long been recognized that certain cases of so-called "Pott's fracture" were complicated with a backward luxation of the foot. What has *not* been recognized is that nearly all of these cases are not really Pott's fractures at all!

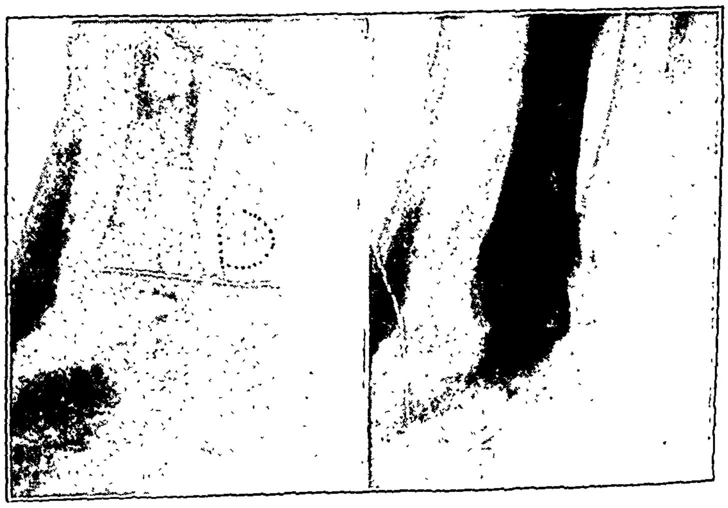

Fig. 2.—Type lesion, with extreme backward displacement. Dotted lines in the left-hand illustration show the wedge broken off the back edge of the tibia, as yet unreduced. The illustration to the right shows reduction of this fragment to an approximately normal site, a reduction incident to the correction (complete in this instance) of the great total displacement of the foot backward. In the second view the fragment seems much smaller. This must be the result of a change in the angle-bearing of this fragment in relation to the roentgenogram.

Of all the cases of ankle fracture I have seen in the last seven years, there has been but *one* of posterior luxation in which the fracture lesion here described has not been present—only one case of real posterior dislocation with Pott's fracture.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] The article by Speed in Surgery, Gynecology and Obstetrics for July, 1914, which does describe such cases had not been printed at the time this paper was read.

[2] I put the matter on record at a clinical meeting of the Boston City Hospital, and in my Dislocations and Joint-Fractures, W. B. Saunders & Co., Philadelphia, 1910, 540 et seq. (Figs. 951, 955, 956, 958, 977, 992, 1001, 1018, 1026, 1056, 1059, 1061 and 1067). Stimson records a couple of old cases belonging in this class (Fractures and Dislocations) and Brackett, E. G., of Boston (shown March 2, 1910), and Darrach, W., of New York, have each shown plates of single cases (not published).

In the rest (fifty-three cases of which I have records, more or less full, and others seen in hospital consultations, etc., which I cannot now trace), all have had the complicated lesion that gives the occasion for this paper.

They are no more to be classed as Pott's fractures than are the simple fibular breaks or the "inversion Pott's" cases that are indiscriminately lumped together under "Pott's" in the usual hospital records.

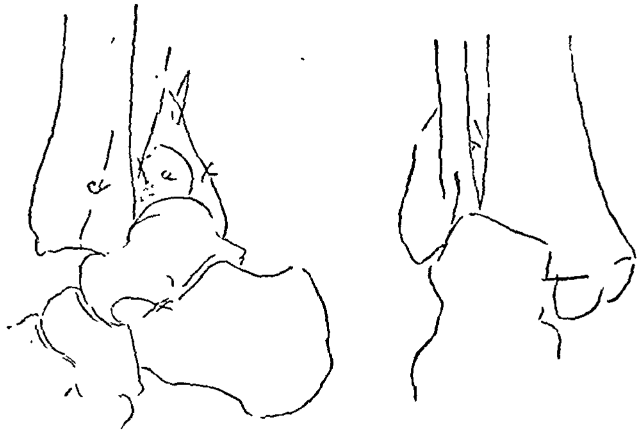

Fig. 3.—Type lesion, extreme displacement back and outward: *a*, posterior tibial fragment; *b*, *b′*, outlines belonging to the broken fibula; *c*, line of the tibial surface from which fragment *a* was broken away.

As I see ankle fractures in the mass, there are the following:

(*a*) Fibular fractures, *above* the joint level, first and commonest; (fractures of the external malleolus alone are rare).
(*b*) Pott's fractures of the type Pott really described.
(*c*) "Inversion Pott's fractures."
(*d*) The type here considered.
(*e*) Fractures just above the joint, and separation of the epiphyses.

I am not sure that our present type—Class *d*—is not more frequently met with than the "inversion Pott's" type.

My attention was first called to the lesion here considered through certain old ankle fractures that came to me for reconstructive operation — cases that presented extreme backward displacement of the foot, with the condition herewith sketched.

I had not previously met such cases and could find no description to fit them.

From that time I looked for fresh cases—and found them—as will be discussed presently. Most of these cases were under my care.

Quite a number of the cases and plates referred to here, however, have been from those services of the City Hospital with which I have no direct connection.

The frequency with which this lesion has been overlooked and left unreduced by skilled surgeons (despite good roentgenograms) seems to me an additional reason for erecting a separate class for it.

Not only is this lesion not a simple variant of Pott's fracture, but any attempt to treat it like a Pott's fracture ends (in a large percentage of cases) in serious disaster.

A Pott's fracture or an "inversion Pott's" is bad enough, with the two sides of the articular mortise gone; but when we have the astragalus driven clear back of the mortise and deprived not only of *lateral* support, but of any *vertical* bearing as well, the condition is apt to be hopeless unless properly handled.

If the foot and leg rest on the heel, of course the tendency is toward spontaneous reduction; but this occurs only in a portion of the cases: in many, the displacement resists even a considerable force directed toward its reduction.

Such a case, unrelieved, must end in a new joint between the tibia and the forward slant or neck of the astragalus, with limited dorsal flexion, and without any precise support at the sides.

Having seen such results, I can not speak well of them.

Back in 1904-7, among the cases sent to me for reconstruction of damaged ankles, were three absolutely crippled ankles with backward displacement of the foot that distinctly belonged to this type.

They were repaired fairly well by combining a bimalleolar osteotomy (with deliberate forcible rupture of most of the ligament) with the preparation of a new concave joint surface on the tibia with chisel and curet (approximately at the normal site) —a concavity into which the displaced astragalus was shifted forward approximately into its former position. The cases all recovered improved if not normal function.

After these cases had been dealt with, I was on the alert for fresh cases, and found them, and am still finding them.[3]

In 1908, A. H., a student of the Massachusetts Institute of Technology, was brought into my office with an ankle smashed and luxated backward and outward. Obviously, this was the case I had been looking for. The fracture of the fibula and the tearing away of the internal malleolus were obvious; the foot was also luxated backward (and in this case outward as well). Reduction under light anesthesia was easy. Roentgen-ray plates taken shortly after showed a fragment broken off the posterior articular face of the tibia.

This patient got an almost perfect ankle.[4] The Roentgen ray showed a wedge from the tibia, then already reduced, that had been displaced backward with the luxated foot; both malleoli were fractured.

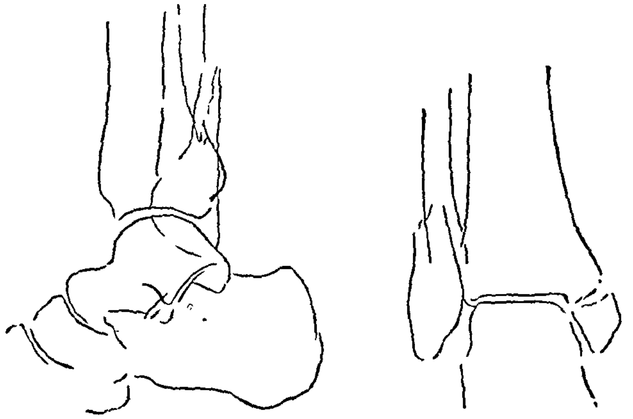

Fig. 4.—Same case as shown in *Figure 3*, after reduction. From roentgenograms taken four days after those shown in *Figure 3*.

The other fresh cases were almost identical with this one.

The worst of the displacement is often dealt with before the surgeon sees the case. It is, moreover, unjustifiable for the surgeon to wait to get pictures before reducing so painful a luxation as is the one under consideration.

---

[3] Four have come to hand since this text was written.

[4] I kept track of him for a few months only, through Dr. Walter Baer of Baltimore. The Roentgen-ray plates the patient took to Baltimore, and I have been unable to recover them.

The illustrations and the appended legends really tell the whole story.

We are dealing with an injury in which the dislocation backward is the important lesion.

This displacement once corrected, we have (substantially) a bimalleolar fracture.

Unless we recognize it and reduce it, we have to reckon with the meanest and most serious lesion that occurs at the ankle.[5]

MECHANISM

A twist is usually given as the cause of the injury.

One patient misstepped the edge of a mat in wrestling; one did the same thing in gymnasium "tumbling;" one twisted her foot outward as she stooped from her chair to pick up a rolling spool, a rug slipping under her foot; another, in walking, twisted her foot out on the edge of a rug that slid, etc.

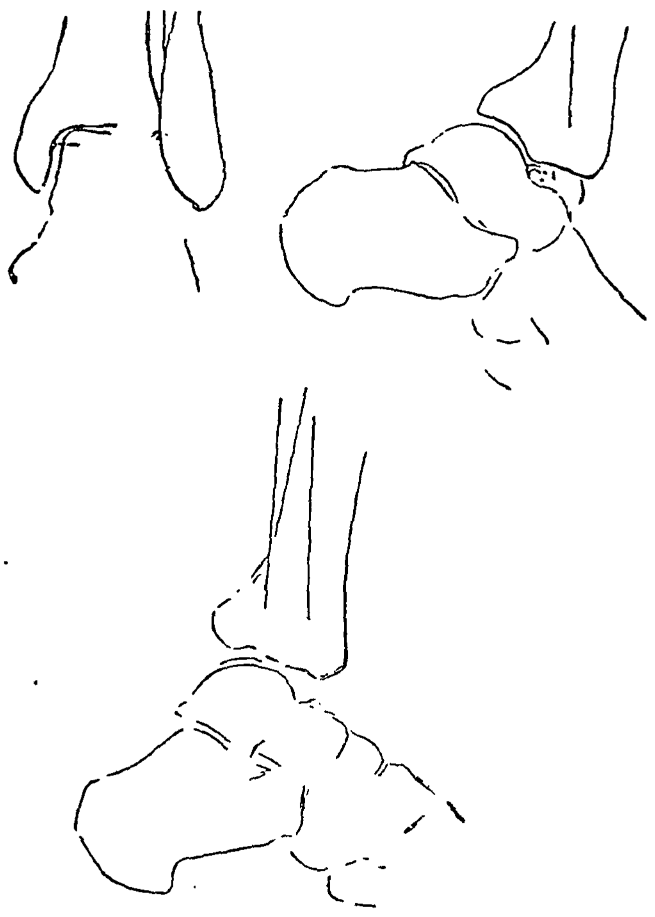

Fig. 5.—Old case. End-result of poor treatment shown in the two upper tracings. Below is shown the lateral view of the imperfect, but sufficient, operative reduction. The clinical result in this case (as in several others of the series) was markedly better, even than the plates suggest.

Apparently an outward and backward twist of the foot is usual.

Apparently the break is often sustained while weight is borne on the ball of the foot, not on the flat foot surface.

A disproportionate number of these cases have been encountered in private practice, which means only that the lesion is not, as a rule, the result of industrial accidents.

TREATMENT

Reduction is simple if the lesion is understood.

All that is called for is forward traction, with the muscles relaxed in moderate plantar flexion; reduce so, and then lock the reduction in maximum dorsal flexion. Hold in plaster.

Results are bad if the lesion is not understood, unless spontaneous reduction has occurred.

If reduction, spontaneous or operative, has been accomplished, repair is prompt, and the results are excellent—in no way worse than in Pott's fracture.

The after-treatment is that of Pott's fracture, save that early mobilization is absolutely essential, and no weight should be borne on the foot for at least seven or eight weeks.

The important thing is to know, and to be on the lookout for, this common and neglected lesion. Given an understanding of what we are dealing with, the rest of the story is simple. But it is important to know that the lesion does occur, to be on the lookout for it, to recognize it, and to deal with it intelligently.

520 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

Dr. J. D. Griffith, Kansas City, Mo.: The most interesting feature in Dr. Cotton's cases is the distinct line between this form of fracture and what he outlines as the genuine Pott's fracture. I have found in my little work at home that there is a fracture which we have ordinarily termed Pott's fracture that we cannot get to stay in position. As I did not know of Dr. Cotton's extreme dorsal flexion, I could not use that; but I have used this method several times in reducing these fractures and maintaining them, whereas in Pott's fracture, rotation inward, almost varus, of the plantar surface of the foot will generally give a good clinical result. These cases require straight-out extension first. Otherwise, one cannot do anything with them; and I cannot yet understand the reason why. I have not been able to determine it. If Dr. Cotton brought that reason out in his paper, I did not get it. Therefore, I ask him to explain it. These are the cases in which we get shortening after a number of months. The patient comes in and says, "I was fixed up, but I cannot use the leg"; and by measurements and roentgenogram one finds that the tibia is rubbing on the back part of the astragalus, instead of in front. These cases are hard to get at; after six or eight weeks I have tried two or three times before I could get any good result, and then, not a perfect one.

Dr. Gwilym G. Davis, Philadelphia: The trouble that I have found in fractures around the ankle is, first of all, in reposition. Dr. Cotton did not give the details regarding his after-treatment; but in attempting reduction, one method of rendering it easier is to place the leg in the Pott's position. The difficulty in some instances seems to be due to the tension of the Achilles tendon. By placing the leg on its outer side and flexing markedly at the knee, you relax the tendon. Some ankle fractures, in which replacement is difficult, can be replaced when the Achilles tendon is so relaxed. In still more difficult cases, it is a justifiable procedure to do a tenotomy. That seems to relax markedly the structures around the ankle and enables us to make a reposition. Otherwise, it is extremely difficult, or almost impossible. What are Dr. Cotton's views concerning the advisability of doing this in certain cases.

Dr. H. W. Orr, Lincoln, Neb.: Dr. Cotton has rendered the section a real service by calling attention to the necessity for a more careful classification of these cases. To me, however, one of the most important things he said was in emphasizing the necessity of reposition of the fragments as nearly complete as possible. I have had occasion, as we all have, to attempt to patch up bad results of this sort; and it is usually because the surgeon or the general practitioner has neglected roentgenoscopy in confirming the replacing of the fragments. I have sometimes used to advantage the position that Dr. Davis recommends and have found that when careful manipulation failed to replace the fragments, they could be molded into place by the tips of the fingers.

Dr. John Prentiss Lord, Omaha: Dr. Cotton has the secret of greater success in the future of these cases.

---

[5] Nothing above or below the ankle joint proper is more troublesome, unless we except astragalus and calcis lesions.

We should begin to look for them and we will surely find that these fractures of the ankle are often atypical. The common fault has been to call everything Pott's fracture, with the result that the treatment given to many of them is wholly inadequate in view of these more recent facts. A method for the replacement of small fragments that I think is not very commonly used has been of assistance to me in some of the old cases. In these conditions the small fragments have infiltration about them, and partial union which resist ordinary methods. An open operation may sometimes be avoided by the use of an awl or drill, with which to enter the fracture area and push the fragments about, just as wanted. Then, by properly checking with the Roentgen ray, we can ascertain when we have the fragments in the best position.

Dr. W. Russell MacAusland, Boston: Will Dr. Cotton explain the surgical details of his treatment in a case of six months' duration?

Dr. F. E. Peckham, Providence, R. I.: It would be well if more attention were paid to the Roentgen ray in these cases. The general practitioner is apt to fix the fracture in the best way he can clinically; and if it looks pretty well, he thinks that it is all right. That, I think, is the reason for the bad after-results. To my mind, such a paper as this would tend to increase the use of the Roentgen ray, and thus allow us to obtain accurate knowledge. I had a similar fracture some years ago, in which both malleoli were broken, leaving a spicule of bone sticking into the astragalus. The result was that at every step the patient took, she felt as if a tack were sticking into the bone. Although a roentgenogram had been taken and many physicians had examined it, the woman was still on crutches at the end of two years. The removal of the spicule stopped the pain, but reconstruction work was necessary—an osteotomy of both malleoli, to place the ankle in good position. She now has a useful foot with some limitation of motion. Dr. Cotton's ideas with regard to the after-treatment and his suggestions have changed my own ideas somewhat. Will he give a brief statement of his views as to the after-treatment?

Dr. D. B. Phemister, Chicago: I have seen about half a dozen of these old and neglected cases from one to three years after the fracture occurred. All were in bad shape. After from nine months to a year, bony union occurs. This posteriorly displaced fragment is then fixed in its old position and an imperfect articular surface is produced. In one case, two years old, I cut down and reduced the astragalus, placing it in the anterior articular surface, left the posterior prominence, and got a bad result with very little improvement. In the second case I did a remodeling, and there I got a bad result—or, rather, not a good ankle. It has occurred to me that perhaps the anterior surface of the tibia could be chiseled away, this posterior, newly-formed articular surface left, and then a supramalleolar osteotomy done. The foot could then be thrown forward, so that the line of force would fall on top of the astragalus, and a good result obtained in that way, as Dr. Cotton has obtained it in Pott's fracture with outward displacement. Has Dr. Cotton treated any cases in that way?

Dr. F. J. Cotton, Boston: Answering Dr. Griffith's question about the deformity, the trouble is that no ligaments and no tibial surface are left that are useful. Even after reduction under ether, unless the straight-out extension of the foot is made first, the astragalus may be driven up against the articular surfaces, and the whole thing may go back with astonishing force. That is the reason for the recurrence of the deformity. I was afraid Dr. Davis would get the point confused. These cases are not Pott's fractures. They are a little like them, but are distinct from them in causation and in the way in which they should be handled. About the question of position, I would say that I use the one Dr. Davis spoke of, and usually flex the knee somewhat in carrying out ankle reduction. With regard to cutting the tendon of Achilles, I have done that in tarsal fractures, but I dislike to do it, because a certain amount of atrophy is caused, and it takes a while for the function to come back. In traumatic cases one has trouble in getting function anyway. Another reason why I dislike to do this cutting is that in putting the cases up in dorsal flexion, it is the Achilles tendon that is depended on. Some cases, however, cannot be treated without open operation, which is undesirable. If one can avoid it, I should say that it is better to do so. With regard to Dr. Lord's statements, I have used a drill or awl and left it in to pin the fragments with, but I have never used such an instrument to drive them about. That point is interesting. Dr. MacAusland asked a question about the treatment in old fractures. I have done three things in my cases. In most of them I made an incision outside and inside. Then, after a section of both malleoli above the joint-level, I loosened up the whole joint, and then cut out, if necessary, a fresh joint-surface on the front part of the tibia to slip the astragalus into. This gives a little shortening; then the foot can be brought down and forward and things placed where they are wanted. That is what I have done in most cases of ankle-reconstruction. In one case in which the trouble was not so much loss of dorsal flexion as an enormous callus, I dug out most of the posterior fragment and set the tendons in a new sheath. In another case I cut away the front edge, but did not do the supramalleolar osteotomy, and got a pretty good foot. As to Dr. Peckham's remark, there is no question that the Roentgen ray should be used more carefully; but if you once get the pathology in your mind, there is no difficulty in making the diagnosis without it. In a great many cases you get along better if you do reduction promptly because there is a good deal of reaction. I want to emphasize that these cases are not Pott's fractures. They ought to be considered as a different class. If they are so handled the result is all right; a good many are not treated properly because this has not been recognized.

THE AUTONOMIC RECIPROCAL ACTIVITIES OF BRAIN AND VISCERA [*]

WALTER TIMME, M.D.

Consulting Neurologist, New Rochelle Hospital; Assistant Physician, Neurological Institute; Chief-of-Clinic, Neurological Department, Vanderbilt Clinic

NEW YORK

A decade has now passed since Langley and the English School contributed to our knowledge of nervous anatomy and physiology a comprehensive plan of the structure and workings of that part of the nervous system which supplies the smooth muscle fibers of the body, the cardiac muscle and the glandular tissues, and to which they gave the broad term "autonomic system," so called from the fact that it acts independently of the cerebrospinal system. Yet there still seems to be confusion not only in the nomenclature, but also in the interpretation of the many experiments that have been made by various investigators in this field of research. We have, for example, the term "vegetative" used by the Viennese School instead of "autonomic" for the entire system of ganglia and nerves and end-organs — *vegetative,* because through its means the normal continuity of life and of the vital functions is preserved. The representatives of this school are Eppinger, H. H. Meyer, Gottlieb and Hess. Since the popular term "sympathetic" is misapplied to the system and its different parts indiscriminately, it would be well perhaps to sketch rapidly the anatomic and physiologic characteristics of the autonomic system, adopting the classification of Langley.

The entire autonomic system is divided into various parts, depending on the position of the cells of origin of the nerve fibers of the system in the cerebrospinal axis. These cells of origin, termed by Edinger, Jacobsohn and others nuclei sympathici, are found in certain definite areas of the brain and cord. Corresponding with these areas, then, we have the following divisions of the system:

---

[*] Read before the New York Neurological Society, April, 1914.

1. Midbrain autonomic division, consisting of the cells with their axons which emerge from beneath the superior corpora quadrigemina supplying the iris and ciliary muscle.
2. Bulbar autonomic, of which the fibers emerge from beneath the floor of the fourth ventricle to pass out with the seventh nerve, nervus intermedius, ninth and tenth nerves, to supply the vessels and glands of the mouth, pharynx, nose, esophagus, stomach, small intestine, part of large intestine, trachea and lungs.
3. Thoracic autonomic, or sympathetic system proper, arising from the sympathetic cells of the lateral portion of the anterior horns of the spinal cord from the first thoracic to the fourth lumbar segments, and passing out by the white rami to the gangliated cord and its connections to supply the skin, arteries, muscles, glands, abdominal viscera and internal generative organs.
4. Sacral autonomic, leaving the cord from the first to the third sacral segments as the pelvic nerve, to the ganglia of the anus, rectum, descending colon, bladder, urethra and external genitals.

The fibers, as they leave their cells of origin in the cord or brain, continue their course until each one arrives at a ganglion. In this ganglion, the terminal arborizations of each fiber, or of its branches, are connected with one cell for each individual fiber, and no more than one. These original fibers from the central system to a ganglion are known as "preganglionic" fibers. The axons arising from the ganglionic cells wend their way to the peripheral end-organs of various tissues, and never, under any circumstances, pass to other cells of the same system. Therefore, there are no commissural fibers in the autonomic system. These secondary fibers from ganglion cell to the periphery are called "postganglionic" fibers. The mechanism of ganglion cell and arborization of preganglionic fiber, together with the hypothetic intervening membrane, is known as the ganglionic synapse.

There are two great gangliated cords, situated on either side of the vertebral column, consisting of a series of ganglia connected by short intervening cords. These two gangliated cords extend from the base of the skull to the coccyx. Superiorly they connect with plexuses that enter the cranial cavity, while inferiorly they converge on the sacrum and terminate in a connecting loop on the coccyx. The ganglia of the gangliated cord are known as vertebral ganglia, while those of the great plexuses more peripherally situated are called prevertebral ganglia.

The short cords uniting the spinal nerves with the ganglia and fibers of the autonomic system are called the rami communicantes. The white ramus communicans is composed largely of fine medullated fibers passing from the spinal nerves to the gangliated cord, and not from all the spinal nerves, but only from those from the first thoracic to the fourth lumbar segments of the cord. The gray ramus, on the other hand, is composed for the most part of pale, non-medullated fibers, passing from the gangliated cord to all the spinal nerves, at every level. At the next anatomic fact we have a curious resemblance between the two extreme divisions of the autonomic system. It is that the sacral visceral nerves correspond to white rami communicantes, for they pass directly to the visceral ganglia of the prevertebral plexuses, without connecting with the gangliated cord. The similar condition exists with the craniobulbar autonomic division — that of the vagus — for here also the visceral branches of the vagus, the glossopharyngeal, the facial and the short branches of the oculomotor to the ciliary ganglion pass to the visceral ganglia directly, as white rami communicantes.

There are other points of resemblance between these extremes to be seen directly. Thus the craniobulbar and sacral divisions are local in their supply, whereas the thoracic autonomic, or sympathetic proper, is almost universal. That is, each of the first two has its area of control distinct from the other, anatomically, while the sympathetic sends fibers not only to its own territory proper, but in addition, it also sends fibers to the same structures as the other two, so that the tissues supplied by the craniobulbar and sacral autonomic have a double innervation, while those supplied by the sympathetic have only the one. Where there is this double supply, the two kinds of nerves are not necessarily opposed; but if their effect is different, then all the central strands of one system have one effect, and those of the other system have one and the opposite effect.

With this short explanation of the chief anatomic and physiologic characteristics of the autonomic system, let us proceed to a consideration of the reciprocal effects of the activities of the parts of the system presiding over the viscera, and their relation to visceral activity. It may not be amiss to consider first the curious conditions that obtain in the lowest form of vertebrate life which, in the course of evolution, in a great increasing series of complexities, led to the seemingly hopeless intricacies in the economy of the highest type, man. In the amphioxus as the prototype, we find the following interesting and important features:

The development of the amphioxus from the fertilization of the egg to the end of the embryonic stage, and thence through the growth of the larva, can be studied microscopically with comparatively little difficulty. This has been done in late years especially by Hatschek[1] of the university of Prague, and in earlier years by Kowalevsky of St. Petersburg.[2] Of interest to us in this development of *Amphioxus lanceolatus* is simply the origin and evolution of the primitive nervous system, with its earliest connections to other parts of the living structure. The growth of the edges of the neural furrow from the turning in of the epiblast begins at the *posterior* end, at the position of the gastrula mouth, and advances to the anterior end. The remains of the gastrula mouth continue as an opening between the archenteron and the neural canal — a condition typical of all vertebrates — termed the neuro-enteric canal. At a later stage of development it is at this point that the anus perforates, and at the same time the communication between the neural canal and the archenteron is interrupted. These two canals have therefore, as their point of connection, the morphologic posterior end. This primitive nervous structure and the end of the alimentary canal are thus closely related in the evolution of the animal. One other point in interest for us is the double service rendered by the mouth to the animal when fully developed. All observers agree that the animals emit their sexual products through the oral aperture, the male the sperm, the female the eggs, so that the nervous control of the ingestion of food and of the emission of sexual products must be closely related.

---

[2] Kowalevsky, A.: Entwicklungsgeschichte des Amphioxus lanceolatus, Kiev, 1870.

When we arrive at an extremely high vertebrate type, the mammal, we find curious resemblances in the results of physiologic and pathologic experimentation to these observed characteristics of amphioxus. At the risk of much repetition, I should like to refer to my experiments on cats in this connection. In one series of experiments, I diminished the influence of the craniobulbar autonomic,[3] that is, the vagus, on the viscera, by tying off the vagus, and at times both vagi, below the esophageal plexus in the thorax. This limited the effect, if any, to the abdominal viscera entirely. After some months, the animals, which seemed none the worse for this deprivation, were killed and among the findings were the following: The stomach was enlarged and thickened, and the peptic glands were largely increased in number. Of greater interest to the present subject, however, was the unexpected discovery of the great increase both in length and caliber of the colon and rectum. The normal length of the large intestine in cats, from the ileocecal junction to the anus, is on an average 200 mm. On the operated animals the length of the intestine was uniformly increased to 300 and 325 mm., and its circumference, which normally is about 35 mm., was increased to 65 mm. Therefore it is a fair inference that any inhibition exerted by the brain on the vagus nerve impulses to diminish their intensity produces profound effects in the vegetative life of the cells of the alimentary canal, causing a hyperplasia. The close connection which we saw existed between the primitive neural canal of the amphioxus and the posterior end of the archenteron has apparently its counterpart in the highly developed organic structure of the higher class, mammalia. And we shall see later on that in the genus homo, cerebral activities that depress the vagus nerve cause physiologic effects on the intestine that in the light of what has just been presented are readily understandable.

From the short description of the anatomic characteristics of the autonomic system which has just been given, we see that the viscera generally have a double nervous supply, the one from the sympathetic via the vertebral and prevertebral ganglia, and the other from either one or the other of the autonomic divisions. These two sets of nerve fibers convey a continuous stream of current to the tissues; but from the probability that their end-organs in the tissues are different from one another, class for class, their effects on the viscus are of a balancing character. As a result, the activity of the organ is commensurate with the work that in a given case is required of it, the repair and growth of its cellular elements controlled, the blood-supply properly limited; and all these various activities are constantly at work, independent of our will, and indeed, largely of our consciousness. But such a compensating balancing mechanism is dependent on many factors other than these, and yet on factors that are influenced *indirectly* by the will and consciousness, so that if one set of nerve fibers is depressed, the other overacts its part, and the converse. But it would seem that if one set is entirely destroyed, the other, having no physiologic antagonist, ceases its influence. In the experiments cited, the vagus nerve was never completely severed, but simply *partially* destroyed by a moderately tight ligature. In the cases of complete vagus section as carried out by Langley, Cannon, Pawlow and Schiff, these hyperplasias were not produced.

Now, we can produce conditions in the various parts of this autonomic system comparable to such a pressure neuritis in its temporary effects, by means of drugs, psychic disturbances and various physiologic stimuli. Let us take up the effects of drugs and psychic disturbances solely. The Viennese School, Eppinger, Hess, H. H. Meyer, Gottlieb and others, have demonstrated that certain groups of poisons have, with some limitations, selective effects on the end-organs, or synapses, or central cells of either system. And the group of these agents that stimulates the one system depresses the other. So we have the so-called cholin group, and pilocarpin and physostigmin, all acting as *stimulants* to the autonomic nerve ends, while atropin with its family *depresses* the same ends. The central stimulants of the two systems are picrotoxin for the autonomic, and cocain, caffein, atropin and thermin for the sympathetic, while the corresponding depressants are botulismus toxin and other decomposition products for the autonomic, and morphin, chloral and the antipyretics as sympathetic central depressants. Epinephrin is a stimulant of the sympathetic ends and centrum both and a depressant to the autonomic.

With these means at our disposal, we are in a position to determine generally the interrelation of the nervous system and the organs it supplies. For example, we administer the autonomic stimulant, pilocarpin, to a patient, and if his autonomic system is functionating normally, we soon observe the tissues supplied by its nerves overact, and he shows myosis, paralysis of accommodation, peristaltic paralysis, bladder contractions, asthma due to bronchial spasm, bradycardia, pallor of the skin, and an increase of glandular secretion throughout the body, notably of sweat. These manifestations are accompanied by cerebral manifestations such as psychomotor inhibition, fear and depression. Conversely, in patients that present depressions, with diminished psychomotor activity, we find an equivalent to an autonomic stimulating effect, in that they have paralysis of peristalsis, slow pulse, cold and clammy skin and subnormal temperatures.

If atropin is given to this person in full doses, the picture changes entirely, for atropin stimulates the sympathetic and depresses the autonomic. Here we see a relaxation of the spasmodic action of the smooth muscle fibers, so that peristaltic action is increased, the bronchial spasm relieved, the skin becomes dry and warm, the heart regains and even exceeds its normal rate, the pupils become large and mobile, and the whole picture is one of intense activity. Mentally, the person is alert, with great psychomotor activity, flushed face, and with his initiative restored and increased. Conversely, the emotional excitement, the intense activity, the euphoria, exhibited by certain psychic disturbances is accompanied by the visceral manifestations of sympathetic stimulation: namely, increased heart action with a feeling of bodily warmth, enlarged pupils, excessive appetite, and increased peristalsis.

These two examples may be taken as indicative of the complementary activities of the two systems. How it comes that cerebral activity is transferred to the cells of the sympathetic nuclei in the cord, or vice versa, is unknown; for while Bechterew and others have gone so far as to state that there are certain areas of the cortex which control the autonomic activities, especially those of erection, of the production of sweat and of intestinal peristalsis, yet proof is wanting. Müller is of the opinion that even the will is powerless to influence the functionating of the autonomic system.

---

[3] Timme, W.: Nervous System in Hyperplasia, Jour. Nerv. and Ment. Dis., May, 1913.

In opposition, Lewandowsky cites the fact of the voluntary emission of urine. Yet, as a matter of fact, how often do we see patients who, though their nervous and urinary system are apparently intact, cannot void urine even if they will?

There seems to be some intermediary between the will and the autonomic function. The following case is illustrative: Some time ago there came a man to the Charité in Berlin, who could cause the pilomotor muscles of his arms to raise the hair of the arms, and produce goose flesh at will. He could voluntarily cause his pupils to dilate and contract, and he had some control over the rapidity of his heart. He was presented as a case of "voluntary autonomic control" —a manifest contradiction in terms. When closely questioned, he admitted that the effects were produced not immediately by his will, but always by the intermediation of some association called into being by him. Thus, when dilating his pupils, he always imagined himself looking into space, under which conditions the pupil does dilate. For the goose-flesh effect, he would picture to himself his arm plunged into ice water, and the result ensued.

We all know that various associations produce autonomic effects without our will, and it is reasonable to suppose that if we can recall these associations through our will, the same autonomic effects will be produced. Joy causes a rapid heart action; shame is accompanied by blushing; fear sends the blood from the face and lips, and dries the mouth; psychic irritation may cause vomiting, or asthma, or diarrhea, and sexual excitement is followed by erection. Any of these effects can be produced by calling up the associations which accompanied their presence at some previous time, so that only indirectly can the will control the autonomic mechanism — a far different matter from the voluntary absolutism over the cerebrospinal. This is of far-reaching importance, for as our moods depend largely on the varying adjustments of ourself to our environment, on the one hand; and as these moods are made up of such components as were just mentioned, joy, fear, anger, shame, on the other, we see that the harmony of the activities of the internal organs depends partly on our proper adjustment to our surroundings. Our will, as such, can help us not at all to overcome our difficulties in the internal economy, but only so far as it can make our voluntary activities harmonize with their environment. Reciprocally, confusion in the internal economy, by a disturbance of the autonomic system, unless thoroughly compensated by the opposing sympathetic, produces changes of blood-pressure, differences in the ratio of the quantities of the various hormones in the blood, and changes in secretion; all of which influence the activity of the cortex, causing finally the different moods which make our adjustment to our surroundings so difficult. And now we find ourselves in an extremely vicious circle. The extrication therefrom is the problem of modern medicine.

But there is one peculiar condition to which I should like to call attention. It is that when disease, or perverted function of either the spinal tracts or centers or in the brain itself causes a cessation or diminution of the reciprocal activities between the brain and the particular viscus in question, then the activity seems to be transferred to some other viscus and a substituted result follows. Thus I have under my care a patient suffering with spinal lues. He is impotent. Yet, when he is in psychosexual excitement, he invariably vomits, and the tension under which he was is immediately relieved thereby. A second patient, whose sexual development is far backward and who does not comprehend the nature of reproduction, is nauseated whenever she is in the company of boys of her age, and frequently vomits under a little added excitement. As she herself explains it, the vomiting relieves her mind. We need recall only the condition in the amphioxus previously described for an analog.

Many attempts have been made to trace anatomically the path of influences from the cortex and other cerebral areas to the bulbar and spinal sympathetic nuclei, and on the other hand the track of the painful and other sensations from the viscera to the cortex. But the sum of our knowledge at present is merely that there exist certain areas in the brain whose stimulation produces certain activities in the viscera. For example, there is a point in the hypothalamic region which, when irritated, produces dilatation of the pupil (Kreidl). The floor of the third ventricle contains an area which partially controls the sugar tolerance. Bladder contractions may be called forth by stimulating a part of the hypothalamus; but these results are quite isolated and want further proof. As for tracts of conduction for these impulses, we know simply that the cervical sympathetic and the superior cervical ganglion are the carriers of the current from the cerebrum and midbrain to the ciliary muscle influencing the tone of the pupil. And that is all. Müller believes that there is the same possibility of changes occurring in the excitability of the medulla and cord as occur with the changes in mood in the psychic centers, and thus we can understand in a measure the production of effects in the viscera through a disturbance of their spinal centers. The other question, the manner of conduction of painful impulses from the viscera to the cortex, is explained by many — Sherrington, Müller, Head and others — as due to the process of "irradiation" from the termination of the afferent autonomic fiber in the spinal ganglion to the spinal afferent nerve in juxtaposition to it, and thence to the cortex. A new theory of the function of the nodes of Ranvier, in which these nodes serve as channels of communication between highly charged fibers and those less markedly so, will perhaps explain the difficulty underlying the meaning of the term "irradiation."[4] The carrying of the current by spinal nerves causes presumably the projection of the pain area to the peripheral zone supplied by these nerves — "Head zones."

We have now seen in the lowest vertebrate type, the amphioxus, in the mammalian cat, and in the human being, based on embryologic development directly observed, on physiologic and pathologic experimentation, on clinically observed facts and on pharmacologic experience that there is a close relationship between the activity of the brain and that of the viscera, and that in spite of the autonomicity of the one and the primacy of the other, each is complementary to the other in a broad sense, and depends on it for its own normally functionating existence.

---

Truth or Happiness.—Henri Poincaré starts one of his books with the remark that the chief aim of man is to search for truth. Nine people out ten will tell you that the chief end is to search for happiness. These are the two points of view and they split up the whole world into two kinds of people.—*Scientific American.*

RELATION BETWEEN CHLORID RETENTION, EDEMA AND "ACIDOSIS" *

MARTIN H. FISCHER, M.D.
CINCINNATI

It has been noted by different authors that in edemas of various types, as in those associated with heart disease, certain types of nephritis, etc., there is evidence of chlorid retention in the body. From this it has been quite generally concluded that in these conditions the kidneys are unable to eliminate chlorid (or, as ordinarily stated, are unable to eliminate sodium chlorid) and that its retention in the body is responsible for the edema. On such reasoning has been based the widely approved therapy of sodium chlorid restriction, and since a lessening of edema has at times been observed in patients following such restriction, the argument as a whole has been regarded as entirely sound.

Against it have stood, on the one hand, the failure of good observers to see any clinical improvement following careful efforts at applying the principles of sodium chlorid restriction, and on the other, the experimental facts developed in my studies of water absorption by protoplasm. According to these studies the hydrophilic (protein) colloids of the body and their state are chiefly responsible for the amount of water absorbed and held by any cell, tissue or organ under physiologic and pathologic circumstances. There exists a complete analogy between the absorption of water by simple protein colloids and by living cells. The presence of any salt, including sodium chlorid, reduces the amount of water absorbed by any (protein) colloid, and similarly the amount held by tissues either under normal circumstances or in states of abnormally great hydration (edema). These considerations have compelled the conclusion that sodium chlorid restriction as a scheme of therapy is not only wrong in principle, but also harmful in practice.

It is the purpose of these paragraphs to indicate why sodium chlorid retention and edema go hand in hand. *Sodium chlorid retention is not due to an inability of the kidneys to eliminate it, but to a change in the proteins (and other colloids) of the body as a whole. Sodium chlorid retention does not lead to edema, but the changes which lead to edema and to sodium chlorid retention are the same, consisting, in the main, of an abnormal production and accumulation of acid in the body.*

Proofs for this may be brought from both a clinical and an experimental side. So far as the clinical aspects are concerned, it is sufficient to emphasize that sodium chlorid retention is a constant accompaniment of all pathologic conditions in which there is evidence of an abnormal production and accumulation of acid in the body, as betrayed through a persistently high hydrogen ion or titration acidity of the urine, through an increased hydrogen ion acidity of the blood, an increased hydrogen ion acidity of the saliva or other secretions from the body, through a high relative or absolute ammonia excretion in the urine, a low carbon dioxid content of the blood or alveolar air, etc. Because such acid intoxication is exceedingly common in many different clinical states it is readily apparent why sodium chlorid retention has long been observed in pneumonia, in many of the infectious diseases, in the pernicious vomiting and intoxication of pregnancy (eclampsia), in the cyclic vomiting of children, in diabetes, in carbohydrate starvation, in the severer types of the circulatory disturbances, in the severer anemias, in poisonings with arsenic, lead, phosphorus, chloroform, ether and alcohol, and in the generalized parenchymatous nephritides when accompanied by a generalized edema. *The water retention likely to be observed in all these states is not secondary to the sodium chlorid retention, but both are due to the existent acid intoxication. The presence of acid in abnormal amount in the body not only increases the hydration capacity of the (protein) body colloids, but also increases at the same time their capacity for holding chlorid.*

Experimental proof of this may be easily brought. When protein (carefully washed fibrin or gelatin) is thrown into a salt solution it not only absorbs water from the salt solution, but salt as well. On the addition of acid, the amount of water absorbed is increased (the protein becomes "edematous"), but the absorption of salt is also increased. The presence of acid, in other words, leads not only to greater swelling, but also to sodium chlorid retention. Experiments were made by placing weighed amounts of fibrin or gelatin in definite volumes of neutral or acidified sodium chlorid solutions of definite strength kept in carefully stoppered flasks. After varying periods of time the solutions about the swollen protein were filtered off and the chlorid in them determined by titration with silver nitrate according to Volhard's method. The following experiments suffice to illustrate the values obtained:

Experiment A.—A dry gelatin plate weighing 0.813 gm. is placed in each of the following solutions:

1. 75 c.c. 1/6 molar NaCl + 25 c.c. H_2O
2. 75 c.c. 1/6 molar NaCl + 25 c.c. N/10 HNO_3

Titration (of an aliquot portion) of the surrounding fluids nineteen hours later shows the former to contain 0.00303 gm. chlorin (=0.005 gm. sodium chlorid) more than the latter. In other words, the gelatin in the acid solution has absorbed this amount of chlorin (or sodium chlorid) more than the gelatin in the neutral medium. Twenty-three hours later the difference is still more striking. At this time the surrounding liquid in the first mixture contains 0.00606 gm. chlorin (=0.01 gm. sodium chlorid) more than the second; or, conversely expressed, this much more chlorin (or sodium chlorid) has been absorbed by the gelatin in the acid medium than by that in the neutral one.

Experiment B.—Three gm. powdered fibrin are placed in each of four flasks containing, respectively, the following solutions:

1. 85 c.c. 1/8 molar NaCl + 15 c.c. H_2O
2. 85 c.c. 1/8 molar NaCl + 5 c.c. N/10 HNO_3 + 10 c.c. H_2O
3. 85 c.c. 1/8 molar NaCl + 10 c.c. N/10 HNO_3 + 5 c.c. H_2O
4. 85 c.c. 1/8 molar NaCl + 15 c.c. N/10 HNO_3

Nineteen hours later the excesses of chlorin absorbed by the fibrin in the acid solutions over and above the chlorin absorbed in the neutral mixture are, respectively, 0.00303, 0.004545 and 0.010605 gm.; or, recalculated in terms of sodium chlorid, 0.005, 0.0075 and 0.0175 gm.

Experiment C.—Three gm. powdered fibrin are placed in each of five flasks containing, respectively, the following solutions:

---

* From the Joseph Eichberg Laboratory of Physiology in the University of Cincinnati.

1. 40 c.c. 1/6 molar NaCl + 10 c.c. H_2O
2. 40 c.c. 1/6 molar NaCl + 2.5 c.c. N/10 Lactic acid + 7.5 c.c. H_2O
3. 40 c.c. 1/6 molar NaCl + 5 c.c. N/10 Lactic acid + 5 c.c. H_2O
4. 40 c.c. 1/6 molar NaCl + 7.5 c.c. N/10 Lactic acid + 2.5 c.c. H_2O
5. 40 c.c. 1/6 molar NaCl + 10 c.c. N/10 Lactic acid

Twenty hours later the excesses of chlorin absorbed by the fibrin in the acid solutions over and above the chlorin absorbed in the neutral mixture are, respectively, 0.0010605, 0.0037875, 0.006969 and 0.0113625 gm.; or, expressed in equivalents of sodium chlorid, 0.00175, 0.00625, 0.0115 and 0.01875 gm.

It has been customary in the modern writings on chlorid retention to assume that it is retained as sodium chlorid, and it is for this reason that in the experiments thus far detailed we have recalculated the value of the chlorid retention in terms of sodium chlorid. Chlorid is, however, better retained by acidified protein than by neutral protein even when it is offered in another form. Experiment D demonstrates the increased chlorid absorption under the influence of an acid in the case of calcium chlorid.

Experiment D.—Three gm. powdered fibrin are placed in each of five flasks containing, respectively, the following solutions:

1. 40 c.c. 1/6 molar $CaCl_2$ + 10 c.c. H_2O
2. 40 c.c. 1/6 molar $CaCl_2$ + 2.5 c.c. N/10 HNO_3 + 7.5 c.c. H_2O
3. 40 c.c. 1/6 molar $CaCl_2$ + 5 c.c. N/10 HNO_3 + 5 c.c. H_2O
4. 40 c.c. 1/6 molar $CaCl_2$ + 7.5 c.c. N/10 HNO_3 + 2.5 c.c. H_2O
5. 40 c.c. 1/6 molar $CaCl_2$ + 10 c.c. N/10 HNO_3

Twenty-four hours later the excesses of chlorin absorbed by the fibrin in the acid solutions over and above the chlorin absorbed in the neutral mixture are, respectively, 0.00303, 0.004545, 0.00606 and 0.010605 gm.; or, expressed in equivalents of calcium chlorid, 0.004735, 0.0071025, 0.00947 and 0.0165725 gm.

It would take us too far afield to discuss why chlorid is better retained by protein in the presence of acid than in its absence. It is sufficient to point out that the observed behavior is probably nothing but an isolated illustration of the adsorption of a dissolved substance by a colloid, which, as so frequently the case, is decidedly better when an acid is present than when it is absent. To the adsorption effect may, perhaps, be added a chemical one, for there is some evidence that an acid protein combines chemically with neutral salts in a way that neutral protein does not.

The increased amount of chlorid retained by proteins under the influence of acid is of a magnitude to cover easily any amount ever found retained by patients. Rarely are more than from about 10 to 50 gm. of (sodium) chlorid held in the body. Choosing for illustration Experiment A as a basis for calculation, we note that at the end of nineteen hours the acidified gelatin has absorbed an amount of sodium chlorid in excess of that absorbed by the neutral gelatin amounting to 0.61 per cent. of the original dry weight of the protein. At the end of another twenty-three hours the figure has risen to 1.22 per cent. If we choose the very liberal figure that but one-fourth the normal body weight is dry substance (of which more than 95 per cent. is colloid), this means that a man weighing 75 kg. (165 pounds), developing the ability to retain even 0.61 per cent. more salt is already able to retain 114 gm. of sodium chlorid, or if the higher figure is chosen, twice this amount.

These experiments have also a general biologic interest in connection with the question of the "permeability" of cells to different substances. It is scarcely conceivable that any one will maintain gelatin disks or fragments of powdered fibrin to be surrounded by "membranes," and yet observations of the type described in these paragraphs when made on living cells or tissues are constantly used as "proofs" for the existence of "membranes" about cells and of their alterable "permeability." Thus, it has been maintained that "living" cells are "impermeable" to sodium chlorid and to other salts, but become "permeable" on the addition of acid or of substances which indirectly lead to a production and accumulation of acid in the cells (chloroform, ether, cyanid, etc.). Would any one by similar reasoning maintain that gelatin plates and fibrin flakes lying in a "physiologic" sodium chlorid solution are "osmotic" systems surrounded by "impermeable" membranes which become "permeable" to sodium chlorid when an acid is added?

Perhaps these experiments will serve to illustrate anew the fruitful consequences of the application of colloid-chemical principles to medical and biologic problems. As they have proved adequate in the explanation of the many phenomena characteristic of water absorption by protoplasm they will also explain without contradiction the absorption and secretion of dissolved substances.

THE OCCURRENCE OF EDEMA FROM LARGE DOSES OF SODIUM BICARBONATE

LOUIS A. LEVISON, M.D.

TOLEDO, OHIO

There are a number of pathologic conditions in which large doses of sodium bicarbonate or other alkalies are indicated. The report of the two cases below, particularly Case 1, may serve to draw attention to an occasional consequence of such large administration of alkalies, which may lead to wrong conclusions if the possibility of its occurrence is not kept in mind. The condition referred to is the occasional appearance of generalized or localized edema in the course of administration of sodium bicarbonate.

Case 1.—Woman, aged 51, was seen first, July 30, 1913. The patient had had diabetes mellitus for several years to her knowledge, and doubtless for some time before its discovery. The condition which I was called to see was a large carbuncle on the back between the shoulders. The urine at this time contained 5 per cent. of sugar. Diacetic acid and acetone were present. The carbuncle was incised and dressed daily with iodin and sterile gauze. The presence of diacetic acid and acetone in the urine precluded the institution of a carbohydrate-free diet and no attempt was made to reduce the carbohydrate intake to a minimum. The infection between the shoulders did not get along satisfactorily, several new boils developed at various points, emaciation was rapid, and the prognosis looked doubtful. The treatment from July 30 to August 15 consisted in a moderate reduction of carbohydrates, an abundance of meats, eggs, green vegetables, cream, coffee and tea. Forty to sixty grains of sodium bicarbonate were given four times daily during this period. The ferric chlorid reaction for diacetic acid remained constant, however. Drowsiness appeared August 15 and went on to a state of semicoma. There were movements in response to stimuli, the patient would swallow when drink was placed to her mouth, there was no response to questions and the sphincters were relaxed. The daily amount of sodium bicarbonate was increased at the first sign of approaching coma until the patient was getting 6 drams by mouth and one or two rectal injections daily, each containing 1 ounce of sodium bicarbonate. It is not possible to say how much of this was absorbed, as the injections were not well retained. The foregoing intensive form of alkaline medication did not prevent the drowsiness from deepening into a state of semicoma. The coma did not become absolute. The patient would swallow at any time, so it was possible to keep up the alkalies by mouth. Edema of the fingers and hands was noted at the beginning of this semicomatose period. The feet and ankles were next involved. The edema increased until the patient presented a condition of complete anasarca —edema of the extremities, face, eyelids, forehead, abdominal wall and back. Definite ascites could not be ascertained. Nephritis, heart, liver or other involvement as a cause for the edema could be ruled out. The condition was recognized and the sodium bicarbonate discontinued. The edema began to decrease appreciably the second day after, and was gone one week after the alkaline medication had been stopped. The patient made a slow recovery from her acidosis, the carbuncle and furunculosis disappeared, the diabetes was eventually controlled by a suitable dietetic regimen, and at the present moment (November, 1914) she is feeling well and attending to her household affairs.

Case 2.—Woman, aged 24, convent nun, was examined in August, 1914. Her complaint was a pain in the epigastric region which had been present nearly every day for one year. A similar condition had existed when she was 17 years old. The pain came on a few minutes after eating and lasted one or two hours. The intensity of the pain varied from a dull ache to a sharp, knife-like pain. It was more severe after the heavy midday meal than after the lighter breakfast or supper. There was occasional nausea in the morning, but no vomiting. The pain was relieved at once by sodium bicarbonate or other alkaline treatment. The usual weight was 154, the present weight 132. The history and examination led to a diagnosis of ulcer of the stomach or duodenum. The patient was placed on an ulcer diet and kept in bed. She was given a powder containing sodium bicarbonate and calcined magnesia and directed to use a level teaspoonful in milk every three hours. This treatment gave her symptomatic relief and its continuance was advised when the patient left the hospital. She was then not seen for a period of three weeks, during which time the foregoing alkaline mixture was used freely and in greater amount than had been advised. The exact amount of sodium bicarbonate which was used daily could not be determined, but was approximately 4 or 5 drams. Examination at the end of this three-week period showed a marked edema of the feet, ankles and the lower part of the legs. The edema was similar in its general appearance and pitting characteristics to the edema of a cardiac trouble, but it could not be explained by any trouble in the heart, kidneys, liver or elsewhere. The possibility of a sodium bicarbonate edema was recognized, the alkaline treatment was discontinued, and without rest in bed, change in her habits, or other therapeutic agent, the edema disappeared completely in three days. (The subsequent history of this patient will not be related, as it does not have to do with the title of this article.)

The treatment of diabetics with threatened acidosis and coma by means of sodium bicarbonate is a common procedure. Staubli and Blum[1] state that such medication may cause an increase in body weight without real obesity because of a watery saturation of the tissues. The body weight rapidly falls when the alkaline medication is stopped. They believed that the sodium bicarbonate was retained in the tissues and attracted water.

E. Pfeiffer[2] has also considered the pathogenesis of sodium bicarbonate edema. He thinks the explanation is to be found in the increased amount of sodium in the tissues. This view is not held by Widal, Lemierre and Cotoni.[3] They do not believe that it is a question of sodium alone or the excessive amounts ingested. They have shown that a diabetic retains chlorids and water under the influence of sodium bicarbonate, which retention is in proportion to the condition of the kidneys and the degree of acidosis.

The property which sodium bicarbonate possesses of producing a chlorid retention, and in marked cases edema, is not peculiar to diabetics. The amount necessary to produce a retention of chlorids has been determined experimentally to be 20 gm. or more daily. This amount is larger than the usually prescribed therapeutic dose in stomach affections, but may be much below the amount given in cases of threatened diabetic coma.

In a general way the chlorid retention is in proportion to the amount of sodium bicarbonate ingested, but that is not the only factor. Cachectic and toxic diabetics, individuals with poor renal elimination, and emaciated subjects rapidly progress to chlorid and water retention, sometimes edema, from doses of sodium bicarbonate which in milder diabetics or individuals in a fair state of nutrition and having good elimination would produce only the "preedemic" state of the French writers. Widal believes further that the sodium chlorid content of the food plays a part in determining the amount of chlorid retention and edema after the use of sodium bicarbonate.

Charcot and Vulpian, and then Hayem[4] called attention to the occurrence of edema or water retention after the administration of sodium bicarbonate to healthy men as far back as 1890. Hayem was able to demonstrate such a retention after the use of from 20 to 30 gm. of sodium bicarbonate daily. This corresponds to Case 2 reported above. More recently, Blum demonstrated the same thing, but thinks that the water retention does not go on to the edema stage in healthy individuals. It is rather difficult to determine this point in an experimental way in healthy persons, because large amounts of sodium bicarbonate given to such persons causes diarrhea, vomiting and other digestive troubles which necessitate the discontinuance of the drug. Blum was able, however, to determine this point with two normal persons. One was a healthy man of 28, who was put on a chlorid-free diet to which was added 12 gm. of sodium chlorid daily. The chlorid balance was determined, and then 40 gm. of sodium bicarbonate was given daily for twelve consecutive days. During this period there was a chlorid retention of 32 gm. and an increase of body weight of 2.5 kg. This chlorid retention and increased body weight disappeared promptly on stopping the sodium bicarbonate. The experiment was later repeated on the same man with identical results, the figures varying but slightly.

Widal, who seems to have given most attention to sodium bicarbonate edema, reports a number of cases.

[4] Hayem: Leçons de thérapeutique; les médications, Paris, 1890, Series 2, p. 222.

One case (the others were similar) concerned a much emaciated diabetic of 28 with threatening acidosis. Forty gm. of sodium bicarbonate had been given daily for six days. The dose was then raised to 80 gm. daily, under which treatment his stupor began to lessen. The body weight increased 3 kg. during the first three days of this alkaline medication, and at the end of eight days the increase amounted to 9 kg. Edema appeared at this point and involved the hands, feet, legs, thighs, abdomen and face. The sodium bicarbonate was stopped and in three days the body weight had decreased 6 kg., with disappearance of the edema. The increase in body weight and edema corresponded with a fall in the urinary chlorids from between 18 or 31 gm. daily to 7 gm., the diet being the same. The urinary chlorids then jumped to 35 gm. daily, when the sodium bicarbonate was stopped. Later in an experimental way, Widal was able to increase or decrease the body weight of this patient at will by adding or taking away sodium bicarbonate. A chlorid retention was uniformly found to correspond to the period of increased weight.

CONCLUSIONS

1. Sodium bicarbonate in large doses may cause an increase in body weight which may go on to the appearance of edema.
2. This increase in weight is caused by a retention of chlorids in the body with resultant water retention.
3. The increase of body weight or edema is more likely to appear during the administration of large doses of sodium bicarbonate to cachectic diabetics with acidosis.
4. It can be produced in an experimental way in normal individuals.

UNHEATED VACCINES

ARTHUR J. CASSELMAN, M.D.
CAMDEN, N. J.

The purpose of this paper is to encourage the use of unheated vaccines.

The preparation of unheated vaccines, which have had their vegetative powers destroyed by members of the phenol group, has been suggested previously by others. Park and Williams[1] say, "It has lately been suggested that instead of killing by heat the vaccines may be killed by adding, when made, 0.5 per cent. carbolic acid, or 0.25 per cent. cresol compound." This is the only reference I have found, relative to the use of unheated vaccines killed by members of the phenol group.

Crandon[2] gives a summary of the literature on the use of killed and living vaccines, proving conclusively the great advantage of unheated over heated vaccines, as heating even to 60 C. destroys in a great measure their immunizing power.

Two years ago I decided against heating my vaccines, provided I could discover some method of destroying their vegetative powers with less change in their chemical composition than is induced by heat. My choice of germicides finally narrowed down to two: the ultraviolet ray and the phenol group. As yet I have not used the ultraviolet ray. A good method of killing most bacteria I found to be their immersion for twenty-four hours in 0.25 per cent. tricresol solution at 37 C.

TECHNIC

The only liquid used is 0.25 per cent. tricresol in previously sterilized physiologic saline solution. All materials coming in contact with the vaccine, during or after preparation should have been sterilized in advance. The culture medium to be preferred is a 2 per cent. glucose, 6 per cent. glycerol-blood-agar, neutral to — 1 to phenolphthalein. It is sometimes of advantage to run a soft blood medium over a substratum of a more solid medium.

The bacteria are removed from the surface of the culture medium by means of glass rods drawn thin in the Bunsen flame to give them flexibility. The ends of the rods are made sufficiently thick to prevent penetration of the medium. A few drops of the tricresol solution are placed on the surface of the culture and the growth can easily be removed with the aid of these rods, even from a fairly soft medium.

The vaccine is then well emulsified by shaking in a test-tube or flask with beads or broken glass. The emulsion is filtered through sterile paper to remove clumps of bacteria. Sufficient tricresol saline solution is added to bring the minimal dose to 0.05 to 0.1 c.c.

After twenty-four hours in the incubator, the suspension is tested for sterility by inoculating a loopful into a tube of bouillon, a loopful of which is run over each of a number of sterile slants of the medium used in the primary culture. Twenty-four hours in the incubator has been used as the limit of the test for sterility. Objections may be raised against my practice of dividing the vaccine in a number of ampules, before placing in the incubator for twenty-four hours to sterilize, but I consider none of them valid.

ADMINISTRATION

For injection, a 1 to 2 c.c. all glass syringe with platinum-iridium needle will be found economical, as this apparatus may be sterilized without injury by moist or dry heat. A convenient arrangement is to draw out, at the closed end, a moderately heavily walled test tube in which the syringe may be placed, so that the constriction will prevent the point of the needle from reaching the tip of the tube. If the vaccine is to be given at some distant place, this apparatus should be slipped inside a larger tube previous to sterilization. If sterilized by dry heat, a number of these syringes may be kept on hand indefinitely, ready for use.

A method of determining the proper dosage, which is of value in many cases, is to introduce the minimal dose intracutaneously and double the dose daily, until a fairly severe local reaction is obtained, then to give that amount every four or five days. No definite rule of therapeusis can be laid down; experience is necessary for best results. Probably the intravenous route will be found preferable, both as to rapidity and degree of immunity. At present, insufficient work has been done on the subject to justify the intravenous injection of vaccines as a routine procedure.

EXPERIMENTAL

I used an insufficient number of heated vaccines along with the unheated in similar cases to prove definitely the great advantage of the latter; proof of an established fact is unnecessary. But it must be proved that the vegetative power is removed from the bacteria by the action of 0.25 per cent. tricresol for twenty-four hours at 37 C. At least a thousand different vaccines of each micro-organism should be prepared by this method and every one proved sterile. Then perhaps the sterility might be relied on without testing. In the cases in which I have followed the above technic implicitly, the results have usually been better than anticipated. I am still looking for one of the non-spore bearing pathogenic bacteria which will stand 0.25 per cent. tricresol for twenty-four hours at 37 C. without losing its powers of reproduction. I have not experimented with the fungi, but am now experimenting with the tubercle bacillus along these lines. An unheated tuberculin similarly prepared may possibly give the same good immunizing results obtained by the use of living virulent tubercle bacilli by Trudeau, Neufield, Webb, Williams and Barber, Theobald Smith and others.

[2] Crandon, L. R. G.: Surgical After-Treatment, Ed. 1, Chapter lii, by G. P. Sanborn. Philadelphia, W. B. Saunders Company, 1910, p. 763.

The above amounts of members of the phenol group do not interfere with such a delicate immunity reaction as complement fixation and probably have little or no influence on such reactions in vivo. This method of removal of vegetative powers might also be applied to sensitized vaccines.

CONCLUSION

Vaccines should not be heated above 37 C. but their vegetative powers should be destroyed by some method which does not change their immunity reactions from those of living bacteria. A method which is apparently successful with most micro-organisms is the use for this purpose of 0.25 per cent. tricresol solution for twenty-four hours at 37 C. Probably any member of the phenol group in the same bactericidal concentration would be satisfactory.

THE PROBLEMS OF GRADUATE MEDICAL INSTRUCTION *

HORACE D. ARNOLD, M.D.
Dean of the Graduate Medical School of Harvard University
BOSTON

The subject of graduate medical instruction is attracting much attention at the present time and is becoming a very important problem in medical education. When, ten or more years ago, the medical profession began to give serious attention to the problems of medical education in this country, acting through its most representative body—the American Medical Association—efforts for improvement were naturally directed first to the medical schools themselves. You all know how much the Council on Medical Education has accomplished in the ten years since it was organized, in establishing high standards for medical schools, in forcing many of the poorest schools to close their doors, and in making better schools of those that remain. While much still remains to be accomplished in this direction, the problem of the proper training of medical students may be regarded as practically settled.

The most important problem to-day is that of improving the knowledge of those who are already engaged in the practice of medicine. Many of them have received a very inadequate training, and from the point of view of the public welfare it is as important that these physicians should become better trained, as it is that those about to enter the profession should be well trained.

Recognizing the importance of this problem, the Council on Medical Education has undertaken a study of the present status of graduate medical teaching, with a view to making suggestions for its improvement. It recognizes the need of adequate opportunities for graduate medical study, not only because many members of the profession wish for such opportunities, but because they are essential for the public good. This aspect of the problem, the relation of graduate medical teaching to the public welfare, has received altogether too little attention. We have looked at the subject too exclusively from the point of view of academic teaching. It is commendable to encourage students to carry their studies to the limits of knowledge in any subject, and it is a worthy ambition to have the most complete equipment and facilities for such studies. But after all is not the real underlying spirit of our universities a desire to be of service to the community? Do they not aim to furnish the inspiration that will improve the condition of mankind, and raise the standards of civilization? We have been so fully occupied with the details of medical instruction, and with the difficulties of keeping pace with the growth of medical knowledge, that we have given little thought to this deeper problem of public service. Yet the possibility of public service should be one of the strongest arguments to induce medical schools to take up graduate teaching, and it should influence the line of development of this work.

Returning to the problem of the physicians who have had an inadequate training, where shall they get adequate opportunities for further study? To a certain extent it is practicable for them to attend the regular exercises given in the undergraduate schools, especially the didactic lectures and the clinical demonstrations before a class. The presence of graduates at such exercises does not interfere with the regular instruction. This is not true, however, when we come to consider individual instruction in section teaching. As a rule it is inadvisable to admit graduates to sections of undergraduate students, because the graduate should have special instruction, adapted to his individual needs, and this can be given only at the sacrifice of time which should be given to the regular students. Furthermore, few graduates can afford to give the amount of time that would be required to pursue the studies, as arranged in the curriculum of a medical school. Courses should be provided which are especially adapted to their needs.

The poorly trained men need elementary courses, not advanced courses. Should the medical schools provide such courses? Should elementary courses of this character be provided in graduate medical schools? Or should schools be organized for the special purpose of giving courses of this grade to graduates? There are advantages to each of these plans, and disadvantages as well.

Various independent schools for graduates have been organized in the past. They vary from good to very bad. Some are clearly commercial in type, and are carried on for the direct or indirect gain of the instructors. They are as objectionable as the worst type of proprietary medical schools that formerly flourished in this country, and there is equal reason why they should be abolished.

The existence of such schools shows the weakness of the plan of independent schools. There is the same need of high standards in graduate medical teaching as in the best undergraduate medical schools. The

---

* Part of an address before the Harvard Medical Society of New York, Nov. 28, 1914.

good independent schools suffer by being placed in the same class with these poor schools, and they should, for their own reputation, seek affiliation with good medical schools or with universities. It is true that in the past medical schools and universities have generally shown so little interest in graduate medical teaching that it has rarely been practicable to secure such affiliation; but these institutions are beginning to recognize their obligations in this matter, and such affiliation should be more feasible in the future. In the near future I think we shall see the best of the independent schools securing such affiliation, and as more medical schools take up graduate instruction, the independent schools which are below standard will become unprofitable and will cease to exist.

And so we come back to the question whether elementary courses for graduates should be given by medical schools or by graduate departments of medical schools. This question in turn raises a question as to the scope of graduate medical teaching. Should it include only advanced courses, or may it also include elementary courses? From an academic point of view, the graduate medical school would naturally give courses more advanced than those offered in the medical school. But even in the department of arts in our universities we do not find a sharp dividing line between undergraduate and graduate courses, and it is often necessary to allow students who are registered in the graduate school to take courses that are clearly recognized as of undergraduate grade. The question whether elementary medical courses for physicians should be given by the graduate school or by the undergraduate school is a matter of convenience of administration rather than of principle.

Notwithstanding these considerations, it is useful to distinguish those advanced courses, which a graduate school ought to give, from the more elementary courses, which it may give as a matter of convenience. I would suggest therefore that the term "graduate medical course" be understood to mean a fourth-year elective or a course of still higher grade; and that courses of a lower grade, but outside the regular curriculum of the medical school, be designated "polyclinic" courses. (I use this term for lack of a better one, and would welcome a better name.) For the sake of avoiding confusion, I hope that the term "postgraduate" will gradually be dropped.

On this basis a medical school might offer graduate courses, or polyclinic courses, without organizing them as a separate department. It might develop a graduate department or school, or it might develop a polyclinic department or school. If a graduate department is organized, this might, as a matter of convenience, take charge of the administration of polyclinic courses. What should be done will depend on the conditions in each individual school. I believe, however, it is a matter of public duty for all good medical schools to consider seriously what they can properly do in the way of graduate or polyclinic teaching.

A cardinal principle in the consideration of this problem is that a medical school's first duty is to provide adequate undergraduate teaching. Until this is satisfactory, the school should bend all its energies to the improvement of its undergraduate course. It follows, as a matter of course, that Class C and Class B schools should not undertake teaching of this sort. A question arises as to how far Class A schools should enter this field. It should be remembered that only the schools in Class A+ are now considered by the Council to be acceptable without qualification. Class A schools need improvement in certain respects, although they do not need such general improvements as those in Class B. It would be wise then for Class A schools to endeavor to attain or to approach as near as possible to the standards of Class A+. They should therefore guard against any dissipation of their energies in graduate teaching. This is especially true of those schools which rank low in Class A. The better schools of this class might undertake graduate or polyclinic instruction during the summer vacation; or some departments might do this during that part of the school year when they are not engaged in undergraduate teaching.

In the latest classification of medical schools there are twenty-nine schools in Class A+ distributed in twenty states. For various reasons not all of these can wisely undertake graduate instruction on an extensive scale at the present time. It is desirable, however, that all of these schools should consider the problem seriously, and that as many as possible should become centers for giving practicing physicians a better training as well as for training undergraduates.

A considerable number of these schools are already doing work of this character, although very few have organized separate departments or schools for the purpose. It should be clearly understood that valuable work in graduate teaching can be done without such formal organization. It is the quality of the work and not the quantity that is important. Many of these schools can at least offer to qualified students opportunities for advanced study in connection with the research work which is carried on in various departments. One service which the Council on Medical Education can render is to collect data about opportunities of this sort and publish this information. It will then be available for those who seek such opportunities for study. Many students go abroad to study because they do not know about the opportunities which lie close at hand in this country, and they have no ready means of gaining this information.

The standards of graduate instruction should be just as high as those of undergraduate instruction. Therefore a school which is uniformly poor would not be acceptable for graduate teaching. But some schools, which do not rank high when attempting to give a complete medical training, may have some strong departments, which are as good as those of high-grade schools. Graduate teaching by these departments would be acceptable. Therefore some of the poorer medical schools might well consider the proposition of a change to graduate teaching, provided they limited the field of such teaching to those subjects in which the instruction would be on a par with that in the best medical schools. Such schools would generally become polyclinic schools. They should seek affiliation with medical schools of high standing, for only in this way can they wipe out the stigma of their previous low rank.

The limitation of the field of graduate teaching to those subjects which can be well taught is an important consideration also for the independent "polyclinic" or "postgraduate" schools which now exist. Some of these schools have developed certain departments so that they will compare favorably with those of very good medical schools; yet, in attempting to cover the whole field of medicine, they have other departments so poor that the school as a whole must take very low rank, when compared with regular medical schools. Again, we may find in some of these strong departments excellent teachers, who stand very high in the estimation of the profession; while in the same faculty are instructors who would be ranked as incompetent teachers by a low-grade medical school. Now that attention is being directed to standards of graduate instruction, and to the relative standing of these schools, the best men cannot afford to stay in such company. It necessarily follows that these schools must reorganize—perhaps on a more limited scale—or they must suffer a distinct loss of reputation. Such reorganization would greatly facilitate that affiliation with good medical schools which the independent polyclinic and graduate schools should seek. Naturally such changes cannot be brought about at once, but it is time that they be given serious consideration.

Let us pause a moment and summarize the ideas which have been advanced. Graduate medical instruction is one of the most important problems of medical education to-day. It is of great importance for the public welfare, because it aims to give a better training to those who are now practicing medicine. It therefore deserves careful consideration by our best medical schools. Graduate teaching should be on the same high plane as undergraduate teaching, and it should be attempted only so far as it can be placed on this plane. It should be under the control of good medical schools, or of universities; for this is the best way to maintain proper standards. The best independent schools which give instruction for graduates will probably be able to secure, in the near future, affiliation with good medical schools. The others will be forced by public opinion to reorganize and to raise their standards. Otherwise they will suffer in prestige and will become unprofitable. Instruction for graduates must be adapted to the students previous training and experience. Therefore it may range from very elementary courses to the most advanced research work. It is useful to distinguish the advanced courses from those of undergraduate grade; therefore the terms "graduate course" and "polyclinic course" are suggested. Any good medical school may offer to graduates as much or as little as it chooses in this broad range of studies, provided it is good work of its kind.

We may now consider briefly a few general topics in connection with graduate teaching.

ADMISSION REQUIREMENTS

There can be no uniform minimum admission requirements of an educational nature, as in regular medical schools. For the benefit of the public any earnest, reputable practitioner, who is licensed by the proper authorities to practice medicine, should be able to find somewhere an opportunity to improve his medical knowledge. This does not mean that he should be allowed to enter every graduate or polyclinic school, but that some schools should give courses to which poorly trained physicians may be admitted. It should be recognized that these schools are performing as useful duties as the schools which offer only advanced courses. The admission requirements in different schools will therefore vary with the kind of courses offered. The only general principle should be that each individual must have an adequate preparation for any course to which he is admitted.

CERTIFICATES

It is generally recognized that there are serious objections to the custom, which has been common in the "postgraduate" schools, of granting elaborate diplomas after short or inadequate courses. Such a diploma or certificate is likely to deceive the public, who may regard it as equivalent to a degree. People are easily led to believe that the possessor of such a certificate is a full-fledged specialist in a subject mentioned in the certificate. Unscrupulous physicians take advantage of this fact, and no one brings more discredit on the medical profession than these poorly prepared, so-called "specialists." The better "postgraduate" schools acknowledge the existence of this evil and are ready to join in a movement for its eradication.

At the Harvard Medical School, before the graduate school was organized, this custom prevailed of granting a certificate for attendance at single short courses. The certificate was unpretentious in form and it often provoked severe criticism from those who wanted it for advertising purposes; consequently the evil results were avoided in part. When the administrative board of the graduate school considered this problem, it recommended a radical change of policy, and its recommendations were adopted by the faculty of medicine. Since Oct. 1, 1912, certificates have been granted only after four months of continuous work, which has occupied the whole day. This is equivalent to a half-year in the undergraduate school. In addition to this, candidates for certificates must announce the fact that they are candidates at the beginning of their course, they must be accepted as candidates by the administrative board, and they must choose a systematic course of study which receives the board's approval. If their work in the individual courses is approved by the instructors, they are then eligible for an examination. The administrative board will grant a certificate only after this examination has been passed successfully. A student's previous medical or scientific training and experience are considered in deciding whether he may be accepted as a candidate for a certificate.

Under these regulations the school is warranted in setting its stamp of approval on the successful candidates. The certificate was properly given the form of a diploma, and it is signed by the dean and the members of the examining board. In the past two years, out of more than one thousand students only six have received a certificate. The average length of the course of study of these men was between six and seven months. The faculty of medicine has recently adopted the further recommendation of the graduate school, that after June 1, 1915, the time requirement for the certificate be increased to eight months. This will make the work required equivalent to one year in the undergraduate medical school.

What shall be done about students who attend for a shorter period and wish a testimonial or a statement about their work? We have met this problem by granting an "official statement." This is a typewritten statement on the regular letter-head of the school. It is given official standing by the signature of the dean or the secretary. It is a plain statement, attesting the fact of attendance, the duration and character of the course, and any other essential facts, including the marks in any authorized examinations the student may have taken.

When these regulations about certificates and official statements were adopted, we were naturally interested to see whether the effect would be to lower the number of students. If the regulations have kept students away, other attractions have more than offset the loss, for our numbers have shown a gratifying increase. We believe that it is practicable for the better "post-graduate" schools to adopt similar requirements, on the basis of four full months of study as a minimum requirement for a certificate.

STANDARDS FOR GRADUATE MEDICAL SCHOOLS

On what basis may approval of graduate medical schools be granted? Not on admission requirements, for reasons already stated. Not on the requirement of a definite period of attendance, for such a requirement would materially limit the usefulness of the school. However much we may wish graduates to take long courses, the fact remains that after they have established themselves in practice they can seldom leave for more than a short period of study. We should encourage them to improve their medical knowledge, even if they can get only a little at a time. Physicians in the neighborhood of graduate medical schools should even be encouraged to take single exercises, as occasion offers, from time to time. Again, we cannot base our approval of an institution on the number of subjects in which it gives instruction, for some of the best instruction will be given in institutions with a special, limited field.

Approval of these schools may be based fairly on three factors: first, and most important from this point of view, the adoption of satisfactory regulations about granting certificates; second, the limitation of the field of work to subjects in which the equipment and facilities for teaching are equal to those of approved medical schools; third, a guarantee of the quality of instruction by the existence of a corps of instructors who would be acceptable in an approved medical school.

STANDARDS IN SPECIALTIES

The problem of establishing standards of preparation in the various specialties is attracting much attention at the present time. It is a complex problem and one that is difficult to solve, yet it is becoming more and more important for us to reach a sensible solution. It is not my intention to discuss this problem on this occasion, but merely to point out that the graduate medical schools are concerned in its solution. Any standards which may be adopted must insist on a certain amount of systematic advanced instruction. Such instruction can best be organized in graduate medical schools. Therefore the establishment of standards for these schools is an essential part of the solution of the problem of standards in the specialties.

HIGHER DEGREES IN MEDICINE

By this we mean degrees that are higher than that of Doctor of Medicine, and for the acquirement of which the degree of M.D. will be a prerequisite. Here is another important problem that is being forced on us. It is a natural development from the problem of standards in the specialties. If, after graduation, a student has pursued advanced studies for a sufficiently long time, so that he is especially proficient in his chosen subject—in arts, in many of the sciences, and in some professional lines—he is granted a special degree to attest his proficiency. Why should he not receive similar recognition in medicine? From the point of view of the health and benefit of the community, the recognition of special skill or training in medicine is fully as important as in the other subjects in which such recognition is granted.

The universities are recognized as the authorities most able to establish proper standards for advanced study in medicine. Therefore, it is desirable for them to grant such higher degrees. Some universities have already taken a definite stand in this matter. As stated above, the subject is under consideration at Harvard. No one is warranted at present in making a definite statement as to what the decision will be, but it seems likely that Harvard will adopt the plan of a single advanced degree in medicine, and that in the degree mention will be made of the special field of medicine in which distinction has been won. This usage would be similar to that in the case of the degree of Doctor of Philosophy.

The subject of higher degrees in medicine has been selected by the Council on Medical Education as a topic for discussion at its next conference, in February. It is hoped that this discussion may help toward a general agreement as to what is best to be done in this matter.

THE TREATMENT OF HEMORRHAGE BY INJECTION OF BLOOD*

ARTHUR H. CURTIS, M.D.
CHICAGO

Those who have investigated its therapeutic possibilities firmly believe that blood and derivatives of it are of value in the treatment of persistent hemorrhage. Yet there is a surprising failure on the part of the profession to utilize thoroughly this means of treatment, and, in view of this fact, it seems desirable that certain features of interest be made the subject of special consideration.

I. SIMPLE AND SATISFACTORY METHODS FOR BLOOD INJECTION

Those who believe that blood constitutes a valuable remedy in the control of hemorrhage either advocate serum from the lower animals or tend to employ a needlessly elaborate technic when human subjects furnish the supply.

The use of serum from the lower animals is subject to some objection — it may not be available when most desired, anaphylactic reaction is always a possibility, there is some danger of tetanus, and when preserved there is a tendency to contamination as well as possible loss of efficiency because of age.

If human blood be used it is my belief that whole blood possesses the beneficial qualities common to serum or other derivatives and that it does not contain elements which are more likely to be harmful to the patient. This belief is upheld by clinical results.

The methods commonly employed in the preparation of human blood after withdrawal from the donor consist in allowing it to stand until the serum separates, or in centrifuging in case of urgency. The serum is then injected subcutaneously or intramuscularly. A more simple and regularly successful technic, and one which reduces danger of infection to a minimum, consists in injecting whole blood into the patient immediately on withdrawal from the donor. A 20-c.c. or larger ground-glass syringe is sterilized, preferably by the dry method, and the inner surface lubricated with sterile petrolatum. Blood is withdrawn in the usual manner from a cubital vein of the donor; the needle is then inserted beneath the subcutaneous tissues of the back of the patient and the blood injected. There is no need for haste. This procedure not only has the advantages of simplicity and promptness, but does away with likelihood of contamination during transfer of blood.

---

* From the Memorial Institute for Infectious Diseases.

In unusual instances, when much blood must be obtained at one time, it may be aspirated directly into a sterile bottle provided with a coil of wire, immediately defibrinated and kept in the ice-box until desired. This blood should be used within a moderate number of days and contamination must be guarded against.

II. TREATMENT OF HEMORRHAGE FROM THE UTERUS

Leaders in special departments of surgical work are prone to overlook the possibilities of blood therapy. For example, among the many publications recently devoted to the treatment of uterine hemorrhage, there is a general failure to mention the therapeutic value of blood or its derivatives.

Especially in those cases in which discovery or removal of the cause proves impossible, blood is a valuable aid. In many ways it takes precedence over radium and therapy with filtered Roentgen rays, for these are obtainable only in a limited number of large hospitals, and necessitate a considerable outlay of time and money. Moreover, they tend to produce atrophy of the ovaries and are not entirely devoid of danger.

That injected blood is at least worthy of trial is indicated by two cases which represent the results obtainable in patients with "idiopathic" hemorrhage.

Case 1.—A multipara, aged 30, had hemorrhages from the uterus for nine months. Examination was negative. Curettement checked the flow for two months, after which it recurred as previously. At the desire of the patient, supravaginal hysterectomy was performed in preference to blood injection. After three months began continuous bleeding from the cervical stump, associated for the first time with petechial hemorrhages of the lower extremities. Subcutaneous injection of 25 c.c. of whole blood, obtained from the husband, caused prompt cessation of bleeding. This treatment was twice repeated. Hemorrhages did not recur.

Case 2.—Patient, near the menopause, had flowed profusely for many months. Minor surgical measures of various sorts were unavailing. Five subcutaneous injections of blood resulted in cessation of flow. One year later bleeding recurred. Five injections of blood from the husband, given every second day in amounts varying from 10 to 20 c.c., resulted in permanent recovery.

III. BLOOD INJECTION VERSUS TRANSFUSION

It is believed that the transfusion of blood is often advised when less heroic measures would prove quite as satisfactory. Thus in *hemorrhage of the new-born,* when the patient is seen before life is in danger from exsanguination, blood injection is indicated. For the purpose of checking hemorrhage this is essentially as efficacious as transfusion; at least it has proved satisfactory in all except one of several cases so treated by me.

If anemia is profound more blood must be provided. This may be done by any one possessed of ordinary surgical ability. An extremely large (100-c.c.) ground-glass syringe lubricated with liquid petrolatum is employed. This is provided with either a large needle or a small cannula tip. After a 1-inch exposure of the child's external jugular or femoral vein, the syringe is filled and the blood injected into the vein of the patient in the direction of the heart.

In *other types of anemias, notably secondary anemia* consequent to prolonged bleeding, blood injection again has a wide field of usefulness. It is the procedure of choice when bleeding has not been permitted to reach the point of exsanguination.

Likewise in chronic wasting diseases and infections with grave outlook, in tuberculosis with unfavorable prognosis and in other conditions of like nature, the trial of repeated injections of blood merits consideration. Although unable to present an assortment of cases of this type sufficiently large to be convincing from a statistical point of view, I anticipate that the future will show much benefit from this form of therapy. Except in extreme cases in which red cells and hemoglobin have fallen to the point at which they are incapable of performing their necessary share of work, transfusion promises no more permanent aid than the repeated injection of small amounts of whole blood.

SUMMARY

1. Repeated subcutaneous injection of whole blood immediately on withdrawal from a healthy donor is a simple procedure of value in the treatment of hemorrhage.

2. In many cases of uterine hemorrhage this therapy obviates the need of operative interference or expensive and time-consuming Roentgen-ray treatment.

3. For persistent hemorrhage of moderate severity—for example, hemorrhage of the new-born—blood injection rivals transfusion in results achieved, and is the method of choice because it requires little technical skill. In infants with severe anemia, intravenous injection of blood by means of a 100-c.c. lubricated ground-glass syringe is a worthy substitute for a transfusion operation.

4. Hemotherapy for chronic anemias, wasting diseases and infections with grave outlook deserves serious consideration. It is not unlikely that the stimulating effect of repeated injections of blood offers more hope in this field than does the more difficult procedure of one or even two transfusions of large quantities of blood.

104 South Michigan Avenue.

Value of Whole-Time County Health Officer.—North Carolina was one of the first states to employ whole-time county health officers. A recent bulletin of the State Board of Health gives an indication of the value of the service rendered by such officers in improving health conditions and reducing the death-rate. In Robeson county, in which Dr. Boney W. Page, Lumberton, is the whole-time county health officer, the death-rate was reduced from 18 per thousand in 1912 to 12 per thousand in 1914. The reduction in the number of deaths from various diseases for 1914 as compared with 1912 was as follows: tuberculosis, 147 to 70; diarrheal diseases of infants, 90 to 65; typhoid fever, 33 to 9; small-pox, 16 to 1; diphtheria, 14 to 3; whooping-cough, 35 to 9; pneumonia, 130 to 85; total from all diseases, 907 to 730. This showing is made in the face of the fact that 55 per cent. of the population of the county consists of Indians and negroes, and that the death-rate of the negroes is over 40 per cent. higher than that of the white population, and also that the county lies in the malarial area. The death-rate from malaria has been reduced 75 per cent. in three years, and that of other preventable diseases 70 per cent. The saving in lives is said to represent a money value of $290,000.

DOUBLE DETACHMENT OF THE RETINA AS A SEQUENCE TO NEPHRITIS

LEONARD W. JONES, M.D.
ROCHESTER, N. Y.

Albuminuric retinitis as a complication of a nephritic lesion is not an unusual condition. While encountered in from 10 to 25 per cent. of all cases of contracted kidney, it is not seen so frequently in the parenchymatous form of nephritis, nor has it in the latter condition such an evil prognostic significance.

Detachment of the retina, as a result of serous effusion following a lesion of the kidney, is an exceedingly rare affection. The literature on the subject is very scanty and in conversation with local oculists of considerable experience I have been unable to elicit a history of one such case.

The infrequency of this condition is my reason for reporting the following case:

W. K., a telegraph operator, who had five years ago been treated for "kidney trouble" and was thought to have been cured, about the second week in February, 1914, noticed a blurring of vision. This rapidly increased and he found himself unable to read the manuscript of his work. This attack was accompanied by headache and vomiting. The physician whom he consulted diagnosed his condition as glomerular nephritis and an oculist to whom he was referred found albuminuric retinitis present in both eyes.

March 27, I visited him in consultation with his family physician. At that time the patient was confined to bed, being hardly able to sit up, and his vision was reduced to the perception of light and darkness. The examination of the eyes disclosed the following condition:

Right Eye: Vision reduced to perception of light; pupil dilated and did not respond to light. Rotation of the eye was normal. Beyond the dilated pupil there was no external evidence of an eye lesion.

Fundus: There was a grayish reflex instead of the usual pink retinal glow. The optic nerve was decidedly blurred, veins swollen and tortuous. At the region of the macula there was the characteristic appearance of albuminuric retinitis. Running in an inverted horseshoe fashion and beginning about two nerve-heads' width below the papilla was an elevated tumor giving a grayish-green reflex and seen best with a plus 12.00 lens behind the ophthalmoscope. (Optic Nerve seen with plus 1.00.) On top of this tumor were markedly tortuous small blood-vessels. Tension was normal, or if anything, very slightly elevated. The left eye was practically the same as the right. Three days later, I made a second examination. The area of detached retina now extended above as well as below the optic nerve, so that the only attachment of the retina was around the circumference of the papilla. The patient maintained that his vision was somewhat improved, although a test made did not tend to confirm his belief.

Transillumination showed a clear glow, eliminating the remote possibility of a solid tumor, as the cause of the detachment.

Urinalysis: Color, usually light amber, occasionally dark. The specific gravity was 1.002. The albumin ring was well marked. There was no sugar. The sediment was granular, and there were hyaline and epithelial casts, as well as kidney epithelium. The phenolsulphonephthalein test showed an excretion of 15 per cent. in two hours.

Systolic blood-pressure was 210.

There was no edema of ankles, swelling under the eyes, ascites or evidence of serous effusion elsewhere in the body. It may be of interest to note that one married sister had an attack of albuminuria with her last pregnancy. The patient died, April 23, 1914.

While the majority of the well-known text-books say nothing on nephritic conditions as a cause of detached retina, Roemer[1] mentions its possibility and Weeks[2] cites a case very similar to the one just reported.

Two articles by Leber[3] and Verderame[4] discuss this condition.

I am indebted to Drs. David Jewett, van der Beek and Frank Barber for their kind cooperation.

INTRA-URETHRAL BREAKAGE OF VACUUM ELECTRODE

THERON J. KINNEAR, M.D.
SPRINGFIELD, ILL.

The time of the physician is so encroached on nowadays by salesmen who are persistent as to the quality of their wares, that sometimes one is apt to be misled by their statements, and by so doing may cause some disastrous results. As many of these results are never known to any except the man who is unfortunate enough to attain them, it seems to me only just that if one has an untoward accident with a so-called harmless instrument he is only acting fairly in making mention of it, that others may avoid like consequences.

About a year ago a very persistent salesman succeeded in selling me a set of high-frequency vacuum electrodes. Among them was one for intra-urethral treatment. On examining it I remarked to the salesman that I believed it to be a dangerous instrument, since a breakage of the tube would leave a foreign body in a place very difficult to reach; but he assured me that no such thing had ever occurred. Nevertheless, on receipt of the instruments I was slow to make use of this particular one, and for several months it remained only an ornament in my instrument case. At last, however, a case presented itself in which I believed this particular modality might be utilized with benefit, and I proceeded to use the apparatus that I had feared so much at first. I administered a number of treatments with no unpleasant results, but one day while giving a treatment the tube snapped, my patient at once complained of excruciating pain and I realized that my forebodings had come true.

On attempting to remove the broken instrument I encountered much resistance, and it finally dawned on my mind that the vacuum had probably acted to draw the membranes of the urethra into the broken ends of the tube. I felt that I was in a very serious predicament, though not quite so serious as that of my patient. A liberal application of a local anesthetic somewhat relieved the pain that was occasioned by the indrawing of the mucous membranes by the action of the vacuum, and by a great deal of manipulation with a hollow instrument alongside the electrode I managed to admit some air into the outer portion of the electrode, after which it was easily removed.

It had broken about midway of the shaft of the instrument, and the broken end of the portion that remained was about 5 inches down the urethra. My experience with the action of the vacuum with the first portion of the tube led me to exercise a great deal of caution in attempting to remove the latter part that extended well down toward the bladder, and by the

4. Verderame: Klin. Monatsbl. f. Augenh., 1911, xlix, 452.

introduction of an endoscope and manipulation of the mucous membranes that had been drawn into the electrode I finally succeeded in releasing them and admitting air into this portion of the electrode also. After this a large endoscope was introduced in contact with the broken portion, which fortunately fitted inside the endoscope, and a finger introduced into the rectum propelled the glass fragment forward until brought into sight, when it was removed manually. A careful examination of the two fragments disclosed the fact that the break in the instrument had been a clean one and had left no small fragments in the urethra, for which I was very thankful.

The patient apparently seemed to have no particular after-pain or complications of any sort. I have watched the case carefully up to the present time and there is no evidence of stricture or any other organic trouble resulting from this unpleasant incident. But the patient was thereafter very suspicious of any intra-urethral applications, and, in fact, would have been very foolish had he been disposed to have any other attitude toward that line of treatment.

Needless to say, I have not replaced that broken instrument; but I shall keep it to remind me of the folly of taking another man's word against one's own honest convictions. The incident has given me a wholesome fear of using any but absolutely safe instruments in the body cavities.

AN INSTANCE OF PULMONARY SYPHILIS CLOSELY SIMULATING TUBERCULOSIS

GEORGE D. CULVER, M.D.
SAN FRANCISCO

Pulmonary syphilis is so infrequent as to be interesting for its rarity alone. There was added interest in this case because the patient had been treated for pulmonary tuberculosis for months before presenting himself to me on account of the cutaneous lesions, and the mimicry of pulmonary tuberculosis was so good as to condone the error. In fact, the patient afforded an excellent example of how valuable cutaneous and lingual lesions may be in furnishing hints as to the true nature of deeper lying affections.

History.—F. W., man, aged 37, sought advice, June 25, 1914. I had seen him nearly nine years before with an orchitis. He acquired his present infection sixteen years ago, in 1898. For seven months preceding June 25 he had had a persistent cough, especially marked in the morning and accompanied by profuse expectoration. There had also been several slight hemorrhages, and chilly sensations generally in the afternoon, followed by what the patient thought was fever. He had drenching night sweats, and always felt tired and weak on arising. There was marked loss of weight, though his appetite had continued fairly good. There were no gastro-intestinal symptoms aside from a tendency to constipation. Two careful examinations of the sputum for tubercle bacilli were negative. During the last year small gummas appeared on the body and legs, many of which ulcerated and healed, leaving characteristic syphilitic scars. There was one ulcer present on the right knee when he came in. The dorsum of the tongue was deeply fissured, and there were patches of sodden epithelium on the sides, and one small ulcer, making the whole lingual picture typically syphilitic. The voice was clear and there had not been huskiness at any time. Stripped, the patient looked emaciated. The skin was faded, muddy colored, markedly wrinkled and lacking in elasticity. There were sunken supraclavicular and infraclavicular spaces on both sides, and the scapulae were prominent. No distinct difference in the percussion note over the lungs could be detected. There was apparently an abnormally high pitched note over both upper lobes, and there was a distinct increase in the vocal fremitus and vocal resonance in these areas. It appeared as though there was an active tuberculous process in both the apices. Crepitant râles were heard anteriorly in the supraclavicular and infraclavicular regions, and posteriorly in the suprascapular and interscapular areas.

Treatment and Results.—The patient was given 0.45 gm. of neosalvarsan intravenously, and a week later he reported that after the third night his night sweats had disappeared, there was much less coughing, and he was feeling much better. The cough disappeared completely before the end of two weeks following the injection. Intramuscular injections of gray oil (mercurial oil) were begun, but, as it was necessary for him to leave the city, he was given mercury and potassium iodid by mouth, to be continued until he could return for another injection of neosalvarsan. When he did return, ten weeks later, all lesions on the tongue and external surface were healed; he was looking quite well; and all the symptoms and signs of tuberculosis were gone. He is still under treatment for syphilis.

It is difficult to specify definitely the pulmonary condition. The fact that the patient had small cutaneous gummas and a gummatous ulcer of the tongue, associated with the history of repeated hemorrhages, would lead one to believe that there must have been a miliary gummatous process with breaking down somewhere in the bronchi, or deeper, within one or both lungs. The presence of bronchovesicular breathing and râles in both apices would indicate that an infiltration in the mucous membranes, deeper within the lungs, had also occurred. The physical examination did not show evidence of a large gummatous tumor anywhere in the chest, nor were any cavities demonstrable. All the evidence would lead to the conclusion that the process was diffused in the upper parts of the lungs. It was impossible to rule out tuberculosis before treatment was begun, but negative examinations of a fairly profuse mucopurulent sputum combined with a definitely positive diagnosis of syphilis justified treating the positive disease with salvarsan and mercury, and relegating the treatment of a possible accompanying tuberculosis to a later time when the syphilis would be controlled.

I reasoned that if not all the symptoms were due to syphilis, and if the patient were fighting two diseases, one of which could be quickly subdued, he would have a better chance to fight the single disease, tuberculosis, than to fight both syphilis and tuberculosis together.

That all the signs and symptoms simulating tuberculosis should disappear soon after instituting syphilitic treatment is characteristic of syphilis as opposed to tuberculosis, which is slow in improving, even under the most favorable conditions.

A small dose, 0.45 gm., of neosalvarsan was given to avoid a Herxheimer reaction, which in this particular case might have resulted in a marked aggravation of the bronchial and alveolar symptoms. Apparently, the result was as good as could have been obtained from a maximum dose. In fact, it was a demonstration of the correctness of the idea that is now so widely accepted, that a dose of 0.45 gm. of neosalvarsan can achieve everything that a dose of 0.6 or 0.9 gm. can, and with much less danger of disagreeable or dangerous by-effects.

A history of infection is only a small factor in the differential diagnosis between pulmonary syphilis and pulmonary tuberculosis, and may not be of more importance than to put one on the right track for an investigation. Many sufferers with tuberculosis have had syphilis, and indeed the latter is often considered a factor predisposing to tuberculosis. A tuberculous family history is of great importance in the diagnosis of tuberculosis, but is not evidence against syphilis, and it might mislead the physician who has to deal with a case of pulmonary syphilis.

All writers on the subject of lung syphilis agree that the syndromes of pulmonary tuberculosis and pulmonary syphilis are so similar that a positive diagnosis of pulmonary syphilis alone is very difficult to make before the institution of treatment in the cases with recovery, or before necropsy in the fatal cases. The cough, which is one of the first symptoms, is not distinctive.

The sputum in syphilis, like the sputum of chronic bronchitis, may be of a mucopurulent character, or it may even contain elastic tissue, and may be tinged with blood. The inability to find tubercle bacilli after many searchings unfortunately does not exclude tuberculosis. Their presence clinches the diagnosis of tuberculosis, but does not rule out the possibility of syphilis existing with tuberculosis. Hemoptysis is less common in syphilis, and when it does occur, as in the case reported in this article, it is usually not severe.

Dyspnea may be as marked in syphilis as in pulmonary tuberculosis, and therefore is not of any assistance in a differential diagnosis. The temperature may run high, even as high as 106 F., for weeks, as in Roussel's case, or may be hectic.[1] It is more apt to be irregular, but may be entirely absent. Night sweats are not common in lung syphilis, but in the case which I have reported they were present and of a drenching character. Emaciation may be marked in both conditions, for syphilis of the lung is a progressive disease, as is tuberculosis, and in most instances is not discovered until late.

Investigators disagree as to whether or not the physical signs in the lungs can be interpreted with any definiteness in a supposed case of lung syphilis. The signs in the present case were those of tuberculosis, and I was at first under the impression that the patient had a double infection.

Quoting from Roussel,[1] who quotes Fowler, attention is drawn to these possible points of difference between lung syphilis and lung tuberculosis:

> First, tubercle usually affects the apex of the lung, subsequently the apex of the lower lobe. The lesion of syphilis is often about the root and central portion of the lung, and follows no definite line of march. Second, both tubercle and gumma may undergo either necrosis and caseation or fibrous transformation, but with caseous tubercle the tendency toward softening and cavity is the rule, whereas a caseous gumma rarely breaks down. Third, cavities are common in tuberculosis and rare in syphilis, excepting secondary to stenosis of the main bronchi. Fourth, stenosis of the trachea and main bronchi is common in the advanced stages of syphilis, rare in tuberculosis. Fifth, cavities in pulmonary syphilis are generally but not invariably bronchiectatic, and in tuberculosis they are due to destruction of the lung tissue. Sixth, the tendency to the formation of pulmonary aneurysms, which is so marked a feature in tuberculosis, is rarely observed in pulmonary syphilis. Seventh, pulmonary lesions in tuberculosis are very common, whereas in syphilis they are extremely rare.

There are certain positive helps which may aid greatly in the diagnosis. Positive evidence of syphilis, as demonstrated by a positive Wassermann test, or, as in the present case, by active syphilis elsewhere, is sufficient to warrant treating the patient immediately for syphilis. The excellent effect of salvarsan on the mucous membranes makes it our most valuable primary remedy. And this followed by mercury and iodids may produce a quick symptomatic cure.

In any case of chronic pulmonary disease with absence of tubercle bacilli and lacking the various reactions from tuberculin, but presenting symptoms or a history of syphilis, antiluetic treatment is justifiable even if only as a diagnostic measure.

As to the frequency or rareness of pulmonary syphilis of the acquired form as opposed to the congenital form, which is not uncommon, Stengel[2] suggests that the difference of opinion depends on the point of view of the observer, whether he is a clinician or a pathologist, the former believing the condition to be fairly common, the latter that it is very unusual.

Roussel mentions the following groups of cases: that of Carlier in 1882, consisting of 75, with 50 necropsies; that of Hiller in 1884, consisting of 87, 84 of these with necropsies (20 of which had been previously reported by Carlier); that of Connor, consisting of 129 cases of syphilitic stenosis of the bronchi, with reports of necropsies in 56, in 10 of which there were lesions believed to be characteristic of syphilis of the lungs; and lastly, that of Fowler, consisting of 12 specimens found in the museums of London hospitals and the Royal College of Surgeons, which illustrate syphilitic lesions of the lungs of the acquired type.

The number of necropsies in these groups is striking and indicates how malignant pulmonary syphilis is. The improved methods in diagnosis of syphilis, and the present effective mode of treatment by the combined arsenical and mercurial medication should make future statistics more complete with a smaller percentage of fatalities.

Accidents in the Coke Industry.—An investigation by the Bureau of Mines for the year 1913 covering 227 plants in the coke industry of the United States, employing 24,345 men, shows that 46 men were killed, 342 seriously injured and 2,172 slightly injured. This report covers practically one-half the operators and 80 per cent. of the ovens, and the figures are representative of the whole industry. Of the 46 deaths, 20, or 43 per cent., were due to accidents in connection with haulage or transportation systems; 6 were due to coke-drawing machines, representing 13 per cent., and 11 per cent. were due to electricity. As much of the transportation in the coke industry is electrical, a portion of this 11 per cent. of fatalities from electricity would also come under the head of transportation. Twenty-six per cent. of the serious accidents were also due to haulage systems, and 8 per cent. of slight injuries. As the report states, these accidents should be largely preventable and greater precautions should be taken to safeguard employees. In addition to the six fatalities due to the process of making coke, 23 per cent. of serious injuries were due to falls, 12 per cent. of slight injuries to falls, 14 per cent. to hand tools and 16 per cent. to burns. The accidents in this industry compare favorably with those in quarries and metal mine surface injuries.

III

A. STIMULANTS: 2. MEDULLARY—ATROPIN GROUP

Atropin is much the most important member of this group, which includes scopolamin and homatropin and the crude drugs, belladonna, hyoscyamus and stramonium, together with their preparations. The alkaloids of this group are commonly called the mydriatic alkaloids, because dilatation of the pupil is the most characteristic action which they possess in common. While they exhibit individual differences in their actions, they form a fairly well-defined group.

The action of atropin will be discussed in some detail, and the special uses of others will be mentioned, but in the main it is to be understood that the several drugs are used for the same purposes, with the exception of scopolamin. This drug occupies a special field of usefulness because of the fact that while it resembles the other members in a general way, its stimulant action on the central nervous system is so much less pronounced than theirs, while the depression it produces is so much more prominent, that it is used to produce depression, while atropin is used to cause stimulation. This illustrates the difficulty of classifying drugs satisfactorily.

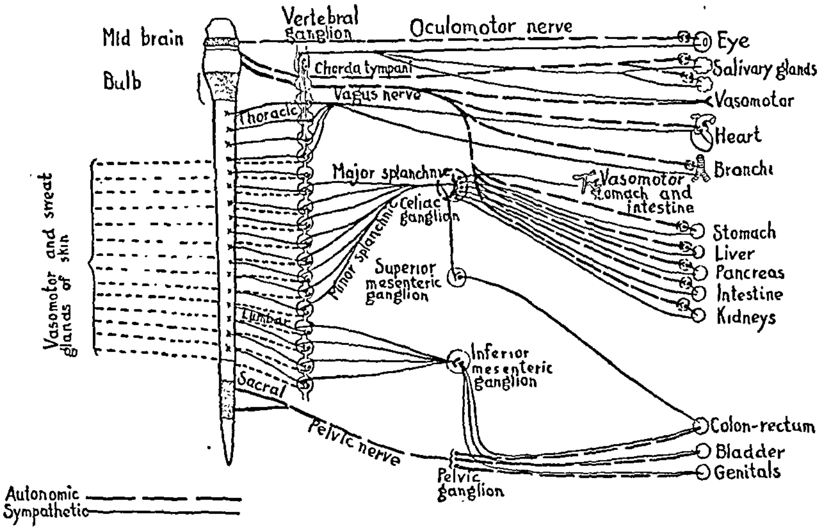

Diagram of the anatomic relations of the autonomic and sympathetic systems (from Meyer and Gottlieb, Experimentelle Pharmakologie, 1911, p. 128).

In practically all cases the actions of alkaloids are so nearly like those of their salts that they are discussed together. It is understood that the salts contain a small amount of acid, which is negligible so far as the pharmacologic actions of the alkaloids are concerned, but for which allowance must sometimes be made in calculating the dose. The principal reason for using salts of the alkaloids is that the salts are more soluble than the alkaloids themselves.

The chemical investigation of the drugs which yield the mydriatic alkaloids presents many difficulties, and some confusion has resulted from the application of the same name to different substances, and of different names to the same substance in slightly different degrees of purity. It is recognized at present that the substance first described as hyoscin was nothing but an impure form of the alkaloid which in pure form was first described correctly under the name of "scopolamin;" hence the two terms are purely synonymous, and only the name "scopolamin" should be used.

Therapeutic doses of atropin exert a greater action on the medulla than on the brain, but with toxic doses the effects on the cerebrum become more pronounced.

Atropin stimulates the respiratory center in the medulla, causing a marked increase in the amount of air breathed in a given period of time. Poisonous doses cause depression of the respiratory and other centers. This action on the respiratory center is of great importance, atropin being one of the most active of the respiratory stimulants which we have.

The vasomotor centers are stimulated by moderate doses of atropin, which cause a scarlet appearance of the face and upper part of the body, due to a dilatation of the vessels of those regions simultaneously with a constriction of the vessels of the splanchnic region. There may be merely a redness of the skin, or there may be a rash, followed by desquamation, but usually the rash disappears within a short time.

The vasoconstriction tends to raise the blood-pressure, but the effects of atropin on the circulation are complex and the height of the blood-pressure with small doses depends on the heart-rate rather than on any vasoconstriction.

The vagus center is stimulated somewhat with the respiratory and vasomotor centers, but this is soon overshadowed by the depression or paralysis of the vagus endings in the heart, which is one of the characteristic actions of all of the mydriatic alkaloids.

The vomiting center in the medulla is not stimulated with moderate amounts, and the action is not usually pronounced even with toxic doses, probably because of the simultaneous narcotic effect. Very small doses, 0.2 mg. ($\frac{1}{300}$ grain) tend to allay nausea.

The actions on the brain cannot be described in detail, and it need only be said that larger doses cause stimulation of certain areas, resulting in increased coordinated movements, talkativeness, excitement and delirium, followed by depression and coma. Atropin in moderate doses does not affect the psychic areas so much as caffein does. It is not used therapeutically for its actions on the brain.

Atropin depresses or paralyzes the endings of the parasympathetic[1] nerve throughout the body, including the oculomotor, chorda tympani, vagus and erigens, and also the sympathetic endings in the sweat-glands in the skin. It will be observed that the sympathetic endings in the sweat-glands behave toward several drugs like the parasympathetic endings (Fig. 1).

---

* This is the third of a series of articles on useful drugs—on practical pharmacology for the general practitioner. As soon as completed, these articles, elaborated by additional subjects, will be published in book form.

[1] Reference to Figure 1, *taken from* Myer and Gottlieb's Pharmacology, Ed. 2, will show the relationship between the sympathetic and parasympathetic nerves. Epinephrin stimulates the myoneural junctions of all of the sympathetic nerves (except those to the vessels and sweat-glands of the skin), while it leaves those of the parasympathetic unaffected. Atropin, on the other hand, paralyzes the endings of those nerves which epinephrin does not affect while it has no influence on those which epinephrin stimulates. *Many other* drugs show similar selective actions with reference to these nerves.

A discussion of the peripheral actions of atropin is largely a discussion of the *functions* of the parasympathetic nerves, for atropin simply abolishes those functions, but it acts on these endings in different parts of the body with varying degrees of intensity. Hence a given dose does not have the same relative effect on all organs which the nerves supply.

Atropin can be brought into contact with the oculomotor endings by dropping a solution into the eye, without inducing its systemic actions, but its actions on other parasympathetic endings cannot be elicited so conveniently.

Depression of the oculomotor endings causes dilatation of the pupil through the unopposed actions of the radiating fibers, and it also causes paralysis of the muscle of accommodation. These actions are prolonged after repeated applications, or after the use of strong solutions, and it may be a week or more before the eye becomes quite normal.

The action of homatropin on the pupil is qualitatively like that of atropin, but the effect is not so lasting. Homatropin is often preferred when an examination of the eye is to be made, but it is not so dependable as atropin, which many oculists continue to use even for the examination of the eye. Dilatation becomes maximal in a period usually varying from half an hour to an hour. Scopolamin acts as a mydriatic in the same way as atropin.

The actions of atropin on the pupil and on accommodation may be counteracted with physostigmin, but this renders the muscles of accommodation hyperexcitable, so that efforts at accommodation result in spasm of the muscles, and reading is attended with discomfort.

Paralysis of the chorda tympani endings interferes with the secretion of the salivary glands, rendering the mouth and throat dry, the voice hoarse, and swallowing difficult. The mucous glands in the nose and respiratory passages and the gastric, pancreatic and biliary secretions, and possibly the secretion of milk, are also inhibited by atropin. The action on the sympathetic endings in the sweat-glands causes the skin to become dry, these being the only sympathetic endings which behave toward a number of drugs like the parasympathetic.

The paralysis of the vagus endings in the heart causes the heart to beat more rapidly; in the stomach and intestine it overcomes the motor influence of the vagus.

The lower part of the colon, the rectum and the uterus are innervated by the erigens, the endings of which atropin paralyzes. The intestinal effects will be discussed in connection with the evacuants.

Depression of the vagus endings in the bronchi result in muscular relaxation, when the muscles are spasmodically contracted in asthma.

Atropin depresses the sensory endings in the skin with which it may be brought into contact in the form of an oleate, or of an ointment of belladonna extract.

Atropin and the other mydriatic alkaloids are absorbed promptly from the gastro-intestinal tract and from the subcutaneous tissues. Some absorption occurs even from the unbroken skin when suitable application is made; at least the drug may reach the sensory endings in sufficient amount to cause analgesia.

The mydriatic alkaloids are excreted in the urine for the greater part, and scopolamin is said to be excreted in human milk to a slight extent.

The fatal dose of atropin is supposed to be about 125 mg. (2 grains), but much smaller amounts give rise to unpleasant and even alarming symptoms of poisoning. These symptoms may be enumerated somewhat in the order of their occurrence with increasing doses as follows: Even the larger therapeutic doses induce redness, or rash of the skin, which results in desquamation; the skin, as well as the nose, mouth, throat and bronchi become dry; the voice becomes hoarse, swallowing difficult; the heart becomes rapid with rise of blood-pressure, and some motor unrest. Talkativeness, and dilatation of the pupils from systemic action occur only with very large doses; these symptoms may be succeeded by coma and respiratory failure ending in death, or there may be convulsions; nausea and vomiting are reported as common symptoms, and these must be of central origin. Small doses of atropin, however, prevent nausea when given with morphin, and even the largest doses of atropin do not cause vomiting after intravenous injections in dogs.

Poisoning by atropin may occur through the accidental taking of a solution intended for external use, or the use of strong solutions in the eye. Belladonna berries are attractive in appearance and are not infrequently eaten by children. Fortunately, they are indigestible and may result in vomiting before a fatal dose has been absorbed.

The symptoms of poisoning by atropin or one of the members of the group are usually so typical as to direct attention to the cause, but where the earlier symptoms are obscure, suspected poisoning may be confirmed by testing the urine for atropin. For this purpose a few drops of the urine are dropped into the eye of a cat; if atropin or any other of the mydriatic alkaloids is present the pupil will dilate widely within about half an hour. The test should be made within thirty-six hours after the poison has been swallowed.

In case of poisoning by the berries, or when one suspects that a poisonous dose of one of these alkaloids remains in the stomach, recourse should be had at once to the stomach-tube. Tannin or potassium permanganate may be added to the water used in washing the stomach, but the use of alkaloidal precipitants or of potassium permanganate does not obviate the necessity of emptying the stomach, for the precipitated alkaloid would be absorbed, though more slowly than the soluble salt, and one cannot be certain that the potassium permanganate has been brought into contact with all of the alkaloid. Excretion should be hastened through the use of diuretics, hot water and tea, and in urgent cases the intravenous injection of normal salt solution under suitable precautions would be justified.

Excessive doses of atropin or the other mydriatic alkaloids may prove fatal in a short time, but such amounts are seldom taken, and the physician is more frequently called on to treat the alarming symptoms which yield to treatment.

Pilocarpin stimulates the salivary and mucous glands, and relieves the dryness of the mouth and throat; morphin is useful only in the early stages of poisoning by atropin, not at all in scopolamin poisoning, in which it is directly contra-indicated.

If depression has already begun in atropin poisoning, or if the dose taken was sufficient to lead one to expect severe depression later, morphin is contra-indicated, or at most small doses should be used in the stage of excitement. Application of cold water or of the ice-bag to the head is useful during delirium. Respiratory failure demands artificial respiration, and in such cases vigorous means should be adopted to secure rapid elimination by intravenous injections of normal salt solution.

THERAPEUTIC USES

Atropin is useful as a respiratory stimulant in various conditions. It is often recommended in the treatment of morphin poisoning, but authorities differ widely in their views concerning the wisdom of this measure, and to a greater extent in regard to the dose which should be employed in any event. Atropin and morphin in small doses are antagonistic in their actions on the respiratory center, but they are synergistic in large doses, both causing depression. The difference in opinion results from the question whether atropin is capable of causing stimulation without subsequent depression, and if this be possible, the next question concerns the amount which can be given without causing severe depression.

It seems probable that moderate doses of atropin are useful in combating the action of a poisonous dose of morphin on the respiratory center, because there seems to be little danger of serious depression from such doses of atropin. The amount which can be given in such cases can hardly be stated in exact figures. If used for this purpose, it is best given in doses of about 1 mg. (1/60 grain). This is repeated every hour until three doses are given if each of the first two doses is followed by improvement in the respiration. This probably represents the maximum that can be given with safety, within a period of six hours. Caffein is safer than atropin and probably deserves the preference in all cases in which respiratory stimulation is required.

Atropin probably deserves to be used more frequently than it is in shock, because it is capable of increasing the heart-rate, when this is unduly slow, and this, with the action on the vasomotor centers, tends to increase the blood-pressure, and the stimulation of the respiratory center should further improve the condition. It would appear to be useful in respiratory and circulatory failure during anesthesia, for, according to Hewitt, cardiac failure during anesthesia is frequently secondary to interference with respiration.

Its use before the administration of chloroform will prevent the dangerous inhibition of the heart which sometimes occurs early in the course of the administration, before the heart is seriously injured by the direct action of the chloroform.

The therapeutic use of atropin as a mydriatic has been indicated in discussing its action on the pupil. It appears to be more certain than homatropin in causing complete paralysis of accommodation, but the latter is preferable as a mydriatic when there is reason to fear glaucoma, because it does not increase the intra-ocular tension so much as atropin. The prolonged action of atropin is preferred in iritis to prevent adhesions and to break up those already formed.

Excessive salivation, sweating from various causes, such as the use of large doses of the antipyretics, and the night sweats of phthisis may be controlled by very small doses of atropin. The application of ointment of atropin or belladonna does not appear to relieve local sweating. Its continued local application to the breast diminishes the flow of milk.

Atropin is used to increase the heart-rate, especially where this is abnormally slow (bradycardia) owing to overactivity of the vagus, but it has much less influence on the rate when this is due to cardiac disease, and when slow rhythm is due to heart-block atropin will not influence the rate. Certain forms of cardiac irregularities due to vagus control are abolished by atropin. Its action on the vagus is much less effective at the extremes of life because the vagus itself has less control over the heart-rate in the young and the aged than during the remainder of life.

Bronchial asthma resulting from spasm of the muscles is often relieved by atropin or one of the crude drugs of this group.

Atropin abolishes spasmodic contraction of the pylorus, and is useful in the treatment of lead colic in which spasm of the muscles of the intestine occurs, and in the same way it is useful in spasm of the muscles of the ureter and of the bile-ducts due to the irritation of calculi.

Atropin is useful in relieving certain neuralgias for which it is commonly applied locally.

Belladonna is used in whooping-cough, in which Cushny suggests that it may allay the excitability of the respiratory center.

Atropin is the physiologic antagonist of those poisons which exert their actions through stimulation of the parasympathetic (vagus, oculomotor, chorda, erigens) nerves, such as [illegible]arpin and muscarin, but it is not [illegible] in detail its actions in antagonizing these poisons. It has been found that animals survive a larger dose of aconitin if atropin be administered than without it. The cardiac effect of aconitin is attributable to vagus influence in part.

Drugs of the atropin group have long enjoyed a special reputation in the treatment of nocturnal enuresis in children, but there is no doubt that they have been used with little discrimination in many cases. Unfortunately, the causes of this condition are not sufficiently understood to enable one to say just when atropin will be useful. Under the circumstances it may be tried when hygienic measures have proved unavailing, but it should not be employed for any considerable period when it does not prove unmistakably useful.

There is no reason to suppose that all cases of nocturnal enuresis arise from the same cause, or that they can be relieved by the same treatment; but it is probable that when it results from an abnormally active reflex operating through the parasympathetic nerve to the bladder, atropin, or one of the other members of the group, may afford relief.

Occasional wetting of the bed by children probably results in some cases from delayed absorption of fluids from the alimentary canal and increased secretion of urine at such time as the sweat-glands of the skin are less active than usual. Atropin would probably aggravate the trouble in such cases.

The recommendation of drugs with such diverse actions as ergot, cantharides, buchu, rhus aromatica, strychnin and arsenic by a prominent writer serves to indicate the vagueness of our knowledge of this condition.

Hyoscyamus is sometimes preferred, probably acting better than belladonna in those cases in which nervousness plays an important rôle.

If belladonna or other drug of this group is used it is preferable to employ fairly large doses at once and abandon it if it does not afford prompt relief.

Hyoscyamus is generally reputed to be more useful than belladonna and stramonium as a sedative to the nervous system; stramonium is little used except as an ingredient of asthma powders, used for smoking.

Scopolamin hydrobromid has a special field of usefulness in quieting the excitement of the insane and producing sleep. It is more effective when given at night than during the day.

Some ophthalmologists prefer it to atropin as a mydriatic, because it is said to be less irritating and to produce a brief but complete dilatation of the pupil with paralysis of accommodation.

Its use with morphin in producing narcosis will be discussed after morphin has been considered.

Extract of belladonna is sometimes applied to the skin in the form of an ointment for the relief of neuralgic pain and for acute inflammatory conditions; the commercial belladonna plaster is widely used by the laity, but it is doubtful whether the belladonna contributes anything to the effect.

It is probable that all of the crude drugs and galenical preparations of this group are superfluous, and that with a better knowledge of the actions of atropin and scopolamin these alkaloids will replace the crude drugs and their galenical preparations as completely as quinin has displaced cinchona and its galenicals.

DOSAGE

The average dose of atropin sulphate is stated to be 0.4 mg. (1/150 grain), but there are many conditions for which this dose would be insufficient and others for which it would be too large.

The dose should be carefully graduated for the specific purpose for which the drug is intended, as one can then accomplish the desired effect with a minimum of side actions.

The smallest therapeutic doses of atropin commonly used are probably those which are added to the laxatives. The official compound laxative pill contains 8 mg. (1/8 grain) of extract of belladonna, or approximately 1/10 mg. (1/650 grain) of atropin. The largest doses commonly used internally are employed for relieving spasm of the intestinal muscle, in which case as much as 3 mg. (1/20 grain) may be needed.

To lessen sweating the dose is 1/4 mg. (1/250 grain); to paralyze the vagus endings in the heart, 1 mg. (1/60 grain); to antagonize morphin poisoning, 1 to 3 mg. (1/60 to 1/20 grain); but, as previously stated, there is considerable diversity of opinion concerning the advisability of the larger dose given here; to antagonize other poisons, such as aconite, pilocarpin, and other drugs which stimulate the autonomic nerves, the dose required will depend on the action elicited by the poison; since aconite stimulates the vagus, this should be paralyzed by atropin, and about 1 to 1.5 mg. (1/60 to 1/40 grain) should be used. Pilocarpin induces excessive secretion of the bronchial and salivary glands, the excessive bronchial secretion constituting a danger with overdoses of pilocarpin, and to antagonize this, 0.5 mg. (1/125 grain) atropin should be used.

Atropin is more effective in antagonizing pilocarpin than is pilocarpin in antagonizing atropin. Some persons appear to be remarkably susceptible to the action of atropin in inducing skin rashes. Dryness of the throat is commonly induced by doses of 1 mg. (1/60 grain) or over.

A dose of 0.2 mg. (1/300 grain) is said to stop the vomiting which small doses of morphin cause in susceptible persons.

Asthma resulting from spasm of the bronchial muscle, whatever the exciting cause, may be relieved by atropin in doses of 0.25 to 0.5 mg. (1/250 to 1/125 grain), repeated several times daily if necessary.

Belladonna and other members of the group are used in the form of cigarets for the relief of asthma. It is stated that the smoke of 4 gm. (60 grains) of stramonium in the form of a cigaret contains 0.4 mg. (1/150 grain) atropin.

Children bear atropin fairly well, and relatively large doses are frequently recommended in the treatment of whooping-cough, and such large doses are required if the depression of the respiratory center is the object to be attained.

As little as 1 drop of a 1:1,000 solution of atropin dropped into the eye will cause dilatation of the pupil, but stronger solutions are required to paralyze the muscles of accommodation, and 1 per cent. solutions are commonly employed for this purpose.

The average dose of scopolamin hydrobromid is 0.5 mg. (1/125 grain); much larger doses are sometimes required for quieting the insane, but even here caution must be shown for it may cause depression of respiration and a rapid fall in the blood-pressure, resulting in collapse.

For use as a mydriatic alone solutions of from 1:500 to 1:1,000 suffice, but where paralysis of accommodation is required, somewhat stronger solutions are necessary (from 1:100 to 1:250).

The average doses of the galenical preparations of the drugs of this group will be given in the discussion of the materia medica.

MATERIA MEDICA *

English authorities advise doses of the drugs of this group which we are accustomed to consider enormous; for example, Leonard Guthrie states that in the treatment of habitual nocturnal enuresis tincture of belladonna should be pushed to full doses, that is, to from 10 to 40 minims for a child of 10 to 12 years. The British tincture of belladonna is required to contain from 0.048 to 0.052 per cent. of alkaloid, or about 50 per cent. more than is required by the U. S. P.

Such doses may prove beneficial in cases of habitual nocturnal enuresis when the treatment in vogue in this country would fail, but such heroic treatment will certainly result in dryness of the throat, rashes and other disagreeable side actions and should not be used except in persistent cases when milder treatment has failed.

One will find formulas prescribing the drugs of this group in text-books which do not take into account the fact that the alkaloids of this group are prone to undergo changes and that we cannot foretell what changes will take place when one of the galenical preparations is mixed with alkaline salts and allowed to stand. A prescription of this nature

---

* Owing to lack of space the materia medica of atropin, scopolamin, homatropin, belladonna, hyoscyamus and stramonium has been largely omitted. It will be included when this series is published in book form.

found in a standard work on therapeutics includes tincture of belladonna, potassium iodid, ammonium carbonate, potassium bicarbonate, camphor water and water.

Any tincture of this group is prescribed preferably alone except that it should be diluted (and flavored, if desired) so that the dose may be measured conveniently. The following illustrates the method of prescribing tincture of belladonna:

	c.c.	
℞ Tincturae belladonnae.......	4	fl ʒi
Syrupi aurantii.............	15	fl ʒiv
Elixiris aromatici....q. s. ad	30	fl ℥i

M. Dose: a teaspoonful.

The smoke of burning belladonna and stramonium leaves has been widely used by inhalation for the relief of asthma. The leaves are ground or granulated in order to prevent their burning with a flame, and a little potassium nitrate is commonly added to secure more uniform combustion. The mixture is burned on a plate, smoked in a clean pipe, or used in the form of cigarets.

W. J. Hadley advised the use of a mixture of equal parts of belladonna, hyoscyamus, and stramonium leaves and potassium nitrate as a fumigation, but there is no advantage in using a mixture of drugs containing such similar constituents, and any one of the leaves may be used with the addition of from one-eighth to one-fourth its weight of potassium nitrate. Half a teaspoonful of the mixture is used at each fumigation.

Therapeutics

PREVENTION IS GREATER THAN CURE

(Continued from page 247)

XVI

INFLUENZA: GRIP

Since the last epidemic of this disease in the United States in the winter of 1889 and 1890, there has been no year without the disease occurring in many parts of the country. In some regions it is present for months, sometimes occurring in small epidemics, at other times in isolated instances. Were the air-passage secretions to be examined in every case of cold and bronchitis, the influenza bacillus of Pfeiffer, discovered by him in 1892, would frequently be found.

While the well-known acute epidemic types of this disease probably always show this bacillus, it is not always discovered in instances that seem similar and are well termed grip or influenza, as distinct from an ordinary cold or bronchitis. Whether another distinct germ causes an inflammation of the air passages simulating influenza (that is, a closely related germ), or whether it is the same germ that has become so attenuated and changed that it is not recognized, has not been determined. To all intents and purposes, clinically and practically, these isolated cases without the true Pfeiffer bacillus should be considered as serious as though that germ were present and should be treated the same, as all of these cases seem readily to develop pneumonic conditions.

The toxin produced or elaborated by the influenza bacillus seems to be a vasomotor depressant, and perhaps acts through the sympathetic system. The small blood-vessels all over the body seem to dilate and produce capillary congestion, especially of the mucous membranes, the most frequent result being a coryza, a pharyngitis, a laryngitis or a tracheitis. The congestion in the larynx causes the harsh, dry, metallic cough which is quite characteristic of this type of influenza. The congestion and swelling of the mucous membrane of the trachea causes a peculiar oppressed feeling, with more or less pain, referred to the upper part of the sternum. The great amount of sneezing which occurs with a typical attack, almost similar to hay-fever, is due to congestion of the mucous membrane of the nostrils. The conjunctivae may also be injected, causing pain in the eyeballs and often a serous conjunctivitis, another typical symptom of influenza. In some seasons there seems to be a special tendency to middle-ear inflammations. At other times there frequently occurs a congested drum, with sometimes a hemorrhagic bleb or vesicle on the drum, a very painful though easily remedied condition.

The almost constantly present lumbar backache at the onset of this disease is probably due to congestion of the kidneys, and albumin is frequently found in the urine of such patients, and occasionally blood-corpuscles. A menorrhagia or a metrorrhagia may occur from the same tendency to dilatation of the blood-vessels. There may even be nosebleed, and occasionally a slight hemoptysis without any other assignable cause and without any subsequent development of tuberculosis or any other disease. With this disease, although the fever may be high, the skin is likely to be moist, and there may be profuse perspiration. The pulse may be slower than we normally expect from the height of the fever, and the blood-pressure is generally lowered; all of these conditions are due to the tendency of the blood-vessels to dilate. This dilatation of the vessels on the surface of the body, with the increased radiation and evaporation, causes the beginning high temperature of typical influenza to be short-lived, although for some days the temperature may rise regularly every afternoon and evening to a gradually decreasing degree.

The heart is generally weak from start to finish in this disease, and even collapse turns can occur. Also, during the first year of the last epidemic many persons were shocked by the disease and collapsed, having no fever and showing no symptoms except a weakened heart and circulation. This is the typical nervous type of the disease. The disease may also cause cerebral symptoms without many catarrhal symptoms, and sleeplessness, irritability and headache are very constant symptoms in all forms of grip; even meningitis can occur from this germ.

Rather an infrequent type of the disease is the bowel type; this can occur without respiratory catarrhal symptoms. Patients so affected have diarrhea, with more or less intestinal irritation, apparently the greatest amount of dilatation of blood-vessels in these cases occurring in the mucous membrane of the intestinal tract. These various types, the catarrhal, the nervous and the abdominal, may be interwoven, and a patient may show symptoms of all three.

The future of every case of influenza is prostration, nervous and muscular debility, with more or less circulatory weakness; in other words, there is exhaustion. The patient's resisting power is reduced, and any defect or diseased condition that he may have is aggravated by an intoxication with this germ.

If no complications occur, the convalescent patient should rest as much as possible, should not be subjected to exposure and should be given tonics, and, if necessary to cause restful sleep, for a short period at least, some hypnotic or some physical method of causing sleep. The most frequent complication is pneumonia, and the type of pneumonia that the influenza germ seems to cause most frequently is the lobular or bronchial pneumonic type; pneumonic congested areas may be found in different parts of one or both lungs. Not infrequently, however, true lobar pneumonia occurs.

The next most frequent complication, as suggested above, is middle-ear catarrh. The various sinuses in the region of the nostrils may become affected; all types of indigestion may occur, and not only sleeplessness and meningismus, but also a very serious meningitis, and even insanity can be caused by these germs and their toxins. Mental depression is a common occurrence, following severe attacks of grip. Pericarditis and endocarditis occur as complications of influenza.

It is thus seen that this disease should always be taken seriously, and every possible means used to prevent contagion, as it is one of the most highly contagious diseases. It spreads with great rapidity, but only by contact, although it may doubtless be transmitted by infected clothing, and perhaps even by letters, as when the last epidemic first reached America, the first persons affected in many cities were post-office clerks.

While no season is exempt from this disease, it occurs most frequently in colder weather, and in the colder climates, and in moist climates. Perhaps the more sunshine, the less frequent the disease. While one attack may protect a person for that season, he seems more susceptible to subsequent attacks in following years. There are doubtless many carriers of this disease who may have a persistent and continued subacute or chronic catarrhal infection and very likely are distributers of the disease to others. When one case occurs in a household, other members of the family become readily infected. The same is true in schools and in stores or buildings in which an infected person is closely associated with others. Many an office with one employee affected will soon, on investigation, show every other employee to be more or less seriously affected. While almost all persons are susceptible to this disease, a few seem to be immune. It is the most frequent of all definite infectious diseases.

Treatment

It having been determined or suspected that a patient has influenza, it is much more important that he remain in bed, or at least in the house, than if he has an ordinary acute cold. Also, it is more essential that he be more or less isolated or that measures be taken that he does not spread the disease by spraying from coughing or sneezing, and that he does not use the same towels, napkins, drinking-cups and eating utensils as other members of his family. The patient should be prohibited from fondling and kissing children. If the patient is a young child in close contact with the mother or nurse, all possible precautions to prevent contagion should be taken.

In a word, each family should be taught that grip is an infection, that it is contagious, that it spreads rapidly, that it may have serious complications and that it frequently leads to pneumonia, which has become in many regions of this country the most frequent cause of death. Therefore, even an apparently mild case of grip or influenza should be treated actively and energetically. As previously stated, whether a schoolchild begins with an acute cold or an influenza, he should be sent home and remain there until he is well, or at least almost well.

As a grip patient is liable to have a chill, or at least feel chilly or have cold sensations up and down the back, anything that makes him warm improves his condition. He may be given hot malted milk, hot tea or hot lemonade, at more or less frequent intervals, until his chilliness has ceased. The patient may be given a hot tub bath and then put into a warm bed in a warm room as an efficient means of making him comfortable and relieving his internal congestions. Hot water bags at the feet and extra coverings to the bed are often needed. A quickly acting stimulant is aromatic spirits of ammonia, given in half teaspoonful doses in hot water or hot lemonade, at intervals of three hours, for three or four times. The various methods suggested for aborting an acute cold may be used in this disease. Much greater care must be exercised, however, if the patient has the influenzal infection than if he has a simple cold, as to when he can return to his work or occupation, or be subjected to exposure to cold or dust, either in a house, building or outdoors.

As soon as the patient feels warm, the temperature may rise quite high, associated with severe headache, backache and irregular pains in other parts of the body. At this time a drug such as acetanilid, antipyrin, acetphenetidinum, or acetylsalicylic acid will be of benefit, provided that the patient is not ambulatory, and that he is not to be subjected to exposure. With this depressing infection such treatment is not wise unless a patient is in bed, or at least remains in the house.

The proper dosage of these drugs has already been suggested, and no one of them should be long continued. The most depressant is undoubtedly acetanilid, and perhaps the least depressant is acetphenetidinum. Should depression occur after one of these drugs has been administered or from the disease, circulatory stimulants such as aromatic ammonia, camphor or caffein should be given and the patient surrounded with dry heat. A hypodermatic injection of strychnin sulphate, 1/30 grain, may be given to stimulate the nerve centers. Cyanosis has not infrequently been caused by acetanilid, but an amount of this drug large enough to cause such a condition should never be given. The following prescription may be suggested:

		Gm.	
℞	Acetanilidi	0|50	gr. viiss
	Sodii bicarbonatis	1|0	gr. xv

M. et fac chartulas 10.

Sig.: One powder, with water, every two hours, except when the patient is sleeping.

Or:

		Gm.	
℞	Acetphenetidini	1|50	
	Phenylis salicylatis	1|50	āā gr. xxv

M. et fac chartulas 5.

Sig.: One powder every three hours.

It should be remembered, as previously noted, that it has been shown that an alkali like sodium bicarbonate inhibits the undesired action of coal-tar drugs on the heart; also, that caffein does not protect a heart from undesirable activities of the coal-tar drugs; in fact, it has been shown to intensify such activity.

In making a diagnosis of the infection present it is well to remember that any of these drugs, and also salicylic acid in any form, may cause eruptions on the skin, either erythematous or urticarial.

But little food is needed during the first twenty-four hours of grip, and it should not be pushed even on the second day, if food is repugnant to the patient. He should have plenty of water and such simple liquid nourishment as he desires. As soon as the appetite returns, food should be pushed. The various catarrhal conditions should be treated as suggested under coryza, pharyngitis and bronchitis. Also, while the patient is kept warm, he should have good fresh air in his room. This is essential with all infections, and especially with infections of the nose, throat and lungs. The bowels should be treated as indications call for. Simple laxatives may be given, if needed, or the soothing bismuth subcarbonate, if there is intestinal inflammation. Phenyl salicylate (salol) may be given, if there is much fermentation in the bowels, or the Bulgarian form of lactic acid bacilli may be given for a few days.

As soon as the patient begins to convalesce, he should be given tonics, and if there is no inflammation in the ears, quinin is valuable. Some form of iron should generally be given, and possibly a bitter tonic before meals. If the patient is not nervous, a small dose of strychnin three times a day is good treatment. On the other hand, it should be urged that strychnin stimulation is overdone, and a patient who cannot sleep should not be given strychnin or quinin later than the noon meal. Sometimes the sleeplessness following influenza is benefited by the administration of one-half to one teaspoonful of good fluidextract of ergot, taken an hour before bedtime. These patients should never be allowed tea or coffee after the noon meal, as they are very susceptible to cerebral stimulation by caffein and are likely to remain awake for hours from such stimulation. All disturbances or diseased conditions left over by grip must be treated energetically, else they tend to be prolonged. There are few germs that seem to be so tenacious and persistent, at least in their unpleasant results, as is the influenza bacillus. All persons are susceptible to serious consequences from influenza.

A schoolchild's desk, pencils, etc., and immediate surroundings should be thoroughly cleaned after the child has been sent home with an acute cold of any kind. This is especially necessary in cases of influenzal infection.

(To be continued)

Antituberculosis Expenditures in 1914.—On the authority of the National Association for the Study and Prevention of Tuberculosis it is asserted that $20,500,000 were spent in 1914 in the campaign against tuberculosis. Of this, 68.8 per cent. came from municipal, county and state or federal sources, which is said to indicate a most gratifying "shifting of the burden of institutional care of the consumptive from the private purse to the general public purse where it rightfully belongs." Five years ago the proportion contributed from the public sources named was only 53 per cent. The states leading in the amounts contributed were New York with $3,200,000; Illinois, $1,700,000; Pennsylvania, $1,600,000; Massachusetts, $1,200,000, and Colorado with $96,500. This is exclusive of contributions from private sources.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

LUETIN.—Luetin is an extract of the killed cultures of several strains of the *Treponema pallidum*, the causative agent of syphilis.

Actions and Uses.—When injected into the skin, luetin provokes no reaction in normal individuals except a very small erythematous area at and around the point of injection. In certain cases of syphilitic infection, a reaction occurs consisting of papules which may become pustules. When the reaction takes the papular form, a large reddish indurated papule (usually from 7 to 10 mm. in diameter) makes its appearance in twenty-four to forty-eight hours and slowly increases for four or five days, after which the inflammatory process begins to recede. The color of the papule gradually becomes dark bluish red. The induration disappears within two weeks, as a rule.

In the pustular form, after the fourth or fifth day, the inflammatory process increases in intensity and the papules become vesicular and later purulent. The pustules rupture spontaneously and the defect caused by the escape of the pustular content becomes quickly covered by a crust that falls off within a few days. A small induration sometimes remains for a few weeks or often months, leaving a small keloid after healing.

In the torpid type of syphilis the site of injection fades to an almost invisible point within three to four days, so that it may be erroneously considered a negative reaction. After ten days, or even longer, the spot suddenly begins to enlarge and goes through the same stages as seen in the pustular type.

Luetin is employed for the diagnosis of syphilis. It is of use in the examination of tertiary cases but rarely gives a positive reaction in the primary cases or in untreated secondary cases. In patients who are under treatment by mercury or salvarsan, the reaction is frequently positive even in cases which fail to give a positive Wassermann reaction.

Dosage.—The amount of luetin to be injected for one test is 0.07 Cc. The material should be properly diluted and injected into, but not under, the skin. A site should be selected on the skin in the upper arm, cleansed and sterilized and the injection made as described.

Pure cultures of several strains of the pallidum are allowed to grow for periods of six, twelve, twenty-four, and fifty days at 37 C. under anaerobic conditions. One set is cultivated in ascitic fluid containing a piece of sterile placenta, and the other in ascitic fluid agar also containing placenta. The lower portion of each solid culture in which a dense growth has occurred is cut out and the tissue removed. The agar columns which contain innumerable spirochetes are then carefully ground in a sterile mortar. The resulting thick paste is gradually diluted by adding, little by little, the fluid culture which also contains an enormous mass of the pure organisms. The dilution is continued until the emulsion becomes perfectly liquid. The preparation is next heated to 60 C. for thirty minutes in a water-bath, and then 0.5 per cent. trikresol is added. When examined under the dark field microscope, numerous dead pallida per field may be seen. Cultures made from this suspension remain sterile, and with them no infection can be produced in the testicles of rabbits. The suspension is kept in a refrigerator when not in use.

Non-Proprietary Preparation:

Luetin, Mulford.—This is supplied in a glass capillary tube provided with a special needle for the intradermal test containing sufficient for a single test, and also in packages containing sufficient for five tests, and in hospital size packages sufficient for fifty tests.

Manufactured by H. K. Mulford Co., Philadelphia.

GLYCOTAURO (See N. N. R., 1914, p. 52).

The following dosage form has been accepted:

Glycotauro Capsules, (half size).—Each capsule contains glycotauro 0.15 Gm. (2½ grains).

THE NEWER EXPERIMENTAL MEDICINE EXEMPLIFIED IN THE STUDY OF NEPHRITIS

It is one of the merits of the modern experimental medicine, which has departed from exclusive attendance at the bedside in order to enter the laboratories of the physiologist, physiologic chemist, pathologist, and pharmacologist, that it is rapidly learning to imitate human disease for purposes of study. A glance at the journals of scientific medicine of the present era discloses not merely the conventional recitals of clinical statistics, of case histories and necropsy reports, but also a newer type of contributions which are concerned with the effects of definite lesions induced according to a preconceived plan, or of pathologic states of organs or perverted metabolic processes initiated at will. Experimental injuries to the pancreas in animals have made possible the imitation of many features of human diabetes; operative interference with the organs within the cranial cavity has furnished a long-desired opportunity to study hitherto obscure diseases involving the pituitary gland and the cerebrospinal system; surgical obstruction of the gastro-enteric tract has duplicated the conditions of intestinal stagnation and so-called alimentary toxemia so as to reproduce symptoms of unexplained origin; intoxications with various drugs have furnished illustrations of disturbed nutrition associated both with upsets of chemical processes in the body and with the consequences of induced degenerative changes in important organs. The catalogue of these and numerous other instances of the distinctly modern method of approaching the problems of the damaged organism becomes the more impressive as one contemplates how recent such researches really are. Lee[1] has reminded us that it is scarcely more than half a century since the demonstrative teaching of Dalton, who came to the College of Physicians and Surgeons at New York in 1854, fresh from the inspiring laboratory of Claude Bernard, created much enthusiasm and inaugurated a new era for American students of medicine.

A recent American experimental contribution[2] to the understanding of nephritis, illustrative of the best type of investigation now being approached in many parts of the world by the newer paths of research medicine, may serve as an illustration of the fruitful results of the modern movement. The nature of the involvement of the kidneys and the rest of the organism in human nephritis has until lately remained nothing less than inexplicable, because with albuminuria as a constant and ever present symptom, the other factors of kidney function may be found to vary in every direction from that of hyperactivity on the one hand to that of extreme inefficiency on the other. With retention of all urinary waste products at one time, with unlike and unequal elimination of different excretory substances under other conditions, with evidence of involvement of organs other than the kidneys in still different circumstances, yet with all of these phenomena accompanied by certain similar clinical manifestations of nephritis, confusion has long reigned supreme.

Gradually, however, it has become possible experimentally to locate or reproduce any single factor at a time out of this bewildering complex of confusion. Experimental pathology has enabled us to localize a renal damage chiefly in the glomeruli or in the tubules, for example. Intoxication with salts of uranium, as is now well known, leads to the development of nephritic conditions. Uranium nephritis is generally classified as of the tubular type; but although the anatomic study of the kidneys usually does not demonstrate any pronounced involvement of the glomeruli, there is other evidence available of the existence of functional changes in the vascular glomerular apparatus which may pronouncedly modify the activity of the kidney. Mosenthal[2] has now demonstrated that it is possible to obtain illustrations of either nitrogen retention, increased nitrogen excretion, or any grade of variation between these extreme effects of the nephritis induced by uranium. Here we have the same ranges that may prevail in human cases.

With large doses of uranium, the nitrogen of the urine becomes diminished and is consequently retained. The quantity of urine may still be large, so that the retention of any urinary constituent cannot be charged to oliguria or anuria. Evidently a kidney insufficiency —an impaired power to eliminate nitrogenous compounds—is responsible for their retention in such cases. With smaller doses of the same poison the story is entirely different. Attending a distinct nephritis, as evidenced by the degree of albuminuria, there may be an unduly increased excretion of water, nitrogen, and sodium chlorid. Simultaneously sugar is present in the urine.

[2] Mosenthal, H. O.: Nitrogen Metabolism and the Significance of the Non-Protein Nitrogen of the Blood in Experimental Uranium Nephritis, Arch. Int. Med., December, 1914, p. 844. The literature on the subject is referred to.

How are we to explain these apparently contradictory phenomena? The diminished excretion is doubtless due to kidney insufficiency; the increased elimination, on the other hand, is due not to any previous retention, which has sometimes been maintained, but to an actually augmented protein destruction. Dosage, that is, the severity of the intoxication, determines the nature of the involvement. The situation is summarized by Mosenthal as follows: The laws governing the elimination of nitrogen in the urine in nephritis are not haphazard or "bizarre," but, such other factors as food intake, normal stools, etc., being constant, depend largely on three conditions: the degree of protein catabolism, the chemical combination in which the nonprotein nitrogen exists in the blood, and the permeability of the kidney.

The investigation of the feces, and particularly of the succus entericus, in some of these well-defined types of nephritis with retention, serves to dispel a widespread belief. The intestines do not supplement the functions of the kidney through vicarious excretion, simply because there is an abnormally large quantity of nitrogen to be eliminated. Each function largely follows its own laws independent, as far as possible, of its neighbor. Even when the urinary excretion is seemingly adequate, the causes of some of the symptom-complexes such as uremia may, according to Mosenthal's belief, lie in the many intermediary cycles of metabolism. In other words, nephritis may become something more than a purely renal or circulatory affair; and Mosenthal adds that human nephritis presents such a many-sided picture that it seems probable that many of the facts worked out for experimental uranium nephritis are applicable to it. The only claim that can be made for them at present, however, is that they be considered as suggestions on which to base further observations.

The frequently reported increase of non-protein nitrogen of the blood in nephritis—another bit of suggestive information acquired as the result of the newer experimental medicine—need not be due, as is so commonly believed, to the retention by an insufficient kidney. Mosenthal reminds us that we must consider further the possibility of inspissation of the blood, due to loss of water; increase of protein catabolism; and the chemical combination in which non-protein nitrogen exists in the blood. Heretofore, general attention has been paid only to the first of these.

In singling out an excellent research conducted under the auspices of the Edward N. Gibbs Prize Fund of the New York Academy of Medicine, we are not unmindful of the comparable studies in the same field of investigation reported in recent months by other workers, notably in American laboratories. Our emphasis is placed rather on an illustration of the promise of progress represented in the newer modes of attacking clinical problems.

GRADUATE MEDICAL INSTRUCTION

The article by Dr. Arnold[1] on graduate medical instruction published this week deals with one of the great present needs in medical education. The time for a careful development of graduate work in this country could never be more opportune, since physicians cannot for the present obtain such work abroad.

As stated in a recent report,[2] the objects of graduate medical instruction are: (*a*) to offer advanced instruction and opportunities for research; (*b*) to prepare physicians for special fields of work; (*c*) to offer opportunities for review and for keeping in touch with the advances in medical science, and (*d*) to make up any deficiencies in previous medical education. Courses meeting some of these purposes are offered by several of the undergraduate medical schools, although usually during the summer or at times, perhaps, when some physicians cannot well leave their practice. Graduate work is more satisfactory, however, if planned and given separately from undergraduate instruction. The physician who has developed an active practice usually realizes the lines along which he needs further instruction, and would gladly take advantage of any opportunities of perfecting himself, if he could do so without undue loss of time, in the few weeks or months he could occasionally spare. Graduate instruction is usually more convenient for the average physician, therefore, if concentrated courses in certain subjects are so arranged as to permit their completion in a comparatively short time. Again, it would doubtless be an advantage if, so far as possible, the various courses offered in any one subject could be scheduled at hours which do not conflict, so that the physician, if he desired, could profitably devote all his available time to any one specialty.

The needs and the convenience of physicians have apparently been given more careful consideration, and graduate medical instruction has reached its highest development, in those cities of Europe having single strong university medical schools and where all grades of instruction for physicians, both laboratory and clinical, are organized under a centralized control. In this country, by comparison, scarcely a beginning of an ideal scheme has been made. In many large cities no graduate work whatever is available; in a few others there are single graduate schools, but the clinical material is limited perhaps to that of a single hospital, or the work is too limited in its scope. In three or four other cities, instead of a single, strong, thoroughly well-organized graduate medical school, there are three or more separate and independent institutions. Such clinical material as is being utilized in these cities, therefore, is divided between these separate institutions, without any attempt to correlate the courses given by one school with the courses given in the others. Thus a physician's opportunities in each school are seriously limited, and if he seeks to take work in two or more different institutions, he finds that the desired courses in one school conflict with those he would like to take elsewhere.

---

[2] Report of the Council on Medical Education to the House of Delegates of the American Medical Association, June, 1914, The Journal A. M. A., July 4, 1914, p. 87.

It is well known that, while a few of the graduate medical schools are doing good work, most of them are proprietary institutions conducted more or less as commercial enterprises. Hence the financial success of the institution, rather than the best interests of the physician seeking graduate instruction, too often dominates the management.

It is encouraging to note that certain universities are beginning to assume a responsibility for graduate medical instruction. Harvard and Tulane universities and the state universities of Minnesota, California and Alabama have established graduate medical schools, and other university medical schools are offering certain courses for graduate physicians. "Graduate medical instruction," as Arnold says, "should be on the same high plane as undergraduate teaching," and "should be under the control of good medical schools or universities."

Another step which may aid in the development of better graduate medical instruction is the establishing of central bureaus in New York, Philadelphia and other cities from which daily bulletins are issued showing what clinics are being held each day, when and where they are held and by whom, so that the visiting physician may attend those in which he may be interested. This scheme at least furnishes an introduction to some of the clinical work being done in each city, and may give many physicians a desire for further graduate medical instruction.

There is no greater need in medicine in this country to-day than a well-developed scheme for graduate medical work, the interests and convenience of the graduate student being ever borne in mind. Such a development would furnish the greatly needed opportunities whereby physicians could keep abreast of the improved methods of diagnosis and treatment, and enable them, in turn, to render better care to the patients depending on them.

CLINICAL DATA OF HUMAN RENAL DISEASE IN ELUCIDATION OF KIDNEY FUNCTION

Most investigations intended to solve the mystery of the renal secretion and disclose the mechanism whereby the urine is produced in the kidneys have depended on the study of animals. The human subject has been referred to far less frequently to elucidate the function of the kidneys, presumably owing to the complexity and intimate association of the different portions of these organs and the consequent difficulty in connecting an experimental finding with a definite anatomic structure. In recent years distinct progress has been made in differentiating the involvement of the different portions of the kidney brought about by the inroad of disease. Types of nephritis which are purely glomerular and such as are interstitial in character have become more easily recognized and distinguished. Fundamental differences in the location of the inflammatory disturbance are now known to be associated not only with distinct histologic appearances in the kidney, but also with clearly recognized clinical varieties of disease. The acute glomerular nephritis, such as may be observed in cases of scarlet fever, is frequently attended with almost complete suppression of urine; the localization of the inflammatory process in the interstitial tissue may present an entirely different urinary condition. If it were possible, therefore, to study the composition of the urine derived from kidneys for which the anatomic basis of the organs was precisely understood, the findings might throw light on the participation and respective rôle of the glomerular and tubular epithelium in the secretion of urine.

Such an investigation on man has been attempted by Dr. J. P. Kinloch[1] at the Ruchill Fever Hospital in Glasgow. His examination of the urine in various forms of nephritis indicates certain functions of the kidney. The glomerulus normally passes out by far the greater part of the water of the urine. This action of the glomerulus is in great part destroyed in glomerular nephritis. Thus a typical diminution in the quantity of urine occurs in the glomerular nephritis of scarlet fever and diphtheria, and this diminution is present at the very commencement of nephritis. In the glomerular nephritis of diphtheria, immediately after the initial diminution the quantity of urine steadily increases, and soon free excretion is in process, while in the glomerular nephritis of scarlet fever diminished excretion is long maintained. In the pure forms of interstitial nephritis in scarlet fever and diphtheria, on the other hand, no diminution of urine occurs other than can be explained by the elimination of an extra amount of water by the lungs and skin in the presence of pyrexia.

With respect to the elimination of the nitrogenous waste products, Kinloch advances the belief that the glomerulus may excrete a larger proportion of them than has hitherto been assumed. He remarks that this would explain the diminished nitrogen percentage and daily output in the acute period of glomerular nephritis in scarlet fever in cases in which the glomerular lesion is extensive. The retention of nitrogen might, however, be explained by supposing that it is dependent on secondary changes resulting from renal disease. The excretion of nitrogen appears to be unaffected by the degenerative changes found in the tubular epithelium. The anatomic evidence shows that there are secondary changes in this epithelium in the various types of nephritis, and this tubular change is most marked in interstitial nephritis, in which nitrogen elimination is free throughout the nephritis.

---

[1] Kinloch, J. P.: The Excretion of Urinary Solids: A Chemical Study of Urine in the Nephritis of Scarlet Fever and Diphtheria, Jour. Path. and Bacteriol., 1914, xix, 77.

The phenomena connected with the renal elimination of other urinary components — chlorids, sulphates, phosphates — seem to be too complicated to permit any final tenable generalizations to be made at the present time. The foregoing studies are among the investigations now being undertaken in many clinical laboratories in which data furnished by human subjects are being used to elucidate the obscure behavior of the kidneys in health and disease.

U. S. PUBLIC HEALTH SERVICE REPORT ON A TUBERCULOSIS TREATMENT

The Journal has already referred to the investigation of the von Ruck treatment for tuberculosis that was being made by the Public Health Service in response to a resolution of the United States Senate. The report of these investigations has just been made public as Senate Document 641. This follows close on the report from the same service on the Friedmann treatment, and, as in the latter, the verdict has been that von Ruck's claims have not been substantiated.

On account of the evident practical difficulties in carrying out the studies on human beings, the investigation was largely confined to the attempt to confirm or disprove by animal experimentation the reliability and success of von Ruck's methods and practices in the production of immunity to tuberculosis. The studies were begun in Asheville at Dr. von Ruck's laboratory, but were later transferred to the Hygienic Laboratory in Washington, the reason given being that Dr. von Ruck would not concede the right of the government's representatives to conduct an independent and uncontrolled investigation, and summarily interrupted the investigation in Asheville. It would seem from the report that the von Rucks did not have sufficient confidence in their methods to be willing to be investigated unless they had supervision and control over the investigation, truly a remarkable stand for a scientist to take.

The pursuance and completion of the investigation seems to have been much facilitated by the fact that in their publications the von Rucks have claimed an experimental basis for their system of tuberculosis therapeutics. They claim that their "vaccine" has been evolved from data derived from animal experimentation and certain serum tests, and the results of its administration are claimed to be shown also by the same methods. It has been claimed that the vaccine is stable, but as is clearly shown in the report, it is "unstable, subject to deterioration, and is impossible of duplication with certainty." From this it would appear, therefore, that it cannot be standardized for practical purposes, since by the time the results of the protracted tests are known, deterioration may have occurred. It will be recalled in this connection that von Ruck had severely criticized the work of Dr. R. S. Cummings[1] as reported in The Journal, in which that author showed that immunity in guinea-pigs was not produced by treatment with the vaccine but that the susceptibility of the animals to tuberculosis was apparently increased as a result of the treatment with the vaccine. From the report to the Senate it would appear that this criticism was unjustified, and that the real reason for the failure of the guinea-pigs to be protected was not the failure to do certain "serum tests" but the deterioration (now admitted by von Ruck) of the vaccine, aside from the fact that it is questionable "if indeed it had ever possessed the immunizing properties which Dr. von Ruck thought to have demonstrated."

Guinea-pigs were not immunized against injections of tubercle bacilli by the use of the vaccine in doses recommended by von Ruck and continued for the length of time, and longer, which he claimed as adequate for the purpose. On the contrary, it was found that most of the animals so treated exhibited increased susceptibility. Von Ruck insists as one of the important links in his work that the immunity of the animals shall be demonstrated by serologic methods before the final tests by inoculation, but the incorrectness of this attitude is shown in the report where the statement appears, "This decisive test [the result of virulent inoculation], having shown that the animals were not immunized, it is a matter of indifference [to me] what degree of supposed immunity they might have shown by serological methods." The experiments made to demonstrate that the serum of persons or animals treated with the vaccine, and said by von Ruck to possess the necessary immune antibodies to destroy the virulence of tubercle bacilli, failed to confirm that claim.

It was not found possible to obtain direct evidence as to whether or not the vaccine would render persons in health immune to tuberculosis, but the report states that the indirect evidence on this point offered by Drs. von Ruck in proof of the success of the vaccine in producing immunity was faulty and inadequate. One of the most striking portions of the report is that which discusses the attempts made in von Ruck's laboratory by some one interested in the outcome of the experiments to alter the entries in the laboratory record book in regard to the use of controls in certain serum tests. Such an occurrence, as the report states, "had the effect of removing the entire test from [my] consideration as a scientific proceeding," and causes speculation as to whether the investigation was not desired for reasons other than purely scientific ones.[2]

THE SMEGMA BACILLUS

Since the search for the tubercle bacillus has now become an indispensable part of the routine examination of many types of clinical material, it is highly important to exclude every source of inaccuracy and every ascertainable possibility of error in diagnosis. The *existence of a cause of confusion in the* smegma bacillus has long been recognized by bacteriologists and well-trained laboratory workers, but the fact is not yet sufficiently appreciated by the physician at the bedside and in the clinic who furnishes the specimens for bacteriologic investigation. Indeed, we do not err seriously in asserting that far too little attention is as yet paid by practitioners to the proper collection and suitable preservation of the specimens intended for subsequent laboratory examination. Urine, sputum, blood, "smears" and comparable materials are in far too many instances transmitted to the clinical chemist and bacteriologist in a condition that is not complimentary to the intelligence or the technic of the physician responsible for their collection. Containers that are unclean and contaminated with unknown products of chemical nature, or that are unsterile and lead to abnormal decomposition and false diagnosis furnish a frequent source of annoyance to the expert who is expected to find in the "specimen" a correct answer to a clinical question. The average practitioner still needs to learn to treat his responsibility in the cooperative undertaking of laboratory clinical diagnosis more seriously.

The widespread existence of the smegma bacillus is a stumbling block in the path of diagnosis because the organism resembles the tubercle bacillus not only in its chief, and hitherto distinctive characteristic — its staining properties — but also in its morphology.[3] The smegma bacillus is found widely distributed over the surface of the human body. It appears in especially large numbers in any place where normal skin secretions are allowed to collect, as about the genitalia, under the foreskin in males, and between the labia in females, about the anus and the perineum, in the umbilicus, in the cerumen of the ear, about the teeth, etc. In this respect its occurrence is dependent on the degree of cleanliness of the patient. It also appears in the urine — more abundantly in females. This fact in particular emphasizes the possibility of a false diagnosis of genito-urinary tuberculosis, so that some writers have ventured the assertion that the confusion and difficulty encountered in the past in the bacteriologic examination of the urine where no account of the smegma bacillus has been taken has actually resulted in useless serious operations.

Fortunately, so far as the examination of the urine is concerned, the possibility of contamination of this secretion is not deep-seated. Smegma bacilli have never been found in the bladder or the deeper portions of the urethra. Some writers have therefore held that catheterization is sufficient to ensure exclusion of contamination of urine with extraneous smegma bacilli; but Young and Churchman[4] insist that the urine cannot be safely collected unless urethral irrigation is previously undertaken. The extreme importance of this feature will be realized in view of the statement of Brereton and Smith[1] that no method of differentiating the tubercle bacillus from the smegma organism by staining is entirely adequate for all cases, and the successful cultivation of the true smegma bacillus is open to question. According to these bacteriologists of the State Laboratory of Hygiene at the University of Wisconsin, however, by thorough cleaning of the genitalia, especially the meatus, and by catheterization, urine to be examined for tubercle bacilli can be collected with a fair degree of certainty of freedom from smegma bacilli. With such precautions, the finding of acid-fast organisms after decolorization with acid alcohol enables one to make a presumptive diagnosis of genito-urinary tuberculosis.

Final differentiation between the two types of bacilli can be made only by animal inoculation, according to Brereton and Smith. All investigators agree on the non-pathogenic character of the smegma organism. The animal experiment can thus be made the arbiter whenever uncertainty is encountered.

Current Comment

RURAL SCHOOL SANITATION

In 1911, the National Council of Education of the National Education Association appointed a committee on health problems in education. At the same time, the Council on Health and Public Instruction of the American Medical Association appointed a committee to cooperate with the National Education Association on this subject. These two committees, acting as a joint committee, have for three years been working in this field. The significance and practical value of the coordination of the efforts of the teaching and medical professions of the United States is apparent. The possibilities of such cooperation can hardly be overestimated. After careful consideration, the committee was unanimous in feeling that possibly the most important and certainly the most neglected field in school hygiene was the problem of rural school sanitation. When an effort was made to formulate plans and remedies, however, it was soon realized that although every one was agreed as to the paramount importance of this field, there was little, if any, definite information available regarding actual conditions. It seemed necessary, therefore, that before any remedies were proposed or even discussed, a reasonable amount of data should be secured. Fortunately these conclusions were completely in harmony with the views and policies of the United States Bureau of Education. As Hon. P. P. Claxton, the commissioner, was a member of the joint committee, it was possible to develop a plan for the study of rural school conditions in which all the forces interested could unite. During the spring of 1913, a field secretary employed by the joint committee made a careful statistical and photographic survey of about one hundred rural schools in four eastern states. At the same time, Prof. F. B. Dresslar of the Peabody College for Teachers of Nashville, Tenn., special agent of the federal Bureau of Education, was collecting a large mass of material on country schoolhouses in different states. Additional material was secured from various sources, principally through state boards of health. All of this information has been carefully collated, with the result that Bulletin 12 of the United States Bureau of Education, entitled "Rural Schoolhouses and Grounds," contains in its two hundred pages probably more information on this subject than has ever before been collected. For the details of this survey, the large mass of illuminating facts brought out and general conclusions drawn therefrom, the reader is referred to the report itself, which can be secured from the Bureau of Education at Washington. As a result of this study, the joint committee of the National Education Association and the American Medical Association has prepared a statement of minimum requirements for rural schools, being a summary of those conditions of location, construction and equipment which are the very least that should be tolerated in rural schools. This pamphlet can be secured from the Bureau of Education at Washington, from Dr. Thomas D. Wood of Columbia University, New York City, or from the American Medical Association. For the first time in the history of education and sanitation in this country, a reasonably comprehensive collection of facts regarding the sanitary condition of rural schools has been made and a standard of minimum sanitary requirements formulated. Parents, teachers, school boards, health officers and the general public have now been given a standard easily applied and within the physical and economic possibilities of any community. Adoption of this standard is the very least that can with decency and fairness to its children be expected of any community. As this standard becomes recognized through the distribution of these pamphlets, it will in a few years be possible to estimate the relative degree of development in any state by the condition of its rural schools. There are many other questions to be considered in solving the health problems in education, but persons interested in the sanitation of rural schools may feel gratified at the substantial and definite progress which has been made through the joint committee in the last three years in this field.

---

[2] Copies of the report may be obtained by applying to the Chairman of the Senate Committee on Public Health and Quarantine, Washington, D. C.

[3] A review of this subject, with references to the literature, has lately been published by Brereton, G. E., and Smith, K. W.: Studies on the Smegma Bacillus, Am. Jour. Med. Sc., 1914, cxlviii, 267.

THE LOCALIZATION OF SECONDARY TUMORS

Why secondary tumors are so frequently located at points of injury remains to be explained. The fact here concerned has often been noted. Recent observations by Jones and Rous[1] at the Rockefeller Institute for Medical Research show that in mice an acute injury caused mechanically to the peritoneum renders it more suitable for the lodgment and growth of mouse tumor. The injury caused, for example, by a smooth glass rod where it lies in contact with the peritoneum develops a condition favorable to tumor implantation. Evidently the resistance manifested by a healthy peritoneum to the lodgment and growth of tumor fragments is not due to a general immunity reaction, but is referable to the physical characters of the lining membrane; for the local injury renders susceptible the part of the peritoneum immediately affected and that part only. Jones and Rous remark that a connective tissue highly cellular and perhaps still proliferating as the result of injury may well elaborate the stroma for a tumor more rapidly than normal connective tissue. In support of this idea they cite the fact that connective tissue reacting to an injury grows profusely and almost immediately when incubated in plasma, whereas normal tissue from the same region shows usually no growth whatever. The New York investigators summarize their observations with the statement that the secondary location of tumors at points of injury may be attributed with good reason to the presence at such points of an active connective tissue capable of elaborating a stroma rapidly and abundantly, for it is the proliferation of the subendothelial connective tissue to form a supporting stroma that determines the fate of free tumor cells, whether these lie on the peritoneum or within a vessel.

SMOOTH MUSCLES AND HEAT PRODUCTION

That heat is a product of muscular activity seems to be so clearly demonstrated by the evidence of everyday experience that we naturally hesitate to dissociate in our minds the idea of work and heat as simultaneous products of the contracting muscles. We exercise on a cold day to keep warm. One frequently hears the familiar comparison of a muscle to a heat engine and is reminded of the high mechanical efficiency of the human engine, that is, the relation of work to the total energy expended. On closer analysis, however, it now seems not improbable that the two products of muscular contraction, heat and work, are independent though simultaneous in their origin, and that any proportion between is accidental. The efficiency of a heat engine is determined by the "difference of absolute temperature obtaining on two sides of the machine." Inasmuch as it is difficult to imagine even minutely localized changes of temperature in the animal body of more than a few degrees, we are now told that we must discard altogether the analogy of the steam engine and seek some other explanation of the mechanism by which the muscle is enabled to transmute the chemical energy of its food into work or heat. "The muscle is, in fact, not a heat engine, but a chemical engine." Despite these newer contentions in what has been termed the "energetics" of muscle, we have scarcely been prepared for the suggestion that smooth muscle may not even produce any heat at all when it contracts. It is recognized that the metabolism of contracting smooth muscle may be comparatively low; and it is thus seen how the accompanying heat production may be correspondingly low. The smooth muscle may even maintain its tension at the cost of much less oxidation of materials than does cross-striated muscle. Modern measurements of the gaseous metabolism point in this direction. But Professor Snyder[1] of the Johns Hopkins University has just reported, as the result of experiments involving extreme precision and elegance of measurement, that there may be an absence of any measurable amounts of heat production accompanying the development of tension after stimulation of a smooth muscle. We promptly call to mind the prominent part taken by smooth muscles in blood-vessels, in the gastro-intestinal tract and in the urinogenital system, and wonder whether, with Snyder, we shall be forced to "abandon the vaguer views physiologists have held" concerning the functions of smooth muscles.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

COLORADO

Personal.—Dr. Augustus E. Greene, who was seriously injured in an automobile accident at Greeley in November, is convalescent and has returned to his home in LaSalle.——Dr. Charles A. Powers, Denver, is reported to be seriously ill with uremia in the Mercy Hospital.——Dr. Francis A. McNeill, Montrose, has been appointed surgeon for the Rico-Wellington Mining Company.

Medical Board Supplants Health Officer.—The county commissioners of El Paso County have named the following to take the place of the county physician, Dr. James H. Brown, Colorado Springs, recently resigned. Dr. Lewis H. McKinnie, Colorado Springs, surgeon; Drs. Leo W. Bortree, Colorado Springs, and Albert H. Peters, Colorado Springs, internists; Dr. Charles O. Giese, Woodmen, tuberculosis; Dr. Alexander C. Magruder, Colorado Springs, diseases of the eye, ear and throat, and Dr. Frank T. Stevens, Colorado Springs, alienist.

Medical Building Dedicated.—The Grabfelder Medical Building at the National Jewish Hospital for Consumptives, Denver, was dedicated, January 10. The building has been erected at a cost of $75,000 and is equipped with the most modern appliances. Mr. Samuel Grabfelder, Philadelphia, who has contributed more than $50,000 to the hospital, in addition to the gift of the medical building, made the presentation address. Rabbi William I. Freeman, founder of the hospital, responded and Dr. Moses Kleiner, Denver, delivered an address on "The Value of the Medical Building." The hospital now has ten buildings and has cared for more than 3,000 patients, two-thirds of whom are said to have been discharged cured.

IDAHO

Physician Exonerated.—The board of directors of the North Idaho Sanatorium, Orofino, after a searching investigation, have exonerated Dr. John W. Givens, superintendent of the institution, of the charges of neglect of duty, mismanagement and cruelty to patients, preferred by an attorney of Orofino.

State Board Criticized.—Moses Alexander, the new governor of Idaho who took office the first of the year, recommends consolidation of the State Board of Health and state dairy, food and sanitary departments, with a physician at their head, and says $32,000 would be ample to run them, or a saving of $31,140. He would retain the state bacteriological station in the capitol building, but would remove the chemical department to the state university at Moscow and would have done there the chemical work that now is done at the Lewiston normal, Albion normal and Academy of Idaho.

ILLINOIS

Loop Hospital Suggested.—Judge Charles N. Goodnow of the Chicago Morals Court has suggested that a hospital be erected in or near the loop to care largely for men, women and children found to be suffering from venereal disease.

Personal.—Dr. Leo M. Czaja, Chicago, sailed from New York, January 13, for work with the Servian Red Cross.——Dr. Charles W. Miller, Peoria, was injured January 12, in a collision between his automobile and a street car.——Drs. Albert M. Earel and Robert S. McCaughney, Hoopeston, have been appointed local surgeons for the Chicago and Eastern Illinois Railroad.——Dr. Anna Dwyer has been appointed a member of the Chicago Morals Commission, of which Dr. George B. Young, health commissioner, is a member ex-officio.

Chicago Victorious in Fight for Theater Ventilation.—A recent report in the *Bulletin of the Department of Health* calls attention to the fact that on Jan. 1, 1913, of 630 motion picture theaters in Chicago only 45 complied with the law as far as ventilation is concerned. On Jan. 1, 1915, the total number of theaters was 616, of which only 17 were still in operation while requiring alterations to make them comply with the law. The next problems to which particular attention will be turned are the ventilation of factories and transportation conditions.

Housing and Medical Arrangements of Industrial Concerns.—The committee on factories of the Chicago Tuberculosis Institute met at the City Club, January 19, to discuss the subject of "The Housing and Arrangements of the Medical Department of Industrial Concerns." At this meeting Charles J. Hatfield, executive secretary of the National Association for the Study and Prevention of Tuberculosis, delivered a short address dealing with his impressions of the tuberculosis situation in Chicago, based on his visits to the various tuberculosis institutions and especially the new Municipal Tuberculosis Sanatorium.

IOWA

Sanatorium for Clinton County.—Physicians of Clinton have endorsed the plan for a county tuberculosis sanatorium to be built at the poor farm at a cost not to exceed $5,000 and a committee was appointed to confer with the board of supervisors regarding the matter.

Personal.—Dr. G. Walter Barr, Keokuk, for several years publicity agent to the Mississippi River Power Company, Keokuk, has resigned.——Dr. M. Charles Mackin, Clarinda, first assistant superintendent of the Clarinda State Hospital, has been appointed superintendent of the State Inebriates Hospital, Knoxville, succeeding Dr. George Donohoe, Knoxville, promoted to superintendent of the State Hospital, Cherokee, succeeding Dr. Matthew N. Voldeng, Cherokee, promoted to superintendent of the new State Epileptic Colony, Woodward.

KANSAS

Trachoma on Reservation.—Dr. Robert S. Magee, Topeka, has reported to the State Board of Health as the result of an examination of 154 children on the Mayetta Reservation, 33 out of 105 white children and 31 out of 49 Indian children, were found to have well-marked cases of trachoma.

Sanatorium Opened.—The Tuberculosis Hospital at Norton has been completed and is ready to receive patients. It can accommodate at present sixteen patients, but expects that the next legislature will make an appropriation sufficient to build two more dormitories so that at least sixty patients may be cared for.

Spread of Small-Pox.—In Pratt, where small-pox has been spreading since September 1, 250 cases were reported early in December. Schools, churches and all other public gatherings have been ordered closed. No deaths were reported.——Over forty-five cases of small-pox are reported from Columbus, Cherokee County. The disease is in very mild form.

---

[1] Snyder, C. D.: Is the Contraction of Smooth Muscle Accompanied by Heat Production? Am. Jour. Physiol., 1914, xxxv, 340.

MARYLAND

Urologic Clinic Open.—The James Buchanan Brady Urological Institute, established through the benefaction of the millionaire of that name, opened January 21. It is expected that later on, probably in the early spring, there will be dedication exercises. The new institute forms an impressive addition to Johns Hopkins Hospital group of buildings.

Personal.—Dr. James McFaddin Dick, Salisbury, underwent an operation for the removal of gall-stones at the Peninsula General Hospital, December 19.——The home of Dr. J. Carl Smith, Ellerslie, was seriously damaged by fire December 13.——Dr. Franklin P. Mall, Baltimore, professor of anatomy at Johns Hopkins Medical School, has been appointed head of the new department of embryology at Carnegie University, Washington, D. C.

Mentality Test in Child Labor Cases.—Arrangements have been made by the State Bureau of Labor Statistics to introduce a mentality test in determining eligibility of children applying for permits to work, that will not only diminish the danger of physical injury but will elevate the standards of child labor. Dr. James A. Nydegger, U. S. P. H. S., has been instructed by the government to cooperate with the bureau in this measure and all children applying for work will be subjected to the test. No permits for labor are given children under 14 years of age, other requirements being that they are physically sound and have received a rudimentary education.

Penitentiary Hospital.—The need of a new hospital at the penitentiary, where modern and sanitary treatment could be given the inmates, has just been realized. The old administration building has been remodeled and converted into a modern hospital. Laboratories, operating rooms, wards and adequate facilities for isolation have been installed. It has a tuberculous ward, open on all sides, allowing an abundance of air and sunshine to penetrate it. A roof garden has also been added to the building, affording the tuberculous patients constant outdoor life. The surgical outfit consists of a large operating room and all necessary sterilizing apparatus of a modern hospital in an adjoining room. The hospital kitchen has been fitted up to the latest idea of diet preparation.

Conference on Tuberculosis.—The governor has issued a proclamation announcing a conference on tuberculosis to be held at the State House, Annapolis, January 22 and 23, for the purpose of devising the proper course to follow in finally stamping out the white plague from the state. All public officers, health officers, physicians, nurses, county commissioners, and other officers of towns and cities are urged to attend the conference. The state is spending nearly $200,000 annually in maintaining sanatoriums for the treatment of this preventable disease. The facts and figures of the State Department of Health indicate that more than 8,000 people are suffering from this disease, and more than 4,000 new cases have been recorded in 1914. The records also show that 2,016 persons died from tuberculosis last year.

MINNESOTA

Contagious Department of Hospital Assured.—Work on the new contagious wards of the Minneapolis City Hospital, which had been suspended for several months on account of lack of funds, will now be taken up actively as the bonds necessary to raise the funds for the completion of four floors were sold January 7.

Leper Colony for Minnesota.—The Minnesota State Medical Society will ask the legislature the coming session, to set aside 10,000 acres in the northern part of the state on which to establish a colony for the segregation of lepers. It is said that there are now in the state fifty persons suffering from leprosy. The plan will also provide for the establishment of a branch hospital at the State University for clinical purposes.

Personal.—Dr. Samuel M. Kirkwood, St. Paul, who went to Montana on account of his health, has located on a ranch at Absarokee, Mont., and is reported to be improving.——Dr. Charles F. McComb, Duluth, has been appointed a member of the Advisory Commission of the State Sanatorium, Walker, vice Dr. James L. Camp, Brainerd.——Dr. John C. Staley, St. Paul, has been given a position on the staff of the American Hospital, Paris, and sailed for Europe, December 30.

NEW YORK

Plan for Better Health Work.—The State Public Health Council was received by the governor, January 12. Dr. Hermann M. Biggs, New York City, who headed the council, made an urgent plea for better health work.

Public Health and Mental Hygiene.—The State Hospital Commission which is charged with the supervision and control of the state hospitals for the insane is planning a campaign of prevention. During the past year 6,061 patients were received at the State Hospitals, of whom about one-quarter owed their breakdown to causes largely under their control. The plans of the commission comprise a series of short illustrated talks on mental hygiene to be delivered in different parts of the state, showing to the public the economic burden imposed on the state through insanity; the causes and prevention of insanity, and the problems of faulty heredity and environment. The plan also includes the giving of assistance to individuals in the form of advice as to how to obtain proper medical treatment and advice as to the maintenance of mental hygiene. The teaching and pathological branch of the service will be under the direction of Dr. August Hoch, New York City. The lectures will be given under the direction of the commission, with the approval of Health Commissioner Biggs, and correspondence with reference to dates for lectures is solicited with health officers and other readers of the *Health News.*

New York City

Protest Against Tooth-Wash Tax.—A committee of prominent New York physicians has been formed to petition congress to revoke the war tax on tooth washes and tooth pastes on the ground that such a tax is a severe blow to the work that has been done by state and municipal public health agencies in behalf of mouth hygiene. The committee has as its chairman Dr. Herbert L. Wheeler of the College of Dental and Oral Surgery, and includes Drs. Francis Delafield, Sigismund S. Goldwater, Thomas Darlington, Ernest Lederle, William S. Bainbridge, H. Holbrook Curtis, William Carr, Victor Hugo Jackson, O. Victor Limerick, William C. Deane, Frank E. Miller, Herbert D. Pease, William Gies and Edmund Prince Fowler.

NORTH DAKOTA

Personal.—Dr. Evan C. Stone, Balfour, while making professional call near that place, was thrown from his bugg in a runaway accident, fracturing his clavicle.——D Richard J. Church, Park River, has been appointed loca surgeon for the Great Northern System.——Dr. Thomas M. Stixrud, Litchville, has been appointed surgeon for the Fargo division of the Northern Pacific System.

Public Health Association Organized.—At a conference of city and county health officers of North Dakota held at Devil's Lake, December 16, in response to the call of Dr. Charles J. McGurren, Devil's Lake, secretary of the State Board of Health, the North Dakota Public Health Association was organized and the following officers were elected: president, Dr. Henry H. Healy; secretary, Dr. Alfred Dean, both of Grand Forks. A committee to outline desired changes in the present state laws was appointed, consisting of Drs. J. W. Cox, Charles J. McGurren, Devil's Lake; Darie Lemieux, Dunseith. It was decided to ask the state legislature for an all-time state health officer and that the State Board of Health should consist of five, including two laymen.

OKLAHOMA

New Hospital at State Penitentiary.—A new convict's hospital at the State Penitentiary, McAlester, is now completed. It has a capacity of fifty beds, with accommodations also for the physicians and nurses in charge and is under the direction of Dr. John W. Echols, the penitentiary physician.

Personal.—Dr. Percy A. Smithe, Enid, sailed for Europe December 19, to join the Red Cross Unit K Hospital at Vienna, as third assistant surgical director of the unit.——Dr. John W. Duke, Guthrie has been appointed state commissioner of health, succeeding Dr. John C. Mahr, Shawnee, who will open a private hospital in Oklahoma City to be known as the Hotel for Sick People.——Dr. David M. Lawson, Nowata, took a bichlorid of mercury tablet in mistake for a headache tablet recently, but prompt treatment placed him out of danger.

PENNSYLVANIA

Philadelphia

Gorgas in Philadelphia.—Dr. William C. Gorgas, Surgeon-General U. S. Army, will address the Philadelphia County Medical Society on the sanitary and hygienic question involving the construction of the Panama Canal, at the Manufacturers Club, January 27. Afterward there will be a reception and supper in honor of Dr. Gorgas.

Change in Title.—An important change in title has just been authorized by the management of the Friends Asylum for the Insane at Frankford, Philadelphia. In deference to advanced public sentiment, application is to be made to the courts for amendment of the charter of the institution so that it will henceforth be officially known as "The Friends Hospital."

To Charge Clinic Patients.—Declaring that the Polyclinic Hospital is being habitually deceived by persons well able to pay for treatment, the faculty committee has announced a new policy which became operative at all clinics after January 15. After this date all patients were required to pay a fee of 25 cents for the first visit and 10 cents for each subsequent treatment.

Contracts Awarded.—On January 15 Dr. S. Lewis Ziegler, Director of Health and Charities, awarded two contracts, one for constructing an observation building at the Municipal Hospital for Contagious Diseases and the other for a Nurses Home at the same institution; the former to cost $68,924 and the latter $51,890. The total cost for the observation house will be $86,346, and for the Nurses Home $62,755.

SOUTH DAKOTA

Hospital Almost Ready.—The new Sacred Heart Hospital, Yankton, erected at a cost of $150,000, is said to be nearly completed and ready for occupancy.

Move into New Offices.—On January 1, Drs. Leslie G. Hill, Charles S. O'Toole, William G. Magee and Olaf Haraldson, moved into a nine-room suite of offices on the second floor of the new Citizens' National Bank Building, Watertown.

TEXAS

Waxahachie Physicians and Dentists Organize.—The physicians and dentists of Waxahachie have organized the Waxahachie Medical Society and have elected the following officers: president, Dr. Dickson G. Thompson; vice-president, Dr. Louis H. Graham; secretary, Dr. Seaborn H. Watson, Jr.

Banquet to Southern Surgeon.—Dr. Bacon Saunders, Fort Worth, newly elected president of the Southern Surgical and Gynecological Association, was the guest of honor at a banquet at the Westbrook Hotel, Fort Worth, December 29, given under the auspices of the Tarrant County Medical Society. Dr. Ira C. Chase, Fort Worth, officiated as toastmaster.

Personal.—Dr. Morris H. Boerner, Austin, state director of the Texas Hookworm Commission, has tendered his resignation to take effect January 15. He expects to go east to pursue graduate study.——Dr. Bascom Kavanaugh, while standing in front of his home in San Augustine, January 6, was shot and dangerously wounded.——Dr. Harold L. Warwick, Fort Worth, has returned from abroad.——Dr. Herschel G. Thomas is said to be seriously ill with pneumonia at his home in Handley.

WASHINGTON

Personal.—Dr. Albert E. Stuht, Spokane, has been elected physician of Spokane County.——Drs. Edward J. Stubbs and Robert D. Forbes, Seattle, have been commissioned as lieutenants in the Royal Army Medical Corps and assigned to duty at the training camp, Bedford, England.——Dr. Olaf T. Melde, Spokane, is ill with inflammatory rheumatism at his house.

Sanatorium Notes.—The Board of Health of Spokane County has approved the plans for the county tuberculosis sanatorium to be erected two miles east of Spokane, at a cost of $50,000.——The first unit of the Seattle City Sanatorium, erected at a cost of nearly $250,000, has been completed. It consists of one hospital building, one children's building, an administration building and a power plant, and will accommodate nearly 200 patients. The city council has allowed $95,000 for the maintenance of the sanatorium for 1915.——A contract for the Edgecliff County Tuberculosis Sanatorium has been awarded for $75,000, and the work is to begin at once.——The new Pierce County Tuberculosis Sanatorium, at Lake View, opened to receive patients, January 4.

WISCONSIN

Medical Women Incorporate.—The Wisconsin Medical Women's Society filed articles of incorporation with the secretary of the state, January 7. The organization has no capital stock and the incorporators are, Drs. Carrie A. Frost, Chippewa Falls, Mary Piper Houck, La Crosse, Helen A. Binnie, Milwaukee, and Maud F. Pratt, Appleton.

Diagnostic Stations to Be Established.—A committee has been appointed by the Milwaukee Medical Society to cooperate with Health Commissioner George C. Ruhland in establishing diagnostic medical stations throughout the city. The plan has been endorsed by the City Club and the school board has signified its willingness to allow public school buildings to be used for this purpose.

CANADA

Queen's University and the War.—No university in Canada has done any better for the war than has Queen's University, Kingston. More than eighty officers and men will go with the second contingent. The faculty of applied sciences especially has been well to the fore.

Talks in Interest of Wounded.—Dr. Brown-Landone, who has been in Toronto in the interests of the wounded from the north of France, addressed the Academy of Medicine on January 15. Transportation difficulties as well as lack of medical and surgical supplies, as dressings, bandages, surgical instruments, etc., occupied most of his attention. At the conclusion a committee of the academy, composed of a member from each hospital staff in the city was organized for the purpose of collecting supplies and forwarding them to Havre, France.

Medical Council Elections, Ontario.—The following are the territorial representatives elected to the Ontario Medical Council: Drs. George R. Cruickshank, Windsor; George M. Brodie, Woodstock; James MacArthur, London; Arthur T. Emmerson, Goderich; John J. Walters, Berlin; Samuel McCallum, Thornbury; Herbert S. Griffin, Hamilton; Eldridge T. Kellam, Niagara Falls; Robert H. Arthurs, Sudbury; Alexander D. Stewart, Fort William; Edmund E. King, Toronto; Herbert J. Hamilton, Toronto; Ferdinand A. Dales, Stouffville; Thomas W. H. Young, Peterboro; Thomas S. Farncomb, Trenton; William E. Spankie, Wolfe Island; William E. Crain, Crysler; J. Fenton Argue, Ottawa. In addition to these the collegiate representatives number six and the homeopathic five.

Personal.—Dr. Andrew Hunter has been appointed to the professorship of chemical pathology in the University of Toronto, replacing Prof. John B. Leathes, Toronto, who recently resigned to go to the University of Sheffield, England.——The Hon. Dr. Henri S. Beland, St. Joseph, Que., who was a member of the Laurier government, was thrice wounded by shell splinters while attending the wounded at Antwerp. A Belgian writing to Canada speaks of Dr. Beland's good work and of "Your brave Canadian, whose services will never be forgotten by many of our force."—Dr. Perry E. Doolittle, Toronto, has been appointed chief commandant of the war automobile organization.——Dr. Oswald Dinnick, formerly of Toronto, but for a number of years practicing in London, England, has resigned his position in a prominent London hospital and gone to the front with the R. A. M. C.——At the suggestion of Sir Ryckman Godlee, Dr. Herbert A. Bruce, Toronto, has organized a Canadian Belgian relief committee for the benefit of the Belgian doctors and pharmacists. Dr. P. Walter H. McKeown, Toronto, is secretary of this committee and Dr. D. J. Gibbs Wishart, Toronto, treasurer. The Canadian professions of physicians and pharmacists are being appealed to for contributions to this cause.

GENERAL

Congress on Local Anesthesia.—A clinical congress for the study of local, spinal and scopolamin-morphin anesthesia will be held in Chicago, January 26 to 28. Evening sessions will be held in the rooms of the Chicago Medical Society, 25 East Washington Street, sixth floor, and clinics will be held at Cook County, Polyclinic, Post-Graduate, Presbyterian, Alexian Brothers and Mary Thompson hospitals and the Illinois Medical School.

The Cutter Lectures.—The Cutter Lectures in Preventive Medicine for the year 1915 will be given at the Harvard Medical School by Dr. Victor C. Vaughan, professor of Hygiene and Physiologic Chemistry and dean of the School of Medicine and Surgery of the University of Michigan, and Dr. Joseph Goldberger, Surgeon, United States Public Health Service, Washington, D. C. Dr. Vaughan will lecture on "The Phenomena of Infection" on April 14, 15 and 16. Dr. Goldberger's subject will be "Diet and Pellagra" and will be given in one lecture April 2. These lectures are given annually under the terms of a bequest from John Clarence Cutter, whose will provided that the lectures so given should be styled the Cutter Lectures on Preventive Medicine, and that they should be delivered in Boston, and be free to the medical profession and the press. Others interested are cordially invited.

Bequests and Donations.—The following bequests and donations have recently been announced:

Home for Crippled Children, Philadelphia, $10,000; Episcopal Hospital, Philadelphia, $5,000 by the will of Letitia H. Harrison.

St. Louis Medical Society, $42,813.39, by the will of Mrs. Franzisca Bartscher in memory of her husband, Dr. Hugo W. Bartscher.

Jewish Hospital, Philadelphia, contingent bequest of $6,000 by the will of Caroline Solomon.

To build a sanatorium at Hot Springs, Ark., Dr. W. G. Choate has been bequeathed $57,000 by Patrick Fenton of Knoxville, Ia.

Presbyterian Hospital, Chicago, $50,000 to be known as the Albert Arnold Sprague endowment; Chicago Orphan Hospital, $5,000 by the will of Albert A. Sprague.

Philadelphia Hospital for the Treatment of Contagious Diseases, $50,000, the fund being devised "to any hospital in Philadelphia which shall be devoted to the treatment of contagious diseases, for the purpose of endowing a ward therein, to be called the Hope Memorial Ward, and in case there shall be no such hospital in the city, at the time of my death, or no hospital which will accept such a legacy on these terms, I then give the said fund to the Episcopal Hospital." Eleven hospitals entered claims for this bequest; Presbyterian Hospital and German Hospital, Philadelphia, each one-fifteenth part of the estate, by the will of James F. Hope.

Germantown Dispensary and Hospital and St. Timothy's Hospital, Roxborough, each $10,000, by the will of Helen Louise Merrick.

Jewish Hospital, Philadelphia, $4,000 contingent bequest by the will of Adam E. Wiegand.

Jewish Hospital, Philadelphia, $3,000 by the will of Annie Price.

State Charities Aid Association, St. John's Guild, New York Nursery and Children's Hospital, each $7,500; New York Infirmary for Women and Children, Babies' Hospital, New York Association for the Blind and Manhattan Eye, Ear and Throat Hospital, each $5,000 by the will of Augustus Cleveland Brown.

St. Luke's Hospital, New York City, $7,000 by the will of Sophia Frances Scott.

FOREIGN

Small-Pox in Vera Cruz.—The state department on January 6 received news that small-pox had broken out in Vera Cruz, Mexico.

Jail Sentence for Slandering Physician.—The penalty of one month's imprisonment was promptly inflicted on a workingman recently, in Germany, for stating that a certain physician had made out a fraudulent death certificate. The workingman's appeal to a higher court, the Reichsgericht at Leipzig, was rejected.

New Japanese Institute for Infectious Diseases.—Dr. Shi-asaburo Kitasato announces that he is no longer director of the Imperial Institute for the Study of Infectious Diseases, home department of the Japanese government. With associates he has severed his connection with the institute and started a new private institution, named Kitasato Institute for Infectious Diseases, Tokyo at Sankocho, Shibaku, Tokyo. Those who will act as directors of laboratories in the institute are: Drs. Taichi Kitashima, Kiyoshi Shiga, Sahachiro Hata, Mikinosuke Miyajima, Shinkichi Umeno, Yutaka Teruuchi and Shigeru Kusama.

Deaths in the Profession Abroad.—Lothar von Frankl-Hochwart, professor of pathology of the nervous system at the University of Vienna, a pioneer in research on neuropathology, especially the physiology and pathology of the hypophysis, bladder and on internal secretions. His death was the result of a tumor in the brain, a subject to which he had devoted years of special research.——Dr. Magen of Breslau, editor of the *Aerztlicher Vereinsblatt*, a leader in matters affecting the economic welfare of the profession, aged 50.——M. Heyde privat-docent of surgery at the University of Dresden, succumbed to typhoid at the front, aged 34.——F. Sasse, who took Rehn's place as chief of the surgical service at Frankfurt a. M., died December 15 from the results of a scratch on the finger at an operation four weeks before, aged 48.

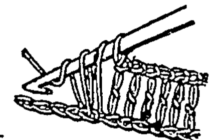
WAR NOTES

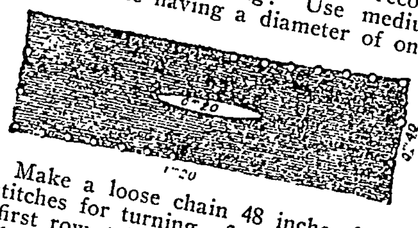
Spinal Meningitis and Diphtheria in the Salisbury Plain Camp.—Six cases of spinal meningitis are reported as occurring in the camp of Canadian soldiers in Salisbury Plain. The Fifth Royal Highlanders are quarantined on account of diphtheria. The situation is not regarded as serious in respect to either disease.

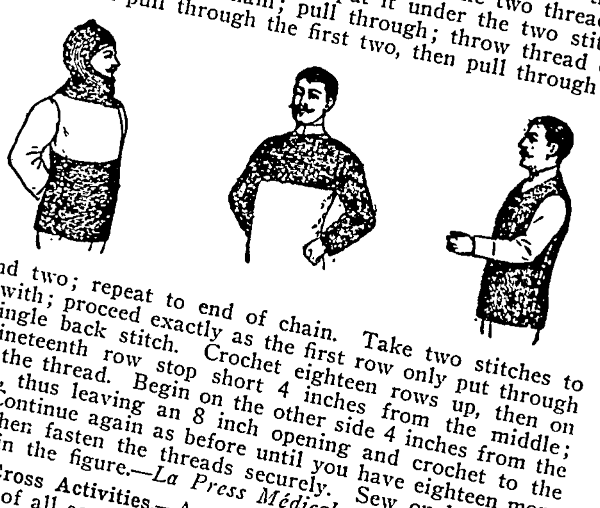
Exposition Showing How the Wounded are Cared For.—An exhibition of models, photographs and diagrams, showing the whole plan of the organized care for the wounded at the front has just been opened at Berlin. The exhibition is in the cupola hall of the Reichstag building and was opened in December with considerable ceremony. From the trench to the convalescent home, the course of the wounded soldier is shown, as also the general arrangements and aspect of a battle field and of a naval battle.

"Michelaines" for the Soldiers.—Dr. Michel, the inventor of the well-known Michel skin clips, has devised a knitted scarf which can be used as a head, throat, chest or arm protector. It consists essentially of a woolen band 48 inches long and 16 inches wide, with a median slit 8 inches long, large enough for the soldier's head to pass through.

The particular crochet stitch which Dr. Michel recommends for this purpose is the following: Use medium sized wool and a crochet needle having a diameter of one-fourth of an inch. 1. Make a loose chain 48 inches long. 2. Crochet two extra stitches for turning. 3. Throw thread over needle. For the first row, take up the two threads of the chain, throw thread over, put it under the two stitches of the first loop of chain; pull through; throw thread over again, then pull through the first two, then pull through the second two; repeat to end of chain. Take two stitches to turn with; proceed exactly as the first row only put through the single back stitch. Crochet eighteen rows up, then on the nineteenth row stop short 4 inches from the middle; break the thread. Begin on the other side 4 inches from the middle, thus leaving an 8 inch opening and crochet to the end. Continue again as before until you have eighteen more rows, then fasten the threads securely. Sew on buttons as shown in the figure.—*La Press Médicale*, Nov. 19, 1914.







Red Cross Activities.—Another large shipment of hospital supplies of all sorts was shipped to Budapest and Vienna by the American Red Cross, January 17, on the steamer *Finland* from New York. The supplies will go via Genoa, Italy, and are consigned to the American Red Cross surgeons and nurses in Austria-Hungary.——The American Red Cross has ordered 17 light automobile ambulances, 12 of which have been given by Yale University and the other 5 by Harvard University. The Yale ambulances will have in Yale colors the inscription, "From the Students of Yale," and the Harvard machines will have in crimson the inscription, "From the Students of Harvard." Painted on the tops will be large red crosses on a white ground. These ambulances will be equipped to carry two wounded soldiers each.——A consignment of twenty cases of hospital clothing and 100 bales of absorbent cotton and bandages sent to the central committee of the German Red Cross in Berlin, has been received.——Dr. Sofie Nordhoff-Jung, associate manager of the American Red Cross Hospital, Munich, acknowledges the receipt of a large quantity of hospital supplies sent by the American Red Cross, including absorbent cotton, gauze, bandages, hospital clothing, etc.——It is reported from Servia that every available building in all the towns near the front has been converted into hospitals and that still wounded soldiers must sleep sometimes on floors in corridors and sheds and that on account of the lack of bandages and gauze, wounds can be dressed only every three or four days. Surgeons are working eighteen hours a day and nurses and local surgeons are laboring to the point of exhaustion. There are 100,000 wounded Servians and Austrians in Servia. There is a lack of absorbent cotton and hospital supplies of all kinds.——The British Red Cross has provided a hospital unit of thirty persons and $20,000 worth of supplies which are being conveyed to Salonica by Sir Thomas Lipton on his yacht.——The American Red Cross on request of Madame Vandervelde, has ordered six sterilizing outfits for the Belgian Red Cross.

Aid for Belgian Physicians.—Dr. F. F. Simpson, treasurer of the committee of American physicians for the aid of the Belgian profession reports that in his stirring appeal for aid for the Belgian physicians, Professor Charles Jacobs of Brussels states that 1,000 doctors are poverty-stricken, and that 2,000 to 3,500 doctors are suffering cruelly through this war. That 2,000 physicians need to be supplied the necessities of life would seem a low estimate. It seems probable that the physicians' families will average four members. That means that 8,000 members of physicians' families are dependent on outside contributions. Four dollars and forty cents will supply sufficient food to sustain life for four for one month. Belgian physicians and their families, therefore, absolutely need at least $8,800 worth of food every month. For the first month contributions of American physicians aggregated $1,414. Will the medical profession of America accept its opportunity and meet its share of this responsibility by prompt and repeated contributions?

Every cent of every dollar contributed will be available for the purchase of supplies as the carrying charges are provided for by the American Commission for Relief in Belgium. The first one thousand dollars contributed have been expended by the executive committee for food and supplies, and the packages properly labeled have been started for their destination.

The full list of names of all contributors up to and including Jan. 16, 1915, follows:

LONDON LETTER

London, Jan. 1, 1915.

The War

THE DISLOCATION OF PRIVATE PRACTICE

Owing to the large number of physicians withdrawn from private practice for service at the front, and the still larger number required for the great army in training in this country, considerable dislocation has been caused in civil practice. The General Medical Council has submitted to the War Office proposals to avoid as far as possible the resulting inconveniences to the civil population from deficiency of medical service, and to the physicians from change of station. These proposals have been accepted. In order that medical officers may as far as possible be able to give part of their time to civil practice in their own districts, the following regulations have been adopted by the War Office: 1. When a mobilized territorial unit is moved from its own locality in Great Britain: (*a*) The medical officers may be allowed to effect exchanges, direct or indirect, with territorial medical officers in the new locality when possible. (*b*) If this is not feasible, the places of medical officers not desiring to accompany their units may be taken by junior medical officers willing to take temporary commissions and serve with such units, the original medical officers being demobilized until the return of the units to their own localities, or until their services can be otherwise utilized there. 2. When a mobilized territorial unit volunteers for imperial service abroad, the medical officer will be given the option of accompanying it or serving with the reserve unit raised for home defense in its stead, vacancies in both units being filled up by junior medical officers with temporary commissions. To facilitate such exchanges, a list is kept at the War Office of junior practitioners willing to accept general service either at home, in the field, or abroad from which substitutes can be detailed as occasion arises. The medical officers themselves might be of assistance in procuring substitutes to take their places possibly from their own neighborhoods, whose names would be placed on the list.

THE BELGIAN "ODYSSEY"

A committee appointed by the British government has issued a report on the reception and employment of the Belgian refugees in this country. It has given a most interesting historical survey. At first the Belgians moved to the nearest place of refuge still held by their army. Gradually, however, they were pushed back to the frontiers, and began to seek shelter in neighboring countries. From first to last it has been calculated that about a million refugees—nearly a sixth of the total population—have abandoned Belgian soil. Of these, Holland received the largest share, 500,000 or more; a large number, especially from the Ardennes and the southern provinces, fled to France. In England about 110,000 arrived and arrangements are being made to bring over more from Holland to relieve the excessive pressure prevailing there. It is characteristic of our national ways that the duty of attending to the refugees should have been undertaken by voluntary organizations. But, however willing private individuals might be to undertake the national duty of relieving the distress of our allies, it soon became evident that the task was assuming such gigantic proportions that no voluntary organization could cope with it. The government then stepped in and offered the refugees the hospitality of the British nation. In one week alone, after the fall of Ostend, 26,000 Belgians were landed at Folkestone. Between September 20 and October 24, 35,000, all destitute, were met at the pier, fed and dispatched to London. Arrangements for feeding and housing were made by the Metropolitan Asylums Board. Some conception of the work done will appear from the fact that from September 10 to November 28, 45,532 refugees passed through the government hostels. The only refugees for whom neither the government nor the War Refugees Committee were responsible were 6,000 Russian and Polish Jews who came chiefly from Antwerp. Their care was undertaken entirely by their coreligionists. The anxiety of all classes in the United Kingdom was shown by the fact that offers of hospitality were received for over 100,000 refugees. The poor vied with the rich in showing practical sympathy. Trade unions subscribed to the wants of their fellow laborers. Families with barely room for themselves pinched and squeezed to give hospitality to the poor Belgians.

With regard to the problem of employment, the Belgian government intimated that it required for military service all unmarried men between the ages of 18 and 30, and asked that no employment should be given to any of that class. Two principles were adopted by the committee: No Belgian labor should be employed until every reasonable effort had been made to find British labor through the agency of the labor exchanges. No Belgian labor should be employed at rates of wages lower or on conditions less favorable than those generally observed in the district. A central register has been prepared of the refugees, classifying them according to sex, age and vocation.

PARIS LETTER

PARIS, Dec. 31, 1914.

The War

THE STATISTICS OF WOUNDS RECEIVED IN WAR

Statistics concerning the results of war-time wounds received at the war department up to the date of December 1 give the following results:

Wounded who have been able to return at once to the front, 54.5 per cent.

Wounded sent away for convalescence, 24.5 per cent.

Wounded under treatment in hospitals, 17.4 per cent.

Dismissed from the army, 1.46 per cent.

Dead, 3.48 per cent.

The figures are particularly interesting for they show that, thanks to the care which our wounded receive in the hospitals, more than half are able to return to the ranks of their commands. They show, moreover, that the mortality from wounds has been reduced to a figure unknown in previous wars.

PREVENTIVE INJECTIONS OF ANTITETANUS SERUM

December 14, Dr. P. Bazy emphasized before the Académie des sciences the necessity of using preventive injections of tetanus antitoxin on all those wounded in war without regard to the origin of the wound. Contrary to general opinion, bullet wounds are frequently infected with Nicolaier's bacillus. In nine out of 120 bullet-wounds not treated with tetanus antitoxin, Bazy has seen tetanus develop; all nine were fatal. Preventive injection ought to be made as early as possible—at the front and in the trains. It appears to give good results, however, even when practiced on the fifth day. Bazy believes that the dose of 10 c.c. adopted in veterinary medicine can be reduced in man, whose weight is so much less, to 1 or 2 c.c. This would help to prevent excessive consumption of the serum even if it is used in all cases.

ASSISTANCE FOR WOUNDED MOSLEMS

A group of orientalists, among whom are M. Paul Boyer, administrator of the Ecole des langues orientales, and some of the professors of the school, have just formed a society called the Société d' assistance morale aux blessés militaires musulmans for the purpose of visiting and in other ways taking an interest in the welfare of wounded Mohammedan soldiers.

PROHIBITION OF REMOVAL OF THE BODIES OF SOLDIERS KILLED BY THE ENEMY

The minister has received many requests for permission to remove the bodies of soldiers killed by the enemy. No such permission has been granted. Removal and transportation of bodies is explicitly forbidden for hygienic reasons, in the zone of military operations, and no favoritism has been shown. Instructions have been given that so far as possible all graves shall be marked.

MEASURES OF WAR HYGIENE

At the last meeting of the Paris section of the Association générale des hygiénistes et techniciens municipaux, the chemist Samuel Bruère, of the laboratory of toxicology, described an economical sand and charcoal filter for the decolorization of water sterilized by potassium permanganate. The filter is composed of a glass lamp-chimney over the bottom of which is tied a piece of fine cloth, and in which is placed successive layers of fine sand, pulverized charcoal and coarser sand. A medium-sized lamp chimney should hold about 10 gm. of charcoal, which is sufficient to decolorize 50 liters (quarts) of water treated with 10 mg. of permanganate per liter, a dose sufficient to destroy in ten minutes all the dangerous germs and toxins in the most contaminated water.

M. G. Risler, president of the section of hygiene of the Musée Social, spoke of the necessity of rebuilding our cities which have been destroyed by the enemy with all possible hygienic improvements, especially from the point of view of the possible extension of the city.

THE PUBLIC FOOD-SUPPLY

The military administration has taken measures to reduce the requisitions of living animals for the intrenched camp of Paris and to reserve the best of these animals which are fit for reproduction and for work for ultimate distribution in the provinces invaded by the enemy.

In view of the necessity of compensating for the ravages made among French flocks and herds, the Académie des sciences believes that in order to increase the animal food-supply, sufficiently to meet the needs of the year 1915 and those following it would be necessary to forbid, as much as possible, the slaughter of young animals and to make as economical arrangements as possible for producing canned, salted and frozen meats. The proposal was made to create, without waiting for the end of the war, large cold-storage warehouses, such as are used abroad, especially in Great Britain, for the preservation of frozen meats. The foundation of abattoirs with refrigerating plants was also recommended for the regions where animals are raised for food.

PROMOTION OF HOSPITAL INTERNS TO THE GRADE OF ASSISTANT SURGEON

To reach the grade of assistant surgeon, it is necessary to have the degree of M.D. Up to the present, therefore, hospital interns, not having received a doctor's degree, were restricted to the subsidiary functions of assistant physician, which corresponds to the grade of sergeant, without possibility of advance and under conditions which did not permit them to render all the medical and surgical service which might be expected from their professional experience. The government has decided that during the war, interns of the hospitals of Paris may be promoted to be assistant surgeons.

DR. MARIE WOUNDED

Among the physicians wounded is Dr. Auguste Marie, physician in chief of the asylums of Villejuif and director of the psychiatric laboratory at the Ecole des Hautes Etudes of Paris. He was struck by a bullet in the head while he was caring for a wounded man in a trench.

A VISIT FROM SWISS PHYSICIANS

A mission of Swiss physicians has come to France to visit our hospitals and sanitary formations. It is composed of Colonel Hauser, chief medical officer of the Swiss army, Colonel de Montmollien, physician of the second division and Majors Roehring and Hepli. The mission visited successively the hospitals of Lyons, Dijon and Paris.

PROPHYLAXIS OF INFECTIOUS DISEASES IN THE ARMY

The administration of the health service of the war department has just sent to physicians of the training camp instructions on the prophylaxis of the principal contagious diseases. It is recommended that young soldiers and new recruits be vaccinated against small-pox on their arrival at the camp. Ten days afterward, the antityphoid vaccination should be begun (four successive injections of 0.5 c.c., 1 c.c., 1.5 c.c. and 2 c.c. of Vincent's vaccine) which ought to be ended six weeks after arrival. The reservists are also examined on their arrival and made to undergo the double vaccination against small-pox and typhoid. The instruction then prescribes various measures of early isolation in cases of scarlet fever, diphtheria, mumps, measles and cerebrospinal meningitis; the disinfection of clothing, bedding, etc., as well as the cleaning of living quarters.

If typhoid should break out, an investigation should be made of the drinking-water of the barracks, which should be effectively purified if found contaminated. Chlorinated lime, 20 per cent. or copper sulphate 5 per cent. or still better, calcium chlorid 2 per cent. are to be used for the daily disinfection of water-closets, and, if necessary, their contents.

The physician of the camp should report the appearance of the first case of contagious disease immediately to the commander and to the director of the health service. He should, moreover, send the director of the health service, on the first, the eleventh and the twenty-first of each month, statistics of the number of cases since the beginning of the epidemic and the number of cases during the ten preceding days.

THE DAIRY HERD OF THE ENTRENCHED CAMP OF PARIS

The population of Paris suffered from lack of milk only at the beginning of the mobilization during the short period while our railways were encumbered otherwise. To prevent suffering, not only among infants but also among the wounded and patients in hospitals, our military authorities have placed in Paris, especially at the Bois de Boulogne and at the Bois de Vincennes a large number of dairy cows. The arrangement presented great difficulties at first; animals which had suffered from underfeeding and disease, inexperienced attendants chosen from among the refugees, etc. Notwithstanding a safe milk has been provided, thanks to the selection of healthy cows used under regular sanitary inspection. Examination by experienced veterinarians weeded out the cows that were not giving milk, those that were pregnant and those infected with various diseases, especially tuberculosis. All the cows (several thousand) were tuberculin-tested. About 15 per cent. reacted and were at once isolated. Those suspected of any local lesion were at once killed. Mammitis, contagious or not, was carefully hunted out. Frequent analyses are made at the laboratory of the service of veterinary inspection at the center markets. All milk found dangerous is denatured and thrown away, while milk which is merely inferior, that is, milk from the healthy udders of tuberculous cows or of cows with mammitis and milk from cows which have not been delivered is placed in containers of special form. It is boiled and used for feeding calves intended for use in future breeding. Milk of the best quality from the selected cows (which is, however, pasteurized as an additional precaution) is distributed free to the amount of 9,000 or 10,000 liters a day, to more than a hundred philanthropic institutions—hospitals, dispensaries, gouttes de lait, etc.

As M. Gabriel Petit, professor at the Ecole vétérinaire d'Alfort, has said, sanitary veterinary inspection has here given an object-lesson with regard to the services which it will render to public hygiene when the scientific control of milk is systematically organized at Paris.

Measures Against Alcoholism

In view of the important results obtained by the anti-alcohol campaign in Sweden and Norway and the recent energetic measures taken in Russia, the Academie des sciences has passed a resolution in favor of the immediate limitation of the number of licenses to sell alcoholic drinks, the definite prohibition of absinthe and similar liquors and the suppression of the privilege of converting wine into brandy.

The Bust of Pasteur at the Academy of Medicine

At the annual public session of the Académie de médecine, the family of Pasteur presented to the academy a portrait bust of the great scientist by Paul Dubois.

Death of Alfred Fournier

French medical science has just sustained a great loss through the death of the celebrated syphilographer, Dr. Jean Alfred Fournier, formerly clinical professor of clinical and syphilitic diseases at the Faculté de médecine de Paris.

Fournier was born in Paris in 1832. He began his medical studies under the direction of Ricord. He received his medical degree in 1860 and was appointed agrégé professor of the Faculté de médecine de Paris three years later. He occupied the medical chair of cutaneous and syphilitic diseases for many years and his remarkable lessons at the hôpital Saint Louis won for him celebrity in scientific circles all over the world. He had been a member of the Académie de médecine since 1880.

Among Fournier's most important works were his "Researches into the Contagion of Chancre" (1857), "Syphilis "Researches on the Incubation of Syphilis" (1865), "Syphilis and Marriage" (1880), of the Brain" (1879), "Syphilis and Marriage" (1880), "Syphilitic Heredity" (1891) and "Treatment of Syphilis" (1909).

Death of Dr. Jacquet

Dr. Lucien Jacquet, physician of the hospitals of Paris, has just died at Royan. He specialized in diseases of the skin, but, unlike many specialists, he took into consideration rather the whole organism with its disturbed functions than the cutaneous lesion by itself. Thus he did not share the general opinion as to the contagious character of alopecia. He regarded it as nervous origin, generally related to dental caries. Of late years, he insisted also on the relations between certain cutaneous affections, such as pimples of the face, and the habit of eating too quickly (tachyphagia). Jacquet was one of the first men in France to warn against the alcohol peril against which he worked by lectures and publications. He was the author, in collaboration with Besnier and Brocq, of a "Dermatologic Practice" and, in collaboration with Brocq, of an "Elementary Outline of Dermatology."

Personal

Dr. Massabuau, agrégé professor at the Faculté de médecine de Montpellier, has been appointed professor of pathologic anatomy at that school.

Dr. Vautrin, agrégé professor at the Faculté de médecine de Nancy, has been appointed professor of clinical surgery at that school.

The Société de chirurgie de Paris has elected the following officers for 1915: president, Dr. Rochard; vice-president, Dr. Picque, and secretary, Dr. J. L. Faure.

BERLIN LETTER

Berlin, Dec. 22, 1914.

The War

HEALTH OF SOLDIERS

The health of our army in general has remained good, although our troops have suffered somewhat from the typhoid epidemics which have prevailed among the civil population in France and Belgium. There has been as yet no great epidemic, and the total number of cases has remained far behind that of the Franco-Prussian War, which amounted to 75,000. The death rate varies much in different army corps, but unfortunately in exceptional cases reaches 20 per cent. Naturally, it is impossible so far to form even an approximate judgment as to the influence of the protective vaccination. The same is true of dysentery, which in the autumn reached a quite marked dissemination, but at present, according to reports received from several sources, appears to have almost completely declined. With reference to the etiology of dysentery, we have gained considerable information through this war; it seems that more organisms are involved than was formerly supposed. The Y bacillus has been found very frequently, especially in cases with a mild course which did not give the impression of dysentery. On the other hand, it has been found that the disease caused by Flexner's germ runs a severe course. Cholera is not present in our army. The cases introduced from Russia and Galicia have been completely isolated. Exanthematic typhus has occurred in a few cases among our troops in Poland.

DISEASES DUE TO CLIMATIC CONDITIONS

The diseases due to cold, especially pneumonia, are strikingly few, considering the long periods that the soldiers lie in the trenches exposed to wind and water.

THE SUBSTITUTES FOR BANDAGE MATERIAL

The authorities have recommended economy in the use of bandage material in view of the interruption of the importation of cotton. Several substitutes have been recommended, particularly lint (charpie), moss and materials made of cellulose.

EPIDEMICS SPREAD FROM RUSSIA

Some cases of cholera have been discovered among the Russians in two prison camps. A few days ago an epidemic of typhus fever broke out among several hundred Russians in the prisoners' camp near Cotbus in the province of Brandenburg. Unfortunately, two Germans also were attacked with this disease and an under-officer of the medical corps died of it. Apart from these two cases, cholera and typhus have been restricted hitherto to the Russians. The principles introduced into practice by Robert Koch have so far yielded brilliant results in the fight against epidemics in war. By immediate isolation of the patients and careful disinfection of all infected excreta, the most effective measures for the localization of the epidemic were carried out at once. In this relation the destruction of lice is of the greatest importance for typhus fever.

This "zoonosis" is very widely distributed in Russia. Our soldiers, and especially the officers, make very lively complaints about the evils which they have to suffer from the vermin in the Polish houses. Besides lice, fleas and bedbugs play a not insignificant rôle. The lack of cleanliness which prevails in Polish dwellings defies all description. For this reason, the soldiers prefer to stay in the artificially constructed rooms in caves or the wooden barracks or tents rather than be quartered in houses. For destruction of lice, articles published in the medical journals recommend certain remedies, the most thorough of which is naturally the burning of worthless clothing. But in addition there is disinfection with a jet of steam and treatment with sulphur fumes. Professor Blaschko recommends for protection against body lice, the anointment of the body with 5 per cent. naphthalin petrolatum or dusting with a naphthalin powder. As a protection against head lice, he recommends as best of all, to cut the hair very short.

TREATMENT OF GUNSHOT WOUNDS

New evidence is continually afforded of the benignity of gunshot wounds. Even wounds of the spinal cord appear not to afford as unfavorable a prognosis as had been assumed from experience in the war in the Balkans and the Russo-Japanese War. In some cases early operations have been quite successful. As a rule, to be sure, severe injuries of the spinal cord result fatally. The extent of injuries which a soldier with a good constitution can overcome is shown by a case in which the soldier was struck at the same time by eight bullets from a machine gun. One struck the head, one went obliquely through the upper jaw, another wounded the chin, one bullet went through the right arm and another wounded the left wrist. Only two were satisfied with wounding his helmet and his boot. It is reported that even this patient is on the road to recovery.

THE FOOD SUPPLY

The instruction of the people in questions regarding nutrition, is conducted with great zeal. Although several experts in scientific matters have stated that the attempt to starve us out has no prospect of success, yet on the other hand, it is self-evident that economy should be practiced in the use of the foodstuffs which we have on hand. In this matter housewives and cooks are the chief ones who must practice precautionary measures. For this reason, physicians, as well as the leaders of the woman movement who have been active in social and philanthropic work, are spreading information both in lectures and in circulars with regard to the nutritional value of the various foodstuffs. A circular published by Rubner and Zuntz, professors of political economy and physiology, has the following advice which, on account of its fundamental importance, may well interest those countries which are not involved in the war at present:

> "1. Treat all nutritious material respectfully and economically and use carefully every utilizable refuse.
>
> 2. Eat the army bread (that is, rye bread with the addition of 20 per cent. of potato starch) and demand it from your baker. It is nourishing and as palatable as plain rye or wheat bread. Potatoes are plenty but the bread cereals will suffice only if from 10 to 20 per cent. of potatoes are baked in the loaves or if less bread and more potatoes are eaten.
>
> 3. Reserve the wheat bread, such as rolls, for patients and invalids and restrict particularly the use of cake, butter cakes and other pastry to the lowest limits for we are short one-third of the previously necessary supply of wheat and wheat flour.
>
> 4. Be sparing in the use of meat, fat and butter. To be sure, we have now an abundant supply of cattle for slaughter because many farmers no longer have the fodder formerly imported, but that is no reason why one should consume more meat. If this happens, the supply will soon become very scanty. The use of meat, fat and butter should be restricted now so that our people will suffer no lack at a later time. Whoever can, should lay in a stock of preserved provisions, that is, smoked ham and bacon and dried sausages and lard for his home use, deliberately and without hurry.
>
> 5. The bulk of the food must be formed by our indigenous vegetable material, potatoes, rye, wheat, oats, buckwheat, vegetables, fresh and preserved fruit. Sugar can be used freely. Sugar, which is on hand in almost excessive quantities, is an excellent nutriment and a substitute for fat and butter. In addition, one should use milk and cheese, particularly skimmed milk and skimmed milk cheese, which are an excellent substitute for meat on account of their protein contents."

Nothing is said in this circular about alcohol but there is in Germany a tendency to temperance, as I have formerly mentioned, which previous to the outbreak of the war had led to very satisfactory results. The use of spirits for beverages, according to the official figures for 1912-1913, had fallen again in the German Empire. The corresponding figures for 1911-1912 were 1,933,532 hectoliters, or 2.9 liters per capita of the population, reckoned as 100 per cent. spirits. The consumption in the last fiscal year amounted to only 1,871,200 hectoliters, or 2.8 liters per capita. This was the figure also in 1909-1910. On the other hand, the employment of tax-free spirits for industrial purposes had increased: 1912-1913, 2.6, as compared with 1911-1912, 2.4 and 1910-1911, 2.2 liters per capita.

Marriages

Warren Barrett Allen, M.D., Oakland, Cal., to Miss Gertrude I. Mitchell of San Francisco, December 9.

Louise Anderson Merrimon, M.D., Asheville, N. C., and Mr. Nelson R. Perry, at Cincinnati, January 6.

Fred Everette Herzer, M.D., to Lavina Alice Baxter, M.D., both of Loma Linda, Cal., January 2.

Dudley Steele Conley, M.D., New York City, to Miss Sidney Ann Boales of St. Louis, January 2.

Joseph Ralph Wagner, M.D., to Harriett Beale Jennings, M.D., both of Palacios, Tex., January 2.

Wesley Lewis Boyden, M.D., Green Bay, Wis., to Miss Ora Lee of Oconto, Wis., January 1.

Ralph Leland Taylor, M.D., to Miss Nelle Warthen, both of Davisboro, Ga., December 23.

Samuel M. Howell, M.D., to Miss Annie Harvey, both of Cartersville, Ga., December 27.

Aristine Pixley Munn, M.D., and Charles Recht, both of New York City, January 2.

John D. Greenamyer, M.D., to Miss Grace Allen, both of Niles, Mich., January 1.

Deaths

Charles William Chancellor, M.D. Jefferson Medical College, 1853; during the Civil War medical director of General Pickett's Brigade in the Confederate service; after the close of the war professor of surgery and dean of the Medical School of Washington University, Baltimore; consul to Havre, France, during the Cleveland administration; school commissioner of Baltimore; for several terms alderman of the city, and in 1877 president of the common council; a member of the board of managers of the Maryland State Hospital for the Insane, and president of the Maryland State Lunacy Commission in 1880; secretary and executive officer of the Maryland State Board of Health in 1885; for the last fourteen years a resident of Washington, D. C.; died at his home in that city, January 3, aged 84.

Edward Maxwell Wiley, M.D. Indiana Medical College, Indianapolis, 1875; of Lexington, Ky.; a Fellow of the American Medical Association; president and censor of the Fayette County Medical Society; for four years superintendent of the Eastern Kentucky State Hospital, Lexington; a neurologist and psychiatrist of high rank; died in St. Joseph's Hospital, Lexington, January 11, after an operation for hypernephroma of the left kidney, aged 64. The regular monthly meeting of the Fayette County Medical Society was devoted to resolutions on Dr. Wiley's death and to eulogies of his worth as a man and a physician.

William Boddie Rogers, M.D. Bellevue Hospital Medical College, 1878; a member of the Tennessee State Medical Association; professor of surgery and dean of the faculty of Memphis Hospital Medical College since 1886; surgeon of the Bluff City Grays during the yellow fever epidemic of 1878-1879; president of the city board of health for three terms; a surgeon of renown and a teacher of great discretion, progressive and yet conservative; died in St. Joseph's Hospital, Memphis, January 13, a day after an operation for ulcer of the stomach, aged 58.

William Pitt Lawrence, M.D. University of Nashville, Tenn., 1878; a member and president in 1908 of the Florida State Medical Association; once president of the Hillsboro County Medical Society; surgeon of volunteers throughout the Spanish-American War, and later on duty during the Boxer uprising in China where he served as acting assistant surgeon U. S. Army for two years and a half; one of the most prominent and respected physicians of Tampa, Fla.; died suddenly at his home in that city, December 24, from heart disease, aged 57.

Walter C. Parker, M.D. Medical College of Ohio, Cincinnati, 1886; a member of the Kentucky State Medical Association and formerly president of the Kentucky Midland Medical Association; local surgeon of the Louisville and Nashville Railway at Versailles, Ky.; died at his home in that place, November 26, from pulmonary tuberculosis, aged 55.

Charles Ross Jackson, M.D. Yale University, New Haven, Conn., 1888; a Fellow of the American Medical Association; founder and first president of the West Side Clinical Society, New York City; consulting physician of the General Hospital, Saranac Lake; formerly adjunct professor of clinical diagnosis in the New York Polyclinic; resident physician at the Lake Placid Club; a prolific writer and a novelist of no mean ability; died at his home in Lake Placid, N. Y., January 4, from angina pectoris, aged 47.

Charles Barkley Warder, M.D. Jefferson Medical College, 1885; University of Pennsylvania, Philadelphia, 1888; a member of the board of managers and for many years medical director of the Stetson Hospital, Philadelphia, and a member of the board of directors of the Philadelphia Hospital Association; a specialist on diseases of the ear, nose and throat; died at his home in Philadelphia, January 5, from cerebral hemorrhage, aged 51.

George Huston Chapman, M.D. Jefferson Medical College, 1874; of Uniontown, Ky.; a member of the Kentucky State Medical Association and president of the Union County Medical Society; chief judge of surgical instruments at the World's Fair, Chicago, in 1893; died suddenly near Uniontown, December 20, from heart disease, aged 65.

Charles Curtiss Wadsworth, M.D. University of Wooster, Cleveland, 1874; a member of the Medical Society of the State of California; formerly president of the San Francisco Medical Society and for ten years secretary of the State Board of Medical Examiners; died at his home in San Francisco, January 1, aged 65.

John Milton Adey, M.D. Albany (N. Y.) Medical College, 1899; for fifteen years registrar of vital statistics of Cohoes, N. Y.; a member of the staff of the Cohoes Hospital and for a time an official of the Vital Statistics Bureau of the New York State Board of Health; died at his home in Cohoes, N. Y., December 26, aged 40.

Miner C. Hazen, M.D. University of Michigan, Ann Arbor, 1855; said to have been the oldest member of the Middlesex County (Conn.) Medical Association; county commissioner for six years and one of the original corporators of the Middlesex County Hospital; died at his home in Haddam, December 25, aged 85.

William D. Howe, M.D. University of Louisville, Ky., 1885; of Carlisle; while under treatment for malignant disease in the Good Samaritan Hospital, Lexington, died January 2 from an incised wound of the thigh severing the femoral artery, self-inflicted it is believed, with suicidal intent, aged 48.

Henry Roberts, M.D. Jefferson Medical College, 1845; a pioneer resident and practitioner of North Scranton, Pa.; postmaster of Providence, Pa., for several years and for nine terms a member of the select council of Scranton; died at the home of his daughter in Towanda, Pa., December 31, aged 93.

Thomas Hutchinson Ashton, M.D. University of Nashville, Tenn., 1865; formerly a member of the Nebraska State Medical Association; surgeon of volunteers during the Civil War; for more than quarter of a century a practitioner of Syracuse, Neb.; died at his home in Lincoln, Neb., December 29, aged 73.

Fred Hamilton Weir, M.D. University of Michigan, Ann Arbor, 1885; of Portland, Ore.; a specialist on diseases of the eye, ear, nose and throat; a member of the Oregon State Medical Association; formerly a resident of Laporte, Ind.; died at his home in Portland, about January 3, aged 50.

Sterling J. Gates, M.D. Tulane University, New Orleans, 1895; also a graduate in pharmacy; a Fellow of the American Medical Association and formerly a practitioner of Franklin, La.; but for the last two years a resident of Cliff, N. Mex.; died at his home in Cliff, about January 4, aged 44.

Calaway Garner Reagin, M.D. Miami Medical College, Cincinnati, 1877; a Confederate veteran; for many years a practitioner of Duquoin, Ill., and once president of the Perry County Medical Society; died at his home in Fort Meade, Fla., December 31, from pneumonia, aged 79.

Franklin A. Clement, M.D. Washington University, St. Louis, 1873; for thirty-five years local surgeon for the Burlington System at Greenfield, Ill., and twice mayor of the city; died at his home December 25, aged 64.

William P. White, M.D. University of Louisville, Ky., 1869; a Confederate veteran and health officer of Louisville, Ky., from 1891 to 1894; died at his home in that city, December 27, from pneumonia, aged 71.

Nathaniel Morton Ransom, M.D. Berkshire Medical College, Pittsfield, Mass., 1861; for more than fifty years a member of the Massachusetts Medical Society; also an adventist clergyman; died at his home in Somerville, Mass., January 8, from arteriosclerosis, aged 85.

Joseph Hunt Wilson, M.D. New York University, New York City, 1850; founder of the Somerville (N. J.) Library and once editor of the *Unionist Gazette;* an employee of the New York Custom House for many years; died at his home in Somerville, January 2, aged 85.

John Otto Grotthuss, M.D. Wisconsin College of Physicians and Surgeons, Milwaukee, 1900; of Stockholm, Wis.; coroner of Pepin County; died in St. John's Hospital, Red Wing, Minn., January 9, from embolism, after an operation for tumor of the bladder, aged 51.

Mahlon Henry Beary, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1880; surgeon of the One Hundred and Twenty-Eighth Pennsylvania Volunteer Infantry during the Civil War; died at his home in Allentown, Pa., September 18, from senile debility, aged 74.

Hercule Dansereau, M.D. Albany (N. Y.) Medical College, 1853; for more than fifty years a resident of Thibodaux, La.; a Confederate veteran; for several years a member of the board of aldermen of Thibodaux; died at his home in that place, January 2, aged 82.

Aaron S. Miller, M.D. New York University, New York City, 1862; a member of the Medical Society of the State of Pennsylvania; died at his home in Saegersville, Pa., December 31, from cerebral hemorrhage, aged 75.

Nelson McGarvin, M.D. Victoria College, Coburg, Ont., 1856; for many years a practitioner of Butte, Mont., but for the last three years a resident of Waterloo, Ont.; died at his home in that place, December 25, aged 84.

Robert S. Tidwell, M.D. University of Tennessee, Nashville, 1890; a Confederate veteran, and for many years resident physician of Tate Springs, Tenn.; died in that place, December 16, from epilepsy, aged 68.

John Miller Smith, M.D. Hahnemann Medical College, Chicago, 1869; one of the oldest practitioners of Lafayette, Ind., died at his country home near that city, December 26, from chronic bronchitis, aged 67.

Tilford T. Metcalf, M.D. Medical College of Ohio, Cincinnati, 1882; for twenty-five years county treasurer of Kenton County, Ky.; died at his home in Independence, December 25, aged 54.

James Winter Wamsley, M.D. Jefferson Medical College, 1893; also a graduate of the Philadelphia College of Pharmacy; died suddenly at his home in Philadelphia, December 21, aged 40.

William Payton Tucker, M.D. Ensworth Medical College, St. Louis, Mo., 1893; formerly of Kansas City, Mo.; died in a sanatorium in Colorado Springs, Colo., December 25, aged 45.

C. DeWitt Hudson, M.D. Georgia College of Eclectic Medicine and Surgery, Atlanta, 1901; president of the Waco (Texas) Sanitarium; died in Kalamazoo, Mich., December 25.

James Dick Wallace, M.D. Rush Medical College, 1893; a member of the Iowa State Medical Society; died at his home in Plover, Ia., December 17, aged 51.

Charles W. Lawton, M.D. University of Southern California, Los Angeles, 1905; of Taft, Cal.; died in a hospital in Bakersfield, Cal., December 21, aged 34.

James B. Ewart, M.D. Memphis Hospital Medical College, Memphis, Tenn., 1891; of Ione, Ark.; died in a hospital in Fort Smith, Ark., December 26, aged 71.

Charles M. Smith, M.D. Albany (N. Y.) Medical College, 1854; a physician and druggist of Albany, N. Y.; died at his home in Albany, September 27, aged 84.

Thomas Smith Middleton, M.D. Medico-Chirurgical College of Philadelphia, 1897; of Chicago; died in New Hope, Pa., December 26, aged 46.

A. E. Van Deventer, M.D. Northwestern University Medical School, Chicago, 1863; died at his home in Oswego, Ill., about December 22.

John H. Morton, M.D. University of Tennessee, Nashville, 1888; died at his home in Knoxville, Tenn., about December 26, aged 52.

Isaac F. Stafford (license, years of practice, Montana, 1889) died at his home in Pony, Mont., December 23, aged 85.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

HAYDEN'S VIBURNUM COMPOUND

Report of the Council on Pharmacy and Chemistry

The following report on Hayden's Viburnum Compound was prepared by a member of the Council's Committee on Therapeutics. The Council held the preparation in conflict with its rules and authorized publication of the referee's report.

W. A. PUCKNER, Secretary.

Hayden's Viburnum Compound, according to the advertising circulars, was first compounded in 1860 by W. R. Hayden. The medical profession is told that W. R. Hayden

> ". . . found by his experiments that a combination of the active principles of *Viburnum Opulus, Dioscorea Villosa,* combined with aromatics, proved a valuable remedy for *Spasmodic Dysmenorrhea.*"

As in 1860 W. R. Hayden was not a physician (he received a diploma from the Eclectic Medical College, New York, in 1867), and, so far as we can learn, he was not a pharmacist or chemist, one wonders what kind of "experiments" he made. Hayden's Viburnum Compound is put on the market by the New York Pharmaceutical Company of Bedford Springs, Mass. The name of this concern may sound imposing, until it is realized that it is merely a trade name adopted by Hayden in exploiting his nostrum.

The advertising matter formerly claimed that Scutellaria (skull-cap) was one of the ingredients of Hayden's Viburnum Compound. As this is no longer mentioned, it is fair to assume that even the manufacturer does not consider the composition to be of vital importance. Stress is laid on the superior efficacy of viburnum opulus in the conditions for which the preparation is recommended; it is emphasized that it is viburnum opulus, and not viburnum prunifolium, that is the important ingredient of Hayden's Viburnum Compound. The label, in accordance with the requirements of the Food and Drugs Act, declares that the preparation contains 50 per cent. alcohol. The claim is made:

> *"It is free from all narcotics and leaves no unpleasant after-effects."*

The medical profession is told that Hayden's Viburnum Compound is a remedy in:

> "Hysteria, Bilious Colic, Cramps of Cholera Morbus, Muscular Cramps, . . . Nervous Diseases of Pregnancy, Threatened Abortion, Post-Partum Pains, Puerperal Convulsions, Rigid Os, Dysmenorrhea, Menorrhagia."

DISCUSSION OF ALLEGED INGREDIENTS

Viburnum Opulus (*Cramp Bark*).—Botanists and pharmaceutical chemists declare that this drug has not been on the American market for many years, if ever, and that the drug used and even described as viburnum opulus is really the bark of another plant. Viburnum opulus and its preparations are therefore to be dropped from the next United States Pharmacopeia. The principal constituents of viburnum opulus are stated to be a glucosid, viburnin, a bitter resin, and a little tannin, with small amounts of earthy carbonates and phosphates and organic acids (Culbreth, Ed. 4, 1906, p. 591). The glucosid and resin being bitter, the drug might have a slight stomachic action (if, indeed, any such effect is actually produced by "bitters"); the small amount of tannin might make it slightly astringent; its fruit acids (citric and malic) might make it slightly diuretic. Even if viburnum opulus were present in Hayden's Viburnum Compound there is no clinical or laboratory proof that it, if given alone—without alcohol or other drug—has any antispasmodic or nervous sedative action.

Dioscorea Villosa (*Wild Yam*).—This drug contains a saponin and an acrid, irritant resin. It has never been proved clinically or experimentally that this drug has any action whatever except that its irritant resin might, if taken in sufficient quantity, cause irritation of the stomach and vomiting.

Aromatics.—The irritation produced by concentrated aromatics causes increased peristalsis and consequently may, if there is no obstruction, relieve intestinal stasis and intestinal colics. Therefore, a preparation containing large amounts of aromatics, especially if given in hot water, would have practically the same effects in the "cramps of a cholera morbus" or other forms of acute diarrhea as a home-brewed cup of spiced tea—and no more.

Alcohol.—This drug is a muscle relaxant, and sufficient doses might, by relieving spasm, relax a muscularly contracted os uteri and relieve post-partum pains. Alcohol dilates the blood-vessels both in the abdomen and on the surface of the body. It may thus either relieve uterine bleeding by lowering the blood-pressure and causing more blood to go to other parts, or increase uterine bleeding by relieving arterial and muscle spasm. Alcohol is also a habit-forming narcotic (Hayden's Viburnum Compound is advertised as "free from all narcotics"!) and when habitually used by either males or females tends to impair the capacity to produce normal offspring.

Even if the manufacturer's "formula" be accepted, Hayden's Viburnum Compound contains no therapeutically active ingredient except alcohol and aromatics. The recommended dose of this preparation is ". . . two teaspoonfuls in six of boiling hot water or milk and one teaspoonful of sugar, every fifteen or twenty minutes until relief is obtained."

> "Frequently after taking the Viburnum Compound the patient will sleep soundly for several hours from the sudden cessation of pain; in such cases she should never be awakened through any fear of oversleeping, as Hayden's Viburnum Compound does not contain any narcotic whatever, nor does it leave any disagreeable after-effects, and it may be given to a child when necessary without any special caution."

Read the foregoing and then remember that it means that one teaspoonful of alcohol (the equivalent of two teaspoonfuls of whisky) is to be given in hot water, every fifteen or twenty minutes until relief is obtained and the patient is asleep. Why not use plain language and say "until she is drunk"?

The thoughtful physician would consider it decidedly unwise to give alcohol to a young girl, to a prospective mother, or to a young mother, except under extraordinary circumstances. He would know that the menstrual pains for which this preparation is recommended are likely to be recurrent, and that the repeated taking of alcohol for recurrent pain is fraught with danger—the danger of initiating the alcohol habit. If, however, a physician does elect to give alcohol as a drug, he must let the conditions that govern each individual case determine whether it is not better to give it as whisky, or to disguise it in a prescription of his own. Above all the physician should be conscious that he is giving the drug, alcohol; and this is not the case when he prescribes a ready-made nostrum. If he writes a prescription containing whisky or other alcoholic he will take measures to avert the dangers inseparable from the use of this drug.

CONCLUSIONS

1. Even if the manufacturer's formula for Hayden's Viburnum Compound be accepted, it is apparent that any therapeutic activity the preparation may have is due essentially to the alcohol and aromatics.

2. Alcohol is a narcotic drug, and a habit-forming drug. Physicians ordering this preparation may, by so doing, be initiating the alcohol habit.

3. Whatever result is obtained by the use of Hayden's Viburnum Compound in the treatment of uterine or pelvic disturbances, is due to the alcohol it contains. The fact that menstrual pains are likely to recur might, when this preparation is relied on, become a factor in the formation of the alcohol habit.

4. Whatever result is obtained by the administration of Hayden's Viburnum Compound in the treatment of gastro-intestinal disturbances is due to the alcohol and the aromatics it contains.

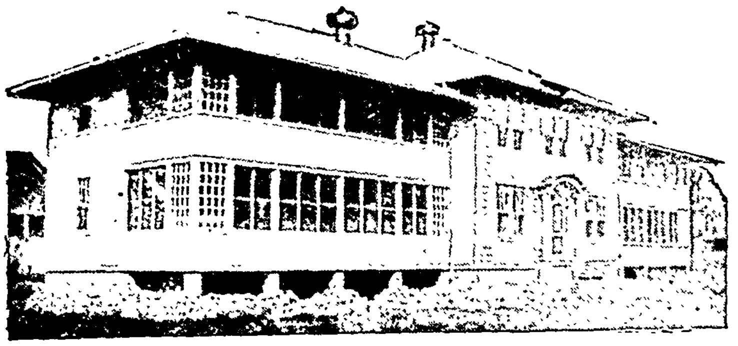
5. Whisky has the same alcoholic content (50 per cent.) as Hayden's Viburnum Compound; the dangers in the use of whisky are well known and its value as a therapeutic agent is being questioned more and more every year.

Holding the exploitation of this proprietary a danger to the public and a detriment to scientific medicine the referee recommends publication of this report as a protest against such irrational therapeutics. The profession should recognize that most, if not all, of the preparations recommended for painful menstruation and for all kinds of pelvic pain contain large percentages of alcohol, and that whatever physiologic effect is produced is, for all practical purposes, due to the alcohol.

Correspondence

Salvarsan and Neosalvarsan in Syphilis

To the Editor:—The article by Drs. Nelson and Haines of Fort Leavenworth, "Observations of the Results of Seven Months' Experience with Salvarsan in the Treatment of Syphilis" (The Journal, Dec. 26, 1914, p. 2277), is of great interest to physicians called on to decide between the use of salvarsan and neosalvarsan. Their conclusion that salvarsan is far more curative than neosalvarsan is, in my opinion, quite correct. My own experience has fixed the superiority of salvarsan at approximately 50 per cent., i. e., four doses of salvarsan given from seven to ten days apart give me curative results equal to six doses of neosalvarsan given at the same intervals, although the clinical results from the first doses of each are the same.



Detroit Tuberculosis Sanatorium.

It is to be regretted that some of the conclusions from their experience are rendered of less value owing to their having used the combined treatment. The quite opposite effects of mercury and salvarsan on the Wassermann positive render such observations rather unintelligible.

Any given number of cases of active secondary syphilis thoroughly treated with mercury alone, by injection or inunction, for six weeks will show a large percentage of negative Wassermanns, although the absence of reinfections after millions of such treatments indicates that mercury is not curative. Mercury is a peacemaker and not a destroyer, the treponemata become inactive, the antibodies disappear, and the serum reaction becomes negative. On the contrary, salvarsan is a destroyer of the treponemata and, responding to the released endotoxins, the antibodies increase and the negative serum test of a latent case of syphilis becomes positive and the positive Wassermann of an active case becomes more positive.

In spite of this fact, numerous reinfections show us that salvarsan when sufficiently used is curative. Observations of many such cases indicate that the serum reaction of a case cured by a sufficient salvarsan treatment without mercury will remain positive, a fading positive, for a month or two after the patient is cured. This fading positive would probably be absent in patients getting mercury also, and likewise, other patients getting the combined treatment would show a negative Wassermann while yet uncured. One drug increases and the other lessens the serum reaction, so what can we judge from such reactions when both drugs have been used?

A serum test which becomes negative during the third or fourth month after the treatment would indicate *not* a cure but the arrival of latency.

It is to be hoped that these careful observers having such controllable cases will supply another series, treated with salvarsan alone. Such observations would be of the greatest value and, as mercury alone has never proved curative, while salvarsan alone has cured many patients once, some twice and in at least one instance, to my knowledge, three times, they would be doing their patients no possible injustice.

The failure of these authors to notice any endotoxin reactions whatever seems impossible. I cannot conceive of seventeen patients with secondary syphilis receiving their first full dose of salvarsan or neosalvarsan (0.1 gm. of salvarsan to each 25 pounds of net weight, or 50 per cent. more of neosalvarsan) without an endotoxin reaction. I do not mean that such patients would become ill, but there would at least be a fractional rise above the temperature of the patient while on the table probably only 0.1 or 0.5 degree, and one or more bowel movements. Either or both of these symptoms constitute a positive endotoxin reaction, but temperatures should be noted hourly. In secondary cases given full doses of salvarsan every week or ten days until the endotoxin reaction cannot be noted by the most careful observation, the patients may, in my opinion, be regarded as cured; they will be found to have usually a fading positive Wassermann which becomes negative in from two to eight weeks.

E. H. Martin, M.D., Hot Springs, Ark.

[The foregoing letter was referred to Dr. Nelson, who replied:]

To the Editor:—We have at this hospital at this time fifty cases of syphilis undergoing treatment with mercury. When this is completed our results will be published. These results I do not feel at liberty to anticipate, but in view of the positive statement in the third paragraph of Dr. Martin's letter will say that in seven weeks of energetic treatment with mercury alone the serum reaction has not been changed in a single case of the fifty under observation. This agrees with work previously done. In reference to the last paragraph concerning reactions, desire to say that while Dr. Martin may not be able to believe in the absence of reactions in the cases mentioned, yet nevertheless it is a fact.

Kent Nelson,
Major, Medical Corps, U. S. Army,
Fort Leavenworth, Kan.

Provision for Tuberculous Infants

To the Editor:—Dr. Alfred F. Hess was certainly correct in his article of recent date on "The Neglect to Provide for the Infant in the Antituberculosis Program." Interest in the child as an important factor in this problem has greatly increased however; and Dr. Sach's letter in your issue of January 2 shows that this includes the infant.

I beg to enclose a photograph of the Anna T. Dodge Pavilion for Children at the Detroit Tuberculosis Sanatorium. One quarter of the space in this building is devoted to the care of infants. It was opened on November 29, 1914, and the age of the youngest patient there at present is nine months.

The building was built especially for children and has many devices for their safety, care and comfort. We have already been obliged to use an isolation room for a child found to be a diphtheria carrier. The building includes a large school-and-play room which has its own screened-in porch. If any of your readers are planning such a building we shall be glad to answer questions about this one.

Herbert M. Rich, M.D., Detroit.

Suspension of Medical Courses in Vienna

To the Editor:—Knowing that many physicians are desirous of hearing the exact conditions in regard to courses and medical work in Vienna, I am taking the liberty of writing you.

Since the war began, no medical courses have been given in Vienna, and none will be until the war is over. The club rooms of the American Medical Association of Vienna will remain open, and information may be obtained by writing our secretary.

All of the clinics in Vienna are running the same as before the war, with a much reduced force of assistants and patients. In regard to medical work in Vienna at the present time, I would not advise any one to come until after the war is over, although for a limited number of men, work could be secured in certain hospitals or clinics.

It is my opinion that as soon as the war is over, the courses and work will begin at once, the same as before.

Frank C. Davis,
President, American Medical Association of Vienna,
Vienna VIII, Schlösselgasse 28.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

HEMOPTYSIS

To the Editor:—From the study of two cases of hemoptysis I am inclined to the belief that hemorrhage from the lungs may occur without any distinct pathology, being brought on by severe constipation. The first patient I had under observation for over two years and the present patient for thirteen months. In neither have I been able to detect any signs of pulmonary consolidation, the health (except for the hemorrhages) has been excellent, both more than maintaining their weight, both negative to intradermal injections of Koch's tuberculin. The hemorrhages occur at various intervals ranging from six weeks to three months, and are always preceded by a period of severe constipation, and cease as soon as the bowels are well cleaned out.

Neither patient has any cardiac disturbance, and having seen both during an attack, I am sure the bleeding is from the lungs and not from the stomach.

I would like to know if others have had similar cases or if any other suggestion as to the cause of the hemorrhages can be given.

S. Salzman, M.D., Toledo, Ohio.

Answer.—References are found in the literature to a number of peculiar cases of hemoptysis, but the titles do not enable us to say whether constipation was a prominent symptom in them. It is easy to understand how intestinal changes might raise the blood-pressure in the venous system so as to provoke hemorrhage in persons specially predisposed. However, it is well to keep in mind other possible causes.

Recurrent hemoptysis in subjects of chronic arthritis has been observed.

Troublesome bleeding from the lungs may occur in diseases accompanied by hemorrhages elsewhere or by hemorrhagic tendencies, as scurvy, leukemia or purpura.

The following additional causes are to be considered: Aneurysm, arteriosclerosis and distomiasis. Distomiasis is a rare condition in this country, but apparently more prevalent than formerly, because of infection by *Paragonimus westermanii.* The symptoms have been summarized by Stiles and Hassell (*Public Health Reports,* 1900, xv).

STATES RECIPROCATING WITH NEW YORK

To the Editor:—I hold a New York state license, 1911. Kindly inform me with what states I may reciprocate. J. H.

Answer.—New York has established reciprocal relations with Delaware, Indiana, Michigan, New Jersey, Ohio, Utah, Virginia and Wisconsin.

Preventogram.—The common drinking cup, the common towel or the common pencil, are common causes of diseases and not uncommonly hasten the common end of mankind.—Pittsburgh *City's Health.*

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Kansas: Topeka, Feb. 9-11, 1915. Sec., Dr. H. A. Dykes, Lebanon.

New York: Albany, Buffalo, New York, Syracuse, Jan. 26-29, 1915. Mr. H. H. Horner, Chief, Examination Division, State Education Bldg., Albany.

New Entrance Requirements for Harvard Medical School

On recommendation of the faculty of medicine, the Harvard Corporation has recently changed the requirements for admission to the Medical School which are now as follows:

Graduates in arts or science of approved colleges or scientific schools who can furnish evidence (a) that they have such knowledge of physics, biology, general chemistry, and organic chemistry, as may be obtained from one year's course in each of these subjects as given in approved colleges and scientific schools (in organic chemistry, half courses of good grade may be accepted); (b) that they have a reading knowledge of French or German.

Students who have completed two years' work in a college or scientific school of high rank, provided they present certificates (a) that they have stood in the upper third of their class, (b) that one year's course has been taken in physics, general chemistry, and organic chemistry, and (c) that they have a reading knowledge of German or French.

This new statement of the entrance requirements differs but slightly from those published in last year's catalogue. The change has not lowered the entrance requirements but has decidedly improved them, since hereafter, every student admitted, whether he holds a collegiate degree or has completed the two years of collegiate work, must have completed courses in the specified sciences and have a reading knowledge of French or German. Formerly degree men were admitted without these specified courses.

Another measure was adopted giving the administrative board the right to refuse applicants if the number seeking admission is too large to be effectively taught. In this connection, it is interesting to note that already three medical schools have limited the number of students to be enrolled: Johns Hopkins admits on the average 90 students in each class; Rush Medical College admits only 100 students each in the classes of the first and second years and 120 students each in the classes of the third and fourth years, and Leland Stanford, Jr., University School of Medicine has limited its enrollment to 25 students in each class. There are other medical colleges with more limited equipment and clinical material which apparently have not appreciated the fact that much better work might be done with smaller classes.

Oregon July Report

Dr. L. H. Hamilton, secretary of the Oregon State Board of Medical Examiners, reports the practical and written examination held at Portland, July 7-9, 1914. The total number of subjects examined in was 15; total number of questions asked, 108; percentage required to pass, 75. The total number of candidates examined was 73, of whom 44 passed, including 9 osteopaths, and 29 failed, including 11 osteopaths and 6 non-graduates. The following colleges were represented:

College	Year Grad.	Total No. Licensed
PASSED		
College of Physicians and Surgeons, Los Angeles	(1914)	1
Hahnemann Medical College of the Pacific	(1914)	1
Bennett College of Eclectic Medicine and Surgery	(1907)	1
Chicago College of Medicine and Surgery	(1908)	1
Chicago Homeopathic Medical College	(1904)	1
Rush Medical College	(1913)	1
University of Illinois	(1914)	1
Tulane University of Louisiana	(1908)	1
Johns Hopkins University	(1914)	2
Boston University	(1912)	1
University of Michigan, Dept. of Med. and Surg.	(1910)	1
University Medical College, Kansas City	(1913)	1
College of Phys. and Surgs., in the City of N. Y.	(1896)	1
Columbia University	(1912) (1914)	2

University and Bellevue Hospital Medical College	(1904)	1
University of Oregon	(1910,1) (1913,1) (1914,8)	10
Willamette University	(1912,2) (1913,1)	3

Medico-Chirurgical College of Philadelphia	(1913)	1
Woman's Medical College of Pennsylvania	(1888) (1901)	2
McGill University	(1896)	1
FAILED		
California Eclectic Medical College	(1914)	1
College of Phys. and Surgs., San Francisco	(1910) (1914)	2
Pacific Medical College*	(1914)	1
Rush Medical College	(1903)	1
Kentucky School of Medicine	(1907)	2
Louisville and Hospital Medical College	(1908)	1
St. Louis University	(1906). (1908)	2
University of Oregon	(1914)	1
Willamette University	(1905)	1
Non-graduates		6

* This is a new institution located at Los Angeles which grants as much as three years of advanced standing for work done in osteopathic colleges, and is, therefore, classified among such schools.

Arizona October Report

Dr. John Wix Thomas, secretary of the Board of Medical Examiners of Arizona, reports the written examination held at Phoenix, Oct. 6-7, 1914. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 10, of whom 6 passed, including 3 osteopaths, and 4 failed, including 1 osteopath. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
College of Physicians and Surgeons, Los Angeles	(1914)	84.4
Chicago College of Medicine and Surgery	(1914)	82.5
Cleveland College of Physicians and Surgeons	(1898)	90.9
FAILED		
Rush Medical College	(1883)	62.3
Sioux City College of Medicine	(1896)	56.2
Pulte Medical College	(1878)	61

Arkansas Eclectic November Report

Dr. C. E. Laws, secretary of the Arkansas Eclectic Medical Board, reports the oral and written examination held at Little Rock, Nov. 10-11, 1914. The total number of subjects examined in was 12; total number of questions asked, 120; percentage required to pass, 75. The total number of candidates examined was 5, of whom 4 passed and 1 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Georgia College of Eclectic Medicine and Surgery	(1910)	83.7
American Medical College	(1909)	81.1
Eclectic Medical University, Kansas City	(1914)	89.1
Eclectic Medical College, Cincinnati	(1912)	90
FAILED		
Bennett Medical College	(1910)	67.2

Delaware December Report

Dr. H. W. Briggs, secretary of the Medical Council of Delaware, reports the written examination held at Dover and Wilmington, Dec. 8-10, 1914. The total number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 8, all of whom passed. One candidate was licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Georgetown University	(1913)	79.6
Howard University	(1913)	87.8
Harvard University	(1914)	85.1

Book Notices

The Occupational Diseases; Their Causation, Symptoms, Treatment and Prevention. By W. Gilman Thompson, M.D., Professor of Medicine, Cornell University Medical College in New York City. Cloth. Price, $6 net. Pp. 724, with 118 illustrations. New York: D. Appleton & Co., 1914.

This book, the first to appear in this country on occupational diseases, is a much needed contribution. The author goes at length into the various phases of the problems and gives a thoroughgoing description of the hazards in the various trades. In the first parts there is a general discussion of the history, etiology and pathology of the commoner trade ailments, and general measures for preventing and treating them. The poisonous substances are then taken up in the order of toxic metals and their compounds, toxic gases, vapors and fumes, toxic fluids and irritant dusts, and in dealing with these the writer has some very practical suggestions as to how intoxication may be lessened. Under the heading "Germs" he includes uncinariasis, with anthrax, foot-and-mouth disease, glanders and septicemia. After dealing with the troubles to which they lay workmen liable, he goes on to the diseases due to the environment in which men work, air pressure, temperature variations, evil effects of light rays and Roentgen rays, and electric shock. There is also a discussion of the occupational diseases as they affect various organs—the blood, nerves, eyes, skin, etc.; something on the influence of alcohol, syphilis and tobacco, and then a grouping of diseases by industries other than those already dealt with. In the appendixes the main hazards and their causes are given in tabular form, and the main provisions of existing laws governing such hazards in the states. Altogether there is the material for an excellent work; but there are so many indications of carelessness in thought and diction that the book falls far short of the front rank.

Pasteur and After Pasteur. By Stephen Paget, F.R.C.S. Cloth. Price 3 shillings 6 pence. Pp. 152, with 8 illustrations. London: Adam and Charles Black, 1914.

This is one of the series of medical history manuals. The selection of Mr. Stephen Paget as the author was most fortunate. His long service as secretary of the Research Defense Society of England, his thorough familiarity with the scientific foundation of medicine, and his extensive writings on scientific subjects, both technical and popular, qualify him admirably for the task of preparing a popular book on Pasteur, his work and its results. The basis of the biographic portion is Radot's well-known "Life of Pasteur." In addition to a sketch of the man and his work, the development of bacteriology and preventive medicine after Pasteur's time is discussed, including the work of Lister, Koch, Roux, Haffkine, Kitasato, Yersin and others. The book is an excellent little manual on the development of modern preventive medicine. It can be read with profit by every physician, and can be recommended without hesitation to laymen desiring information on this subject.

Anoci-Association. By George W. Crile, M.D., Professor of Surgery, School of Medicine, Western Reserve University, and William E. Lower, M.D., Associate Professor of Genito-Urinary Surgery, School of Medicine, Western Reserve University. Edited by Amy F. Rowland. Cloth. Price, $3 net. Pp. 259, with 60 illustrations. Philadelphia: W. B. Saunders Company, 1914.

As a result of the several articles which have appeared during the past few years from the pen of one of the authors of this book, the term "anoci-association" has come to have a definite meaning in surgical practice, a meaning, however, which, judging from some of the criticisms of it, is frequently misunderstood. The idea seems to be prevalent that anoci-association refers to a particular method, or a certain technic in doing a particular thing against which the criticism is directed. As a matter of fact, anoci-association consists in the principles of, or if one may use such a comprehensive term, the philosophy of harmful stimuli; their nature; their effects on the living organism; the manner in which the organism reacts to them; methods of preventing harmful effects, etc. Whether or not one agrees with all of the author's methods is immaterial so long as one recognizes the basic principles; nor need one agree with the author in all of his interpretations, yet it seems scarcely possible for one to follow all of his arguments without being convinced of the underlying truths of anoci-association. It is more than likely that others may, in fact do, differ in points of technic yet accomplish the same result; but, as already stated, it is not a question of points of technic but of principles, and there can be no doubt that the charming enthusiasm of the author in recognizing and promulgating these principles has accomplished and will yet accomplish much good in the manner in which operations are conducted.

Practical Pediatrics. A Modern Clinical Guide in the Diseases of Infants and Children for the Family Physician. By James H. McKee, M.D., Professor of Pediatrics in the Medical Department of Temple University, and William H. Wells, M.D., Assistant Professor of Obstetrics, Jefferson Medical College, Philadelphia. An Appendix on Development and Its Anomalies by John Madison Taylor, A.M., M.D., Associate Professor of Non-Pharmaceutic Therapeutics, Medical Department, Temple University, Philadelphia. Two Volumes. Cloth. Price, $12 net. Pp. 1182, with 386 illustrations. Philadelphia: P. Blakiston's Son & Co., 1914.

This work, taken as a whole, makes at first a rather favorable impression, and on closer analysis falls short of what one can expect of a treatise on this subject to-day. Text-books are not expected to include the very latest current literature, but only that which has been generally accepted and corroborated. The relationship of the thymus to the development of the intellectual faculties is hardly the last word in the physiology of that organ. The same is true of the probable relationship of the pancreas to carbohydrate metabolism. Many of the articles seem diffuse and do not give a clear conception of the diseased conditions. This is especially true of the one on cystitis. Stone is certainly not the commonest cause of vesical inflammation. The chapter on disorders of metabolism dependent on the organic constituents of the food consists of exactly one page; as far as the infant is concerned, four paragraphs. The important contributions of Czerny and Keller, Finkelstein and others are taken care of in one sentence, and the impression is given that there is no such thing as a disturbance due to wrong feeding. Albumin milk is not given in the index, nor could it be located anywhere in the text. To sum up, the work, in certain essentials, falls far short of the standard set by numerous works in the English language.

Allgemeine Chirurgie. Von Dr. Med. Ph. Bockenheimer, Universitätsprofessor für Chirurgie an der Universität in Berlin. I. Teil: Chirurgische Operationslehre. II. Teil: Chirurgische Erkrankungen mit Ausnahme der Geschwülste und Zysten. III. Teil: Geschwülste und Zysten. Paper. Price, 30 marks. Pp. 855, with 1,034 illustrations. Leipzig: Werner Klinkhardt, 1914.

The work is divided into three parts: Part 1 on surgical operations, Part 2 on surgical diseases, exclusive of tumors and cysts, and Part 3 on tumors and cysts. Part 1 is general in character, and treats of operative technic rather than of particular operations. It also contains chapters on wound healing, transplantation of tissue, bandaging, etc. The text is short and to the point, and most of the illustrations are quite satisfactory. Some, however, are out of date: we do not expect, to-day, to see operations on the skull shown with the hair on the scalp and the surgeon's hands bare with neat cuffs on the wrists; and in operations about the axilla, the parts are supposed to be shaved, and not left covered with hair. Part 2 deals with general subjects, such as the various forms of infections, both acute and chronic, injuries, fractures, diseases of the bone, joints, etc. Of this part, those chapters on the diseases of the bones are the most interesting; there are 440 pages, with 498 illustrations, and forty colored plates, from which it necessarily follows that the text must be quite brief; in fact, too brief in places to be entirely satisfactory. Part 3, of 160 pages on tumors, contains nothing especially new. The illustrations, however, are very good, and show many interesting examples of the various growths. The colored plates are particularly fine, showing both macroscopic and microscopic structure.

Miscellany

ALBERT VAN GEHUCHTEN—AN APPRECIATION

A man as charming as he was intellectual, and as beloved as he was famous, was Albert van Gehuchten, professor of the anatomy, pathology and treatment of diseases of the nervous system in the University of Louvain. His sudden death (Dec. 9, 1914) has deprived the world of one of the most skilful investigators and brilliant exponents of biologic science.

In deploring the losses of the rich past in the destruction of the library of Louvain, not many realized at first the even more significant losses to the future. Professor van Gehuchten's city as well as his country home was burned, and with them all the manuscripts containing the records of his research work during the last ten years—research work along the lines of that, which already published, had made such advances in the science of neurology.

Professor van Gehuchten was enthusiastically received in Cambridge, and a position which happened to be vacant was given to him, and through the efforts of Sir William Osler and others, a contribution from the Rockefeller fund was placed at his disposal. He was given the use of the laboratory of the Research Hospital, which was installed in a small separate building, the hospital being occupied by wounded soldiers. There, with a brave and hopeful spirit, he set himself to the task of reproducing the work that was destroyed; and he quickly attracted to him an enthusiastic circle of men who were quickened by his interest and brilliant methods of work.

In spite of his determination, it was a painful struggle against despair which he with so many of his fellow countrymen were obliged to undergo, and he was just rallying to the acceptance of the new condition, and apparently regaining his health and poise, when a sudden attack of pain called his friends into consultation, and a laparotomy was performed, which successfully released a volvulus. To all appearance he was making a good recovery, and was able to carry on his correspondence and see a few friends, when a sharp pain in the region of his heart heralded the end.

Professor van Gehuchten died December 9, in his fifty-fourth year, in Cambridge, the university of refuge to so many distinguished professors of Louvain.

The whole medical world grieves the loss of this most skilful investigator and brilliant exponent of biology.

Dec. 1, 1912, the University of Louvain celebrated Professor van Gehuchten's jubilee of twenty-five years' teaching at that historic seat of learning.

Dr. Mecus, in his presidential address, said, "The work of M. le Professeur van Gehuchten is so stupendous, that when I was asked to preside on the occasion of his jubilee I was afraid that I should not in any sense be able to do justice to it."

He then traced a series of discoveries and methods, which from his first publication on structural muscle cells, through his study of the nervous system, showed him to be one of the greatest masters in the science of neurology. "Our present-day conception of the neuron was placed by him on an unassailable foundation, namely, that the neuron comprises a cellular body, protoplasmic prolongations for cellulipetal transmission, and an axis cylinder prolongation for cellulifugal transmission, both kinds of prolongation having a free termination, the nerve conduction from one neuron to the other being effected by the contiguity of the end ramifications of the axis cylinder of one neuron to the protoplasmic prolongations of the neighboring neuron."

He established methods of methylene blue staining, which he found of greater value in the examination of the more intimate nerve structures in their modification, than the coarser methods of Golgi. His investigations of the phenomena of chromatolysis formed the basis on which he rested his study of the true origin of motor nerves, and later by the discovery of a new method, based on the phenomenon of direct wallerian degeneration, he gave an exactitude to the result of his studies of the intracerebral spinal courses and of the motor nerves and certain central nerve tracts never hitherto attained. He showed that if, instead of dissecting a nerve, it was torn out, degeneration followed not only of the peripheral but also of the central portion of the nerve, such central degeneration being not retrogressive, but descending, like that of the peripheral portion, this being due not to the direct separation of the nerve itself, but to the atrophy of the cells from which it originated and was fatally injured by this violent traumatism.

Dr. F. E. Batten, writing in the *British Medical Journal* an appreciation of this remarkable man's work, says:

"Professor van Gehuchten was a teacher of great capacity, esteemed by his students as much for the high conception he had of his professional duties as for the pains he took to communicate his instruction in an interesting and sympathetic manner, illustrating his points step by step by drawings on the blackboard, demonstrations on the human body, and even by cinematograph films. In his work, van Gehuchten was not only a clinician of great eminence, determining with mathematical exactitude the seat of lesions of the central nervous system, but a bold innovator in the domain of the therapeutics, and especially the surgery of the nervous system. He obtained unlooked-for results in the surgical treatment of cerebral and medullary tumors; in obstinate neuralgia of the trigeminal nerve he proposed excision of the nerve branches to bring about atrophy of the cells from which they originate, and hence destruction of the nerve itself and elimination of all pain; he modified Foerster's operation, and successfully proposed the less complicated method of resection of the internal posterior root filaments instead of the posterior roots.

These clinical and therapeutic triumphs proved to those who were still in doubt, that absolutely pure and disinterested scientific research must finally lead to the elucidation of the most obscure pathologic problems, and thus form the indispensable foundation of medical science."

Regulation of the Practice of Chiropody

Attempts have been numerous in recent years on the part of many of the minor branches of medicine to obtain legislation permitting their followers to assume the title of "doctor," and to provide for educational standards much lower than apply to practitioners of medicine. In contrast the resolutions adopted at a recent meeting of the Chiropody Society of Pennsylvania are encouraging. It is apparent that the followers of this minor branch of medicine are not asking for the privilege of assuming an unearned title of "doctor," but, on the contrary, believe that the regulation of the practice of that branch should be placed in the hands of those who have to do with the licensing of physicians. The resolutions stated in substance that no branch of medicine or surgery is so unimportant as not to merit the care and control of the medical boards in the various states; that the care of the human foot in a scientific manner should be a part of the teaching and practice of medical colleges; that until such time as the medical colleges establish a department of chiropody and furnish an education sufficient for the practicing of chiropody, that schools of chiropody maintaining a proper academic and professional standard should be recognized by the boards of licensure of the various states, and that the practice of chiropody should be regulated by law in the various states.

The Eyes and Vision of Fishes

W. H. Bates, in the *Bulletin of the New York Zoological Society* for November, reports an experimental study undertaken to find out the cause of near-sight, the subjects of the experiments being fishes.

Fishes' eyes compared with human eyes are relatively large, the length of the eye of a fish being ordinarily about one-twentieth of its length, while the length of the eyeball of a man is from a sixtieth to a seventieth of his height. The eyes of fishes are in constant use except when they are asleep. Most fishes have no eyelids, their eyes being protected from injury by a shiny material, or by a thick transparent skin. The puffer, or swellfish, which habitually burrows in sand at the bottom of the water, has eyelids which cover the eyeballs when closed, the lower eyelid being larger than the upper. The iris is usually yellow in fish, but sometimes of other colors. The pupil, while usually round, as in man, was found in some fishes to be pear-shaped, triangular or oval. The size of the pupil apparently does not change much on exposure to bright light, or as rapidly as does the pupil of most air-breathing animals.

In the experimental work the eyes of normal fishes were first examined with the retinoscope; then by electrical stimulation the focus was changed from distant to near objects. The superior oblique muscle was next cut, after which electrical stimulation produced no change in focus or accommodation.

After the muscle had been sutured, the focus again responded to electrical stimulation. Electrical stimulation after removal of the lens produced as much accommodation as before. It was found that, contrary to statements sometimes made, the eyes of fishes when swimming were focused for distant vision. Fishes are able to focus their eyes on near objects (as close as 4 inches) by the action of the superior and inferior oblique muscles; they have no ciliary muscles. It was found possible by operation on the oblique muscles to make the fish near-sighted, far-sighted or astigmatic.

Medicolegal

Delay in Delivery of Dog's Head to Pasteur Institute

(Miller vs. Southern Express Co. (S. C.), 83 S. E. R. 449)

The Supreme Court of South Carolina affirms judgments against the express company for damages for delay in the delivery of a dog's head directed to the Pasteur Institute, Columbia, S. C. The court says that the dog, having bitten the plaintiff's children, was put into a box and kept there for several days until it died. The dog had acted peculiarly, and, when it died, the plaintiff, suspecting hydrophobia, had its head cut off, put into a box and sent to the institute. That was on Monday morning. The box was labeled "mad-dog head," and the express agent informed that it was being sent to Columbia for examination, to see whether the dog was really mad or not.

The evidence tended to show that the box arrived in Columbia on Monday evening and was carried to the institute, but that was closed. It was carried back early Tuesday morning, but the institute had not opened. Later it was carried back and delivered to a carpenter working in the building, but not for the institute. The box was put in the hallway and the officials of the institute did not get it until Wednesday. By that time the head was so badly decomposed that an examination was not made for the reason that in the judgment of the officials it was too late to discover the presence of hydrophobia. The plaintiff claimed on the trial that, as a result of the delay in delivery, he was put to expense and was forced to give, and his children to take, the Pasteur treatment for hydrophobia. The trial resulted in verdicts and judgments for the father and his children in varying amounts not stated in the court's opinion overruling the defendant's exception and affirming such judgments.

Liability for Loss of Life in Burning of Sanatorium

(Green vs. Biggs (N. C.), 83 S. E. R. 553)

The Supreme Court of North Carolina affirms a judgment for damages for the death of a patient in the defendant's sanatorium, which was burned. The court says the principle seems to be generally recognized that a private charitable institution, which has exercised due care in the selection of its employees, cannot be held liable for injuries resulting from their negligence, and the rule is not affected by the fact that some patients or beneficiaries of the institution contribute toward the expense of their care, where the amounts so received are not devoted to private gain, but more effectually to carry out the purposes of the charity. The rule is otherwise where fees are charged with the expectation and hope of securing gain and profit, and the proprietors of institutions of this class are held to the duty of ordinary care in the treatment and protection of those intrusted to them, and are responsible for injuries resulting from failure to perform this duty. The defendant was the proprietor of a private institution, maintained for gain and profit, and the sufficiency of the complaint depended, therefore, on whether it alleged actionable negligence. The complaint alleged that the patient in question was received into the institution of the defendant for hire; that he was old and helpless; that he was placed in an upper room of a wooden building; that the windows of his room were closed, and he could not open them; that the only exit from his room was on the hall; that there was no attendant near him; that the defendant maintained a fire in a furnace under the house night and day; that he had a watchman employed whose duty it was to watch the fires and protect the premises; that the defendant permitted the watchman to leave the premises and put no one in his place; that the fire which caused the death started at or near the furnace, and there was no one present to extinguish it or give the alarm. With these facts admitted, as they were by a demurrer, the jury would have been warranted, on an issue submitted to them, in finding that the defendant did not exercise the care of a person of ordinary prudence, and that this was the cause of death. In passing on the complaint, the court must construe it liberally, and, when so considered and construed, it is of opinion that the complaint stated a cause of action.

Second Injury from Exercising

(Kelley vs. Lembeck & Betz Eagle Brewing Co. (N. J.), 92 Atl. R. 282)

The Supreme Court of New Jersey affirms a judgment for $3,750 in the plaintiff's favor for damages alleged to have been sustained by reason of a fracture of the patella caused by a defective cellar door owned by the defendant. The court says that the accident occurred January 28, and that the plaintiff was taken to a hospital where he remained until February 20, when he went home and put himself under the care of his own physician, who, according to the plaintiff's evidence, advised him after a time to do a little walking indoors. In May, while he was exercising under the instructions of his physician, he sustained a new fracture of the patella, presumably in the same place. Under the charge of the trial court he was allowed to recover for damages resulting from both fractures, if the jury should find that the proximate cause of both was the original negligence of the defendant. The defendant contended that the plaintiff was guilty of contributory negligence in undertaking to use the fractured bone before it had entirely healed, and requested a charge that the jury must not take into account any damages which were the proximate result of the second injury. This request was properly denied, because it required the court to take from the jury the questions whether the second injury was the proximate result of the original fall, and whether the plaintiff was guilty of contributory negligence in the respect just stated. This point, however, was for the jury in both aspects. There was evidence in the case that the plaintiff ought not to have left the hospital so soon, and should not have exercised, as he did. But the plaintiff swore that the hospital surgeon said that he could go, and that he waited another day before leaving. The plaintiff testified, also, that his own physician advised him to walk a little indoors. There was some testimony that the plaintiff was advised to consult a specialist, and did not do so; but it still remained a jury question whether he had used reasonable care in the selection of a physician and in following his instructions. If so, the defendant could not escape liability for a situation which, but for the original injury, never would have arisen.

Society Proceedings

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION

Twenty-Seventh Annual Meeting, held at Asheville, N. C., Dec. 15-17, 1914

The President, DR. JOHN WESLEY LONG, Greensboro, N. C., in the Chair

Officers Elected

President, Dr. Bacon Saunders, Fort Worth, Tex.; vice-presidents, Drs. Thomas S. Cullen, Baltimore, and S. M. D. Clark, New Orleans; secretary, Dr. W. D. Haggard, Nashville. The next annual meeting will be held at Cincinnati.

Simplicity of Transfusion by Means of Kimpton-Brown Tube

DR. J. M. MASON, Birmingham, Ala.: On account of the simplicity of the technic, the certainty of results, and the safety with which the Kimpton-Brown method may be used in the hospital or the home of the patient, it is the most useful method of transfusion devised.

New Method of Lateral Anastomosis of Blood Vessels; Operation for Cure of Arteriovenous Aneurysms

DR. J. SHELTON HORSLEY, Richmond, Va.: I doubt the practical utility of reversal of the circulation. My experiments show that in reversal of the circulation by the end-to-end method the blood returns to the heart by anastomotic venous branches a short distance below the site of operation, and that the arterial blood in the reversed femoral vein never reaches the foot. If the circulation is to be reversed, however, it should always be done by lateral anastomosis and not by the end-to-end method. I have devised a clamp for lateral anastomosis of blood vessels. It is 5 inches in length, has delicate curved blades, and the handles are in an axis with an imaginary line drawn from the tip to the heel of the blades. This permits the handles to lie flat and they are out of the way during suturing. The forceps can also be used for temporary occlusion of blood vessels and for the cure of arteriovenous aneurysms. In a lateral anastomosis the vessels are clamped by two of these forceps and held together by two sutures near the end of the proposed anastomotic opening. The opening is made with scissors and a tractor suture is placed in the outer wall of each vessel but not tied. The suturing is done with a curved needle, the knot being on the outside. A continuous overhand stitch is used, beginning at the angle near the handles, and when the other angle has been reached, one of the tractor sutures in the outer wall is withdrawn and a tractor suture placed so as to unite both walls. This, when pulled on, everts the intima and makes the suturing easier. The thread is tied to the short end which is grasped in the hemostat when the first knot of the continuous suture is made. In using the forceps for arteriovenous aneurysm the vessels are first dissected down to the aneurysm, and first the artery, then the vein, is grasped by the forceps near their point of communication. The communication between them is then divided and the opening sutured. This makes the operation easier even when a tourniquet is applied, but it should be especially valuable where no tourniquet can be used, as in the upper femoral region.

DISCUSSION

DR. E. P. RICHARDSON, Boston: I have used the K-B method in a number of cases and find it extremely simple and efficient. There has been no trouble from the clotting of blood in the tube during the transfer from the donor to the recipient.

DR. JOHN D. S. DAVIS, Birmingham: One advantage of the Kimpton-Brown tube is that we can estimate the amount of blood transfused.

DR. WILLIAM R. JACKSON, Mobile: The only criticism I have to make on the use of this tube is the difficulty of the technic. When you take the tube out and put another one in the vein a blood clot is liable to form in the vein.

Dr. Oscar H. Elbrecht, St. Louis: I have done a number of direct transfusions after the method of Crile on dogs and on four human subjects, and I have been unable to tell whether I got 2 ounces or 2 pints in any of those patients.

Dr. Charles H. Mayo, Rochester, Minn.: In regard to arteriovenous aneurysm, frequently the opening between the artery and vein is only as large as the artery, and whenever it is found that it is not larger than the artery, if a permanent ligature is put around the anastomosis and drawn tight or snug, it will work satisfactorily, although this is contrary to the teachings of the old text books. I have tried it on the popliteal artery and it has worked admirably.

Modification of Lane's Plates

Dr. H. Stuart MacLean, Richmond, Va.: When a Lane plate has first been properly and firmly applied it is calculated to maintain from the outset close, accurate approximation of the fractured ends. It is this rigidity which tends to bring about delayed or non-union. In the process of healing of a transverse fracture of a long bone the natural result is a slight degree of shortening which is explained by absorption of bone tissue from both the fractured ends. It follows then that with the rigidly and accurately applied Lane plate the attrition and absorption in the fractured ends give a degree of actual separation of the ends in from two to four weeks which is as firmly maintained as is the accurate approximation when the plate is first applied. In order to overcome this difficulty I have had the plates made with an oblong opening in one end instead of the usual round opening for the screw. When the plate is applied the screws are placed at the distal end of the oblong opening, and as attrition and absorption occur the action of the muscles along the line of fracture will cause the approximation to be continued by the slipping of the screws in the oblong slot. Roentgenograms show that the screws do slip in this slot from one-third to the entire length of the opening.

DISCUSSION

Dr. Henry O. Marcy, Boston: The less we damage the tissues in treating a fracture, the easier we bring the parts in coaptation and fixation, the safer and surer the result, and the posterior splint which has been developed during twenty years gives fixation of the greatest possible value in the application of mechanical means for the reduction and retention of fractured bones.

Dr. J. M. Mason, Birmingham: There are four points which should govern us in deciding in any individual fracture whether or not it should be treated by the open method. First, any fracture, where coaptation is necessary, and where we are unable to coapt the fragments, should be treated by the open operation. Second, we ought to consider the probable functional result in a given case without perfect reduction. In many instances, especially in women, in fractures about the shoulders and arms and exposed parts of the body, they ought to be informed of the absolute inevitableness of putting a screw in any fracture we are going to open. Then we must consider the possibility of sepsis and non-union.

Dr. H. H. Trout, Norfolk, Va.: We had a series of roentgenograms after Lane plate cases which disclosed a bony deposit opposite the plate.

Dr. W. B. Coley, New York City: The pendulum has swung too far in the direction of the operative treatment of fractures.

Dr. W. D. Haggard, Nashville: Some reference ought to be made to the bone inlay, because it is much more easily applied than the peg or dowel.

Dr. Oscar H. Elbrecht, St. Louis: Ivory plates are absorbed within ten months. The fixation by them is firm and they do not have the objection of the screw, because there is decided traction of one or more screws, thereby producing slight tissue necrosis from pressure of the screw itself.

Dr. Battle Malone, Memphis: In many old cases of non-union, the ones in which we usually make use of transplants, there is such a degree of rarefying osteitis that the bone tissue at that point is not adaptable or suitable for transplantation. It is more preferable to take a transplant from some other part of the body.

Uterine Prolapse

Dr. Charles H. Mayo, Rochester: With retroversion and descent, difficult to replace because of probable associated pelvic lesions or other abdominal complaint, an intra-abdominal operation should be made on the round ligaments. If, as rarely occurs, the cervix remains too far forward, the uterosacral ligaments should also be shortened to bring the uterus to anteversion. The interposition type of operation is efficient in the relief of uterine prolapse associated with extensive cystocele. The best results are secured in women having a firm uterus, which usually means an age limit within the forties. This operation relieves cystocele and descent or the first and second degrees of prolapse. In the third or fourth degrees of complete prolapse in women in the fifties, with a soft degenerating uterus undergoing rapid atrophy and in whom the torsion of the ligaments in anteversion still permits the uterus to be brought out of the body, the operation will undoubtedly fail of relief and another method should be substituted. The modified Kocher operation is occasionally made on women in the forties, in which case the tubes are divided, but it is usually reserved for women well past the change of life with atrophied uteri. For a large group of cases, or the third and fourth degrees of prolapse in patients between 45 and 65 years of age, often with atrophy of the uterus and distention of the vaginal outlet, neither the interposition nor the Kocher types of operation are indicated. In these cases the following is an effectual method of securing relief:

The cervix is grasped with two pairs of volsellum forceps and drawn well out of the vagina. A pear-shaped incision is now made with its apex 1½ inches below the external urinary meatus. It passes down each side of the cystocele and around the cervix. The sides of the incision are grasped and the vaginal wall readily separated from the bladder by blunt gauze dissection. The apex of the vaginal flap attached to the anterior lip of the cervix is turned down and the bladder rapidly separated by gauze dissection from the front of the uterus. As soon as the peritoneal fold is reached, it is incised and divided laterally. The blunt gauze dissection now separates the posterior vaginal wall from the uterus at the side and on to the broad ligaments. The sharp fork retractors are now used to draw the fundus of the uterus out of the incision as in an ordinary hysterectomy and the cervix is restored within the vagina. The broad ligaments are fully spread out on each side. Unless the ovaries are diseased they are not removed. A heavy hysterectomy forceps with long blades now grasps each broad ligament. The uterus is divided a half inch from the forceps and two more pairs are applied, one on each side, with their tips touching the culdesac behind the cervix. The uterus is then cut entirely away.

If there is any tendency of the sigmoid or omentum to prolapse, it is held back by a long pad of gauze inserted into the peritoneal opening. The pairs of forceps, two on each side, are now approximated laterally and a running mattress suture of chromic catgut is applied which passes back and forth behind the forceps completely through both ligaments at such a distance as to tighten the broad ligaments. From 1¼ to 1½ inches approximation of these ligaments is secured. The method of suture is applied so as to interlock and prevent the inward slipping of any vessels. When the suturing reaches the round ligament side it is caught into the flap anteriorly where the bladder has been separated from the interior vaginal wall. This suturing extends backward on each side from this point, catching into the broad ligaments, and then on each side into the angle of the depth of the dissection, thus compelling the bladder to rest on the broad ligaments. The loose ends of the exposed broad ligaments are now approximated by a running bottonhole stitch, extending back to the perineal position and the sides of the vaginal mucosal flaps, and closed by a running catgut suture up and back in a submucous manner. No sutures are exposed.

Radium Treatment of Fibroid Tumors

DR. HOWARD A. KELLY, Baltimore: The thirty-six patients from 30 to 67 years old were treated with radium (gamma) rays. The tumors were pedunculated, as well as interstitial and submucous. With one exception, radium has either caused the tumor to disappear or has so far reduced its size as to render it innocuous. In every case subjected to an intra-uterine radiation the hemorrhage was controlled, and wherever it was desirable amenorrhea has been produced. The treatments, calling for from 300 to 500 mg. of radium element, only lasted a few hours, and, as a rule, did not have to be repeated. Furthermore, they were without risk. Such a treatment is preeminently adapted to tumors in young women, in whom menstruation will sometimes be conserved, and in hemorrhage cases, especially when profound anemia is found. Radium treatment does not preclude, and in no wise complicates, a surgical operation if it is thought best to do one later.

Large Hair Cast of Stomach Successfully Removed by Gastrotomy

DR. RUDOLPH MATAS, New Orleans: A hairball weighing approximately 967 grams was removed from the stomach of a girl 19 years of age. It was shaped like an inverted gourd, and was molded to the contour of the stomach. In the dry state, it measured 18 inches in its longest diameter (along its convexity); 10¼ inches in its greatest circumference; 8¼ inches around its middle portion, and 8⅛ inches in its narrowest circumference. It consisted of a mass of matted black hair which, when dry, was felted, and gave the appearance of the hair of a wild animal. Mixed with the hair were particles of earth and vegetable food stuffs, which had gravitated to the center of the mass. The mass not only filled the stomach in its entirety, but was grasped tightly by its walls in many places. An incision 6½ inches along the anterior surface of the organ was required to permit its extraction. When removed from the stomach, it was covered with a thick slimy coat of extreme foulness. The only space for the passage of food was a narrow interspace between the mass and the lesser curvature, were fluids and semi-solid foods could be forced from the cardia to the pylorus.

Cancer of Prostate

DR. E. S. JUDD, Rochester, Minn.: In my series of 878 prostatectomies, there were 93 cancers. The youngest of these patients was 51 years, the oldest 82. In addition to these, 84 cases were diagnosed cancer but the patients were not operated on because too far advanced. In many cases the symptoms of early cancer of the prostate cannot be differentiated from adenomatous hypertrophy. Pain associated with cancer is usually more constant and more marked in the region of the prostate and is not necessarily associated with micturition. Frequency of urination is also a prominent symptom and usually one of the first to appear. Hematuria was noted in 21.9 per cent. of the cases and was a comparatively late symptom. The specific gravity of the urine was unusually low, in many instances ranging from 1.002 to 1.005. A study of the specimens removed at operation showed that in about 75 per cent. cancer was associated with hypertrophy and in the remaining 25 per cent. cancer occurred in the prostates in which evidence of hypertrophy could not be found. The benignly hypertrophied gland in some of these cases is quite as readily enucleated as in the ordinary case and unless the posterior segment is enlarged the malignant process may easily be overlooked. If the hypertrophied part is more firmly attached posteriorly or shells out with difficulty, there is always suspicion of cancer. Patients who are incurable but fairly comfortable, either with or without catheter, should not be operated on, though certain of those who have not used catheters should be advised to do so, since they may be made more comfortable by its use. In many cases the obstruction to urination is due to a benign hypertrophy. Removing the obstruction and also a part of the cancer will entirely relieve the patients for a time and they will be more comfortable than with any other procedure.

Eighty-two of the 93 patients operated on have been traced. Of these 8 have lived more than 3 years; 12 more than 2 years; 13 more than 1 year; 24 died within the first 6 months; 5 died, date unknown.

Patients still living after 6 months, 3; after 1 year, 7; after 2 years, 4; after 3 years, 3; after 4 years, 2; after 9 years, 1.

The patient who is living and free from symptoms nine years after the operation had a very small cancerous nodule removed. Many of the patients living at the present time are entirely free from symptoms. Three who were operated on within the year, yet more than six months ago, are well. In the cases of recurrence, hematuria was one of the first evidences of the recurrence. Difficulty of urination was also an early symptom and became rapidly marked in a number of cases, necessitating suprapubic cystotomy. Several patients lived more than three years without evidence of trouble, when there was a return of all of their symptoms.

7 Pocket Baby Scale. C. R. Spicer, Chicago.

2. **Colloidal Gold Reaction.**—Summing up the gold chlorid reaction as it occurs in congenital syphilis, Grulee and Moody state: There are two types of reaction which occur in cases of congenital syphilis; one in which the height of the reaction is obtained in the dilutions of 1:40 and 1:80; in higher dilutions there is a distinct tendency to less reaction, and this reaction never continues past the dilutions of 1:640, and infrequently past the dilutions of 1:160. The second reaction approaches closely that of paretic dementia and needs further investigation before it can be properly interpreted. In five cases of tuberculous meningitis the reaction was most marked in the dilutions of 1:160 and 1:320. In two the reaction was greatest in dilutions of 1:640 and 1:1,280; in one at 1:40 and 1:80. In one case the diagnosis of miliary tuberculosis with tuberculosis of the meninges was confirmed at necropsy.

In the cases of congenital syphilis included in this report the cerebrospinal fluid reacted to the colloidal gold chlorid solution always in the lower dilutions, and with a marked degree of regularity strongest in the dilutions of 1:40 and 1:80. In a small group of cases of congenital syphilis the reaction is similar to that of paretic dementia. The reaction as obtained in congenital syphilis is most nearly approached by those conditions which show a slight inflammation of the meninges or brain and are not likely to be confused clinically with syphilis. The reaction in tuberculous meningitis is found to be most intense in the dilutions of 1:160 and 1:320. It is likely that the more rapid the course the more apt is the reaction to occur in the higher dilutions. From the foregoing statistics it is evident that the Lange gold chlorid reaction is of value only as an aid in diagnosis.

5. **Injection of Diphtheria Antitoxin in Children.**—In all, fourteen children received intravenous injections of diph-

theria antitoxin from Schorer. The results and symptoms observed are compared with those obtained in the same epidemic by subcutaneous injection in seven cases. Following intravenous injections the fever and membrane disappeared sooner and the patients felt well; diphtheria bacilli disappeared more rapidly; there were fewer carriers and paralyses were less frequent than when subcutaneous injections were made. Two children died in each series; death occurred from seven to fourteen hours after the first injection in each case. All four children who died had laryngeal diphtheria, but there were seven cases of laryngeal diphtheria in the series that received intravenous injections, and only two in the series given subcutaneous injections. When given intravenously, four injections out of sixteen were followed in from one-half to one and a half hours by striking symptoms. These were usually ushered in by a marked chill, then an elevation of temperature from 103.2 to 104 F., and in two cases by respiratory distress. All of these symptoms disappeared in from three to twenty hours, when the patients usually felt entirely well. That these were serum reactions did not seem to be the case, as in none did the later serum rashes appear. When serum rashes and reactions did occur they did not differ from those following other serum injections, though none occurred in the small series of patients receiving subcutaneous injections.

Schorer does not advocate intravenous injections in all cases, but, he says, intravenous injections undoubtedly produce results more rapidly and so are to be preferred in late and severe cases. Intravenous injections is less painful at the time of administration and later, and because of the smaller number of units necessary intravenous injection is much less expensive. Entrance into the jugular vein in children is not difficult and this vessel affords a ready site for the intravenous injection of diphtheria antitoxin when the median basilic and the cephalic veins are too small. This small series indicates that there are fewer carriers and heart failures are less likely to occur following intravenous injection, but there are more immediate and serum reactions. The immediate reactions are not grave and in themselves did not seem to be a contra-indication to intravenous injection of diphtheria antitoxin.

8. **Relation of Tonsils and Other Throat Conditions to Tuberculcus Cervical Adenitis.**—As the result of his own experience and that of others, Richards recommends that in all cases of cervical adenitis the tonsil be removed as the first procedure. If the glands are broken down, and an operation on them has to be performed, then the tonsil should be removed at the same time. That the removal of the tonsil removes all source of possible danger of infection of the cervical lymph glands is not claimed, since anatomic studies have shown that the entire area of the middle ear, eustachian tube, superior, posterior and lateral pharyngeal wall, the tonsils, base of the tongue, and posterior nares all have their lymphatic drainage area into the cervical lymph glands.

The tonsil, however, being large, and situated in the back of the mouth, in which it is very subject to infection and to pressure during the act of eating and swallowing, is probably the greatest offender. As the tonsil is such a possible portal of infection, and as its removal seems to be followed by no deleterious effects on the organism, and as it is very likely to be a source of entrance for the infection of rheumatism, Richards advises its removal in all cases of cervical adenitis, and in all children whose parents give a history of having had cervical adenitis. At the same time, one cannot say with positiveness that the removal of the tonsil will either cure or prevent cervical adenitis. Richards state that it is not probable that all enlarged cervical lymph glands are tuberculous, presumably about 80 per cent. of them are.

9. **Treatment of Tuberculous Cervical Adenitis.**—Many of the children admitted at Westfield have tuberculous cervical glands. Not many are noticeably large, but they can be readily felt on examination. Almost invariably these children also have enlarged bronchial glands, as evidenced by impaired resonance between the scapulae. As a routine part of their treatment, Chadwick puts these patients on bacillen emulsion, if they do not have more than a degree of rise of temperature, or other signs of active pulmonary disease. The initial dose is one millioneth of a milligram, and the course of treatment extends over a period of about six months, until 10 milligrams is reached; this maximum could be reached in a shorter time, but Chadwick feels that a small dose given over a longer period is more effective, and can be given in this way without causing reactions.

The result of treatment in these children is very satisfactory. The cervical glands decrease perceptibly in size, and the area of dulness over the hilus becomes smaller and less pronounced. The longer the tuberculous disease has existed in a gland the slower will be the effect of treatment. Resolution must necessarily be limited if fibroid changes have taken place. Suppuration has not occurred in any case in which it did not exist prior to treatment. This experience leads Chadwick to the conclusion that surgical interference is only necessary to remove such glands as have become caseous, or fibroid. Extensive dissections are unnecessary in these cases, as the small recently diseased glands that are left will disappear under the influence of tuberculin treatment.

10. **Treatment of Tuberculous Cervical Adenitis.**—Hawes says that surgery, conservative or, in rare cases, radical, depending on the surgeon's skill or lack of it, has its place; tuberculin in some cases does wonders, in other it plays a lesser rôle and at all events, in competent hands can do no harm. Hygienic measures including out-door sleeping, proper diet, exercise and rest, baths and heliotherapy are given their proper place as the basis of all treatment in all forms of tuberculosis while, of the greatest importance, the cleaning up of portals of entry and removal of foci of infection, such as carious teeth, diseased tonsils and adenoids, are recognized as an essential part of treatment for this condition.

25. **Outflow from Liver.**—A consideration of the morphologic structure of the liver suggests that the degree of tension, or the turgescence of Glisson's capsule, as determined by the blood-pressure and the size of the arterioles of the liver, may have a marked influence on the volume of the portal flow. Experiments were made by MacLeod and

Pearce to put this hypothesis to the test, and also with the hope of furnishing further data as to the relative size of the moieties of the portal and the hepatic blood. The total outflow of blood from the liver of the dog was found to vary between 1.06 and 2.40 c.c. per second and 100 gm. of liver. There is only a very general relationship between the magnitude of the flow and the mean arterial blood-pressure. Even after the vessels of the hepatic pedicle have been clamped, blood still collects in the vena cava. Part of this comes from minute lumbar veins; the remainder may be due to collateral circulation. Occlusion of the hepatic artery usually causes the outflow to diminish by about 30 per cent., but since the exact ratio between the flow in the portal vein and the hepatic artery will depend on the extent to which these vessels are under vasomotor control at the time of observation, the diminution may be considerably greater or less than 30 per cent. Occlusion of the portal vein usually diminishes the outflow by about 60 per cent.

Stimulation of the peripheral end of the cut hepatic plexus, with both artery and vein intact, causes an immediate increase in the outflow, after which this returns approximately to its original amount. This return to the normal flow is explained as due to a passive dilatation of the interlobular portal venules resulting from a lowering of the arterial tension in the capsule of Glisson. The changes in outflow following stimulation of the hepatic plexus are very much less marked, or absent altogether, when the hepatic artery is ligated. Injection of epinephrin (2 c.c. of 1 in 10,000) into the portal vein causes an immediate decrease in the outflow. This result is practically the same with unligated as with ligated hepatic arteries. It indicates that the ramifications of the portal vein in the liver are supplied with vasoconstrictor nerve fibers. Since a similar diminution did not occur when the hepatic plexus was stimulated, the portal vasomotor nerve fibers must be very feeble.

32. **Influence of Diet on Necrosis.**—The experiments conducted by Opie and Alford showed that diet exerts a profound influence on the toxicity of certain substances, namely, chloroform, phosphorus, potassium chromate and uranium nitrate, which cause necrosis of the parenchymatous cells of the liver or of the kidney. Susceptibility to intoxication with all of these substances is less after a diet rich in carbohydrate than after a diet consisting of meat. Carbohydrates protect the parenchymatous cells of the liver or of the kidneys from necrosis caused by any one of these substances. Chloroform is much more toxic to animals which have received a diet consisting in great part of fat than to those which have received meat. When fat is fed to the white rat fatty infiltration occurs in the centers of the hepatic lobules and in the loops of Henle of the kidney. The necrosis caused by chloroform has the same location. The solubility of chloroform in fat determines the increased susceptibility of animals which have received fat and stored it in the parenchymatous cells of the liver and kidney.

Susceptibility to intoxication with phosphorus which causes fatty degeneration and necrosis of the liver is not increased by a diet of fat. Necrosis caused by phosphorus occurs in the periphery of the hepatic lobule and exhibits maximum intensity in animals which have received meat. Susceptibility to intoxication with potassium chromate, which causes nephritis with necrosis of the convoluted tubules of the kidney, is not greater after a diet of fat than after a diet of meat. Susceptibility to intoxication with uranium nitrate, which causes nephritis with advanced necrosis of renal tubules, is increased by a diet of fat. The loops of Henle, in which fat is abundant after a diet of fat, are the chief site of necrosis.

33. **Isolation and Cultivation of Tubercle Bacilli.**—The work of Churchman, Krumwiede and Simons, on the effect of various dyes on the growth of micro-organisms, suggested the use of these dyes in the isolation of the tubercle bacillus to Petroff. At first an attempt was made to grow tubercle bacilli directly from the sputum on a medium containing gentian violet. Only a few Gram-positive streptococci and diplococci appeared in the tubes. These organisms were isolated and studied. A dilution of gentian violet 1 to 1,000 failed to inhibit their growth. For the elimination of some of them sodium hydrate proved to be of greater value than antiformin. To determine the bactericidal action of sodium hydrate on the tubercle bacillus, a series of tubes containing 1, 2, 3 and 4 per cent. sodium hydrate were inoculated with tubercle bacilli and left in the incubator for twenty-four hours at 37 C. At the end of that time the tubes were neutralized to litmus with normal hydrochloric acid, centrifugalized, and the sediment containing the tubercle bacilli was inoculated into tubes. After incubation for some time they showed positive growths of tubercle bacilli.

The next step was to determine what stain and dilution were most favorable for the growth of tubercle bacilli. For this purpose a series of medium containing gentian violet, methyl violet, methylene blue, crystal violet and fuchsin in dilutions varying from 1 to 1,000 to 1 to 100,000 were used. Tubercle bacilli will grow well on egg-meat juice medium containing all of the above stains even in dilution as low as 1 to 5,000, with the exception of methylene blue which gave negative results below a dilution of 1 to 25,000. In medium containing this stain the tubercle bacilli grow rather slowly, and the individual organisms are impregnated with the stain. From these results gentian violet was selected as the most favorable stain, on account of its inhibitory action on many organisms. After many attempts it was found that a medium containing whole egg, beef or, preferably, veal juice, and gentian violet gave uniformly positive results. This medium contains: Two parts of egg (white and yolk). One part of meat juice. Gentian violet sufficient to the proportion of 1 to 10,000. Tube about 3 c.c. in each sterile test-tube and inspissate for three successive days; on the first day at 85 C., until all the medium is solidified, changing the places of the tubes if necessary; on the second and third days for not more than one hour at 75 C. For the bovine type omit the glycerin and infuse the meat for twenty-four hours in water.

Method of isolating tubercle bacilli from the sputum: Fresh sputum is advisable. Equal parts of sputum (about 5 c.c.) and 3 per cent. sodium hydrate are well shaken and left in the incubator for twenty to thirty minutes until the sputum is fairly well digested. The sputum is then neutralized to sterile litmus paper with normal hydrochloric acid, centrifugalized, and the sediment inoculated into several test-tubes containing the medium.

Method of isolating tubercle bacilli from the feces: The feces are diluted with about 3 volumes of water and mixed well, then filtered through several thicknesses of gauze to remove solid food particles. The filtrate is saturated with sodium chlorid and left undisturbed for one-half hour. At the end of that time all bacteria will be found floating. This floating film is then collected with a deflagration spoon in a wide mouthed bottle, and an equal volume of normal sodium hydrate is added. This is shaken well and left for digestion in the incubator at 37 C. for three hours, in the meantime being shaken every half hour, neutralized to sterile litmus paper with normal hydrochloric acid centrifugalized, and the sediment inoculated into several test-tubes.

34. **Intraspinal Injections of Serum.**—Auer states that intraspinal injections of serum with and without preservatives (0.3 per cent. trikresol, 0.3 per cent. chloroform, 0.3 per

cent. ether) produce qualitatively the same effect on the medullary centers in the monkey and dog. The effects differ, however, quantitatively with the preservative employed, with the dosage, and with the species of animal used, the monkey being strikingly more resistant than the dog. Broadly stated, the respiration is first increased both in amplitude and rate for a short period of time; then, particularly in the dog, the amplitude decreases and the rate slows and the respiration may even stop for a shorter or longer period of time. The blood-pressure shows an initial rise followed by a gradual drop of varying degree. This drop is usually associated with a marked slowing of the pulse rate in the dog. The normal level is again reached after some minutes.

The ideal preservative for therapeutic serum would seem to be one which could be removed before injection. Ether in this respect is better than chloroform. The opsonins in antimeningitis serum are about equally affected by 0.3 per cent. trikresol, 0.3 per cent. chloroform, or 0.3 per cent. ether when tested after one week, one month and three months. When intraspinal injections are given in the human being it would seem advisable to be prepared to withdraw part of the injected fluid and to administer artificial respiration, if necessary. For a safe withdrawal of fluid the gravity method is the best; for artificial respiration Meltzer's apparatus for pharyngeal insufflation is recommended.

35. **Function of Spleen in Experimental Infection.**—The resistance to an infection with the tubercle bacillus which can be given to mice by the removal of the spleen, Lewis and Margot found, is lost when fresh spleen, either of mouse or sheep, is added to the diet. The logical conclusion that splenic function in its relation to the specific infection is restored by feeding spleen cannot, however, be drawn; because, in the first place, the character of the disease in the splenectomized spleen-fed animals differs somewhat from that in intact animals; and, second, because fresh spleen when fed to splenectomized animals apparently gives rise to an acute intoxication. This intoxication occurs quite regularly in mice. It is manifested in the infected animals and in those not inoculated. It has been seen in one of two splenectomized dogs experimented on. Up to the present it can hardly be definitely characterized but it seems to be best marked out by the specific anorexia associated with it.

36. **Survival and Virulence of Poliomyelitic Micro-Organism.**—The minute micro-organism cultivated by Flexner and his associates from poliomyelitic tissues survives and maintains its pathogenicity in cultures for more than one year. On inoculation into monkeys poliomyelitis may fail to appear on the first injection and yet follow from the effects of successive injections of the culture. Inoculations of cultures into monkeys which fail to produce paralysis may fail also to induce resistance or immunity. In this respect the action of the cultures resembles that of the virus as contained in infected nervous tissues. The lesions occurring in the spinal cord, medulla, and intervertebral ganglia of the monkeys which respond to the several inoculations of the cultures are identical with those present in the nervous organs of the animals responding to injection of the ordinary virus. Glycerinated nervous tissues derived from the monkeys responding to several injections of the cultures transmit experimental poliomyelitis to monkeys on intracerebral inoculation.

The micro-organism inoculated may be recovered in cultures from the monkeys which develop poliomyelitis; but cultivation from the brain tissue is attended with the usual difficulties surrounding the obtaining of the initial growth. The micro-organism cultivated from poliomyelitic tissues is adapted with difficulty to saprophytic conditions of multiplication, but once adapted growth readily takes place on suitable mediums. When, however, as a result of inoculation into monkeys, the parasitic propensities of the micro-organism are restored, it again displays the marked fastidiousness to artificial conditions of multiplication present at the original isolation. The experiments reported by the authors afford additional strong evidence in support of the view that this micro-organism bears an etiologic relationship to epidemic poliomyelitis in the human subject and to experimental poliomyelitis in the monkey.

39 Should We Mourn Loss of European Clinics? W. H. Condit, Minneapolis.

37. **Indirect or External Fixation in Open Treatment of Fractures.**—The following advantages of indirect or external fixation of fractures, especially over the technic of plating are emphasized by Quain. 1. Comparative ease and rapidity of application, permitting a surgeon of good operative judgment and technic, but lacking extensive experience in bone-surgery, to operate with reasonable safety and success and with a minimum destruction of bone elements. 2. The fixation is firm, and permits early movements of neighboring joints. 3. There is no metal in contact with the fracture line. 4. The screws are entirely removable, leaving no foreign body behind. 5. In compound fractures it holds the fragments in place, aids drainage and makes dressing convenient and painless.

46 Value of Periodic Health Examinations. E. L. Fisk, New York.

42. **First Aid in Pulmonary Hemorrhage.**—Freer describes a basket fully equipped to give first aid in hemorrhage and which is in use at the Cook County Tuberculosis Hospital. The basket is about 20x27 inches in size and 6 inches deep. The compartments are so arranged that every article is plainly seen and easily reached. A card is attached, giving on one side the physician's standing order, and on the other side a list of articles contained in the basket arranged according to their use. The list is as follows: 1. One rubber bib. 2. Two towels. 3. Two pus basins. 4. One ice-cap. 5. One bowl (for chipped ice). 6. One teaspoon (for chipped ice). 7. One ice pick. 8. One jar cotton pledgets. 9. One bottle alcohol 4 ounces. 10. One bottle sterile water. 11. One hypodermic syringe. 12. Three hypodermic needles (aseptic). 13. Wires for hypodermic needles. 14. Nitroglycerin tablets 1/100 grain. 15. Atropin sulphate 1/150 grain. 16. Morphin sulphate ¼ grain. 17. Pituitrin. 18. Box amyl nitrite perles. 19. Thirty-six gauze squares 3x6. 20. Solution magnesium sulphate. 21. Glass drinking tube. 22. One 6 pound paper bag.

The nurse who discovers the patient having hemorrhage attends the case; places the patient in the recumbent position with assurance that rest and quiet are of the greatest importance. A second nurse is then pressed into service. She notifies the physician in charge and returns to the bedside as quickly as may be possible with the hemorrhage basket. The assistant now takes the ice-bag and bowl from the basket and proceeds to fill them with chipped ice. The ice-bag is placed over the heart of the patient and chips of ice placed in the patient's mouth as the bleeding diminishes. If for some reason the physician is detained and the hemorrhage is profuse, the nurse proceeds to carry out the standing order by giving 1/100 grain of nitroglycerin, hypodermically. It is necessary, perhaps, that the nurse proceed further by breaking in a piece of gauze, a three minim amyl nitrite perle which is given the patient to inhale, with a word about its effect, as the sensation sometimes frightens the patient exceedingly. All patients receive as soon as possible 1 ounce or more of the saturated solution of magnesium sulphate, repeated as the physician may order. The patient is not permitted to leave his bed under any circumstances.

78. Abstracted in THE JOURNAL, June 20, 1914, p. 1988.

85. **Endo-Aneurysmorrhaphy.**—Seven cases are reported by Gessner. Of the aneurysms three were fusiform, one false, three arteriovenous; of the latter two were varicose aneurysms, one arterial varix. Of the seven cases, four (the one false and three arteriovenous) were due to gunshot injury. Four obliterative operations were done and three restorative. No gangrene, no hemorrhage, no recurrence followed the operation. There was no mortality attributable to the operation, though one patient died of erysipelas eighteen days after operation, the infection being derived from another case; a second patient died of multilocular prostatic abscess forty-three days after operation. In the Charity Hospital of New Orleans, from 1884 to 1903, inclusive, thirty-three cases of popliteal aneurysm were treated, of which seventeen were cured, eight improved, one unimproved, seven died—a gross mortality of 21.21 per cent. for the older methods of treatment.

97. **Decapsulation of Kidney.**—Decapsulation and nephrotomy in Huggins' opinion are entitled to a place in the treatment of nephritis. The success and value of the operation will depend entirely on the care and judgment with which cases are selected. It is not to be used until all other methods have failed, and when employed it must not be done indiscriminately. Its use seems to be indicated: in toxic nephritis following acute poisoning by mercury or phenol; in nephritis following infection, especially the acute infectious diseases, such as scarlet fever, etc., in which there is great edema or in the presence of uremia—its use should be considered as soon as medical measures have been thoroughly tried without relief. This is true especially in young adults and children; in severe hemorrhage complicating chronic nephritis, when the bleeding is practically limited to one side. In these cases a nephrotomy should be done to make sure of the exact cause of the hemorrhage. It may be indicated for the relief of renal pain which sometimes occurs in the course of chronic nephritis. It may be of value in uremia and anuria during the course of chronic nephritis, merely as an emergency measure. In eclampsia, when the symptoms are due to faulty action of the kidney, and in cases in which improvement does not follow delivery of child. Cases of movable kidney associated with albuminuric casts and hematuria, in which the urinary signs result from the trauma incident to the mobility, may be cured by decapsulation and fixation, but when coincident with chronic Bright's, only temporary good is effected.

10. **Relation of Bile Pigments to Hemoglobin.**—Summarizing the data obtained in their investigation, Barratt and Yorke find that consequent on intravenous injection of hemoglobin solution there is a distinct and immediate increase not only in the concentration of bile pigment, but also in the amount of bile pigment excreted. During the three or four hours following the injection of hemoglobin the amount of pigment excreted may increase to from four to six times the amount found in the samples examined before the injection. Two hypotheses are advanced to explain this increase in amount of pigment excreted, first, that the hemoglobin injected is actually converted by the liver into bile pigment, and second, that it merely stimulates the liver cells to an increased production of bile pigment. Against the former hypothesis is the fact that the increase of pigment is not so great as might be anticipated from the relatively large quantities of hemoglobin introduced into the circulation and consequent high degree of hemoglobinemia resulting (up to 20 per cent.). The amount of hemoglobin solution found in the plasma of normal rabbits is exceedingly small, varying from 0.02 to 0.05 per cent. This fact seems to indicate that the degree of red cell destruction normally occurring in the living animal is slight. Assuming that the pigment of the normal bile is derived entirely from hemoglobin set free by the disintegration of erythrocytes normally occurring in the living animal, then it is rather surprising that when the degree of hemoglobinemia is increased 400 times, the amount of bile pigment should only be increased at the most sixfold.

13. **Changes in Neutrophil Blood Picture of Arneth in Children.**—The number of polymorphonuclear neutrophil leukocytes in the blood of children living in tropical Queensland was found distinctly decreased by Breinl and Priestley, the number of the eosinophil leukocytes markedly increased. The Arneth count performed on 150 schoolchildren living in tropical Queensland showed a marked shift to the left, the Arneth index being 74.5 as compared to 40 normal individuals (Arneth) in Europe. The "shift to the left" in the Arneth blood picture is, in the author's opinion, due to the effect of a tropical climate on the white race living in the tropics.

15. **Blood Conditions of Children of European Descent.**—Careful blood examinations were performed by Breinl and Priestley on 574 schoolchildren of European descent, of ages between 7 and 15, of whom the majority had been born and had resided in tropical Queensland during their whole life. The results indicate: 1. That the average number of red blood corpuscles is not diminished when compared with analogous figures for children born and bred in a temperate climate. 2. That the average hemoglobin content of the blood is normal. 3. That the number of leukocytes is slightly increased. 4. That the average blood-pressure does not show any difference from that of normal children in temperate climes.

20. **Potassium Permanganate in Sloughing Wounds.**—For several years past Rogers has treated cancrum oris with very frequent washing with a dark purple solution of potassium permanganate (about 1 in 500), together with swabbing the ulcerated surface with a 1 per cent. solution two or three times a day. In several cases this treatment has stopped the sloughing of the tissues, and complete healing has followed, while in more than one patient recovery from kala-azar has ensued. In the case of a most extensive and deeply sloughing bed sore right across the sacrum, occurring in a remarkable case of streptococcal pneumonia and septicemia, in which the patient who had got over the lung inflammation, but was slowly sinking, apparently through septic absorption from the sloughing sacral ulcer, several layers of lint soaked in 1 per cent. solution of potassium permanganate, and covered with water-proof material, were placed on the bed sore and changed every four hours with the result that the ulcer rapidly cleaned up and began to heal, and the man ultimately left the hospital cured. In another case of a severe bed sore in a bad case of typhoid in an obese subject, an equally favorable result was obtained by this treatment after other means had failed. In two cases of suppurative onychia after a variety of antiseptic applications during several weeks had completely failed to control the infection, the application of a strong solution of permanganate, until it was no longer decolorized on coming into contact with the discharge squeezed out from around the nail, completely cleared up the condition within three or four days.

Rogers believes that the most important action of potassium permanganate is its power of oxidizing and rendering harmless the toxins produced by bacteria, which produce a negative chemotaxis, and thus prevent the phagocytic polynuclear leukocytes from dealing with the invading organisms. When their toxins are destroyed by the permanganate they no longer repel the phagocytes, which can now protect the system against their invasion in a manner which nonoxidizing antiseptics fail to allow. Rogers is of the opinion that the use of strong permanganate solutions, not less than 1 in 500, for irrigating all dust and earth-infected wounds is well worthy of trial in the field.

21. **Iodin as an Antiseptic in Joint Injuries.**—Thorough skin toilet, paring of every particle of soiled and badly damaged tissue, swilling with iodin 2 per cent. in alcohol and with saline alternately, closure of the wounds by piling up the skin edges with mattress sutures to ensure complete coaptation, and the avoidance of artificial drainage—have been employed in all cases of lacerated wounds and compound fractures, and wounds of joints treated by Wildey in the naval hospitals of Chatham, Plymouth, and Haslar during a period of four years. No other antiseptic than iodin is used in contact with the wounds. The results have been most gratifying. Sepsis has been extremely rare, and when it has occurred has invariably originated in the skin wound and never in the depths of the wound. The mattress sutures employed reduce the chances of infection by the skin wound. Every effort is made to secure rapid healing of the skin. Every particle of damaged skin is removed, plastic maneuvers being sometimes necessary to secure easy coaptation. A loose stitch or two permits free drainage of serum, and these gaps are closed as soon as possible. It is a great safeguard to spray the wound daily with iodin.

24. **Is Emetin Sufficient to Bring About Radical Cure in Amebiasis?**—The following line of treatment is suggested by Phillips. The administration of emetin hypodermically for at least ten days or longer if the state of the patient demands it, followed by the oral administration of the drug. This is to be followed by subsequent courses of increasing intervals, as is the practice with syphilis or malaria, and in the intervals courses of calomel combined with thymol; if this is not sufficient, some other intestinal parasiticide should be tried. No man should be considered cured until, after several examinations, no cysts of *Entameba histolytica* are to be found in the feces. Further, all carriers, even though they may never have had dysenteric or other symptoms, are to be considered as cases of amebiasis and treated as such.

27. **Operation for Movable Kidney.**—The principle of Thompson's operation is the insertion of the kidney into, and its suspension by a sling, and the fixation of the latter to the posterior abdominal wall. The sling consists of a net made from chromicized catgut, or floss silk, the material varying according to the predilection of the surgeon. These slings are made in various sizes to meet the requirements of the particular case. A gap is left at the hilum 2 inches long by 1 inch broad, so that the border of the net here falls well short of the vessels and duct, and thus no pressure can be exercised on these important structures. The convex border is left open to facilitate the insertion of the kidney into the sling, and at the ends of this opening two free ligatures are left open for the purpose of lacing up the gap, and then used to sling the net to the abdominal wall. The complete sling is thus reinform with a permanent gap at the hilum and a temporary slit along the outer border, the size of the mesh being about 0.5 cm.

The kidney, having been exposed in the usual way, is inserted through the gap and by the help of the slit into the sling; it is then laced in, but loosely, and when this is completed the ligatures are knotted and thus fixed, the lower ligature ending above opposite the costal groove on the kidney. One or two fixation sutures include the net and kidney and maintain the proper relative positions of both. The kidney having been invested, the next step is to fix it in position by the free ligatures along the outer border. One is passed external to the normal position of the kidney over the twelfth, or if necessary the eleventh rib, the other through the muscles near the lower end of the viscus and the two ends tied loosely under the skin in order that the kidney may be free to move with respiration and adapt itself spontaneously to the exact position, after the patient has been placed in bed with the foot blocked up. The remaining steps of the operation are as usual. Thompson claims that the netting will provoke a celluloplastic exudation which will surround and infiltrate the mesh-work, and in time form by organization a firm adventitious tissue capsule in addition to the extraneous capsule already present.

Journal of Tropical Medicine and Hygiene, London

December 15, XVII, No. 24, pp. 369-380

30 *Occurrence of Certain Structures in Erythrocytes of Guinea-Pigs and Their Relationship to So-Called Parasite of Yellow Fever. C. M. Wenyon and G. C. Low.
31 Transmission of Trypanosoma Brucei of Nigeria by Glossina Tachinoides. G. H. Gallagher.

30. **Erythrocytes of Guinea-Pigs and Their Relationship to Parasite of Yellow Fever.**—In the blood of normal guinea-pigs, born and bred in England, Wenyon and Low found bodies indistinguishable from the so-called *Paraplasma flavigenum* of Seidelin. In most cases these appear to be definite structures which probably have to do with the development or degeneration of the red cells. They are not parasitic because they occur in the blood of newly born animals, not forgetting even the possibility of a placental transmission. The apparent success of the inoculation into guinea-pigs of such bodies from yellow fever cases is due to a failure of a sufficient examination of control animals. The authors are convinced that the evidence in favor of the yellow fever bodies being parasites thus breaks down, and that the presence of such bodies in yellow fever bears, therefore, no diagnostic significance apart from the evidence of blood alteration.

Lancet, London

December 26, II, No. 4765, pp. 1451-1502

32 *Modern Aspects of Certain Problems in Pathology of Mental Disorders. E. Goodall.
33 Case of Intestinal Obstruction. A. W. Jones.
34 Stretchers for Wounded in Trenches. G. K. Aubrey.

32. **Certain Problems in Pathology of Mental Disorders.**—Out of 19 cases of dementia paralytica examined by Goodall in which 0.2 c.c. of pure cerebrospinal fluid was used for the test, 11 gave a positive Wassermann and 8 a negative one; and out of 14 cases in which 1 c.c. was used, 10 gave a positive and 4 a negative reaction. Whereas the figures for other forms of insanity were, with 0.2 c.c. all negative in 13 cases; with 1 c.c., 5 positive out of 12; but as 3 of these were certainly or possibly cases of cerebrospinal lues, only 2 out of 12 were positive in non-general paralytics and non-syphilitics with 1 c.c. as against 10 out of 14. The deductions drawn by Goodall in respect to the employment of increasing strengths of cerebrospinal fluid amboceptor are that a positive Wassermann with 0.2 c.c. of a 1 in 10 solution indicates dementia paralytica, but a negative reaction with any strength up to even 1 c.c. of the pure fluid does not exclude this disease if only once obtained; that negative reactions with large amounts of fluid are not infrequently obtained in, at any rate, the more quiescent periods of the disease, or in slowly progressive cases; that in such periods and cases the complement-deviation method cannot be relied on for diagnosis between dementia paralytica and cerebrospinal lues.

Goodall and his associate, Schöelberg, also tested the hemolytic property of the serum and of the cerebrospinal fluid, respectively, from patients with mental disorder, against sheep's blood corpuscles. Fourteen cases of insanity other than of general paralysis and fourteen cases of general paralysis are dealt with. As regards the non-general paralytics there is absence of hemolysis with the "normal" cerebrospinal fluid in every case; from which it is to be inferred that complement or hemolytic amboceptor, or both are lacking in the cerebrospinal fluid. The addition of hemolytic serum (on the basis of the titer ascertained for the Wassermann test) made no difference except in one case (hemolysis); the subsequent addition of complement produced hemolysis in all the other tubes. In 4 out of 14 tubes containing complement $H = +$, but in the remaining 10 $H =$ slight or absent, showing that either insufficient complement had been used or that amboceptor was deficient, or showing both. The appearance of hemolysis in 5 out of 8 cases, on adding amboceptor shows that amboceptor was deficient in them; but in the remaining 3 hemolysis was brought about on further addition of complement.

As regards the general paralytics (14 cases) there is absence of hemolysis in all but two of the "normal" tubes, in which it occurred to a slight extent. The addition of hemolytic serum made no difference except in one case, in which hemolysis resulted. In the other cases hemolysis was produced by subsequent addition of complement. In 8 out of the 14 complement-holding tubes $H = +$; in 4 others $H =$ slight; in 2 others H was absent. In 5 of these last 6 (H slight or absent) hemolysis was rendered complete or brought about by adding amboceptor or amboceptor and complement. The conclusion is that there is absence or deficiency of complement in the cerebrospinal fluid in dementia paralytica, and there is sometimes deficiency, at any rate, of amboceptor.

38. **Contracted Pelvis.**—Nebesky states that in 10.5 per cent. of 15,998 obstetric cases at the Innsbruck maternity the accoucheur had to contend with a contracted pelvis. About 44 per cent. of the women were primiparae, and 61.4 per cent. of the total 1,673 pelves were of the flat type with evidences of rachitis in 18.3 per cent. and of rachitis plus contraction in an additional 8.9 per cent. He devotes nearly a hundred pages to analysis of this material from various standpoints. Fully 10 per cent. more of the children die with pelvic than with cephalic presentation. He repudiates prophylactic version, and with transverse presentation seeks to change it to vertex by manipulation from without. In case of prolapse of the cord, he reduces this before proceeding farther. With primiparae and with a moderately contracted pelvis, expectant management of the case should be the rule.

If the history of former deliveries or the size of the head suggests that spontaneous delivery cannot be expected, then cesarean section should be done at once, just after or before the first labor pains. This has several advantages, and the transperitoneal incision in the cervix he commends as the preferable technic. By operating thus early, complications are avoided and the mother is saved unnecessary stress. If complications are already installed, we must be ready to sacrifice the child in the interests of the mother, and a cautious attempt at forceps extraction may save the fetus from perforation. No form of cesarean section is applicable, he thinks, in infected cases of contracted pelvis. If cesarean section is refused, then premature artificial delivery is the next best. It should be managed with cephalic presentation the same as a normal delivery. Since the above principles have been systematically applied, 3.7 per cent. more children have been born alive with simple flat pelvis; 9.4 per cent. more with rachitic flat; 6.7 per cent. more with generally contracted pelvis, and 23.1 per cent. more with rachitic contracted pelvis. Only 11.1 per cent. of 898 children died among the multiparae, in contrast to 18.3 per cent. of 2,431 in the cases in former years managed under different principles.

46. **Upset in Fluid and Salt Balance in Obesity.**—Düring writes from the pharmacologic institute at Basel, in charge of Prof. A. Jaquet, to report extensive and protracted study of the metabolism in five cases of constitutional obesity. The findings show that a large part of the excess in weight is due, not to deposits of fat, but to retention of water. It is impossible to say whether this is the result of insufficiency on the part of the kidneys or to constitutional anomalies in the tissue cells with abnormal osmotic processes. There was also in his cases a tendency to a neuropathic constitution. Disturbance of kidney functioning may accompany emotional stress, neurasthenia, epileptic seizures, etc., confirming the influence of the nervous system on kidney functioning. He cites a number of cases in which after a severe fright adults increased in weight by more than 70 pounds in three months and the weight persisted at this high figure. One patient was a nervous woman of 43 weighing about 149 pounds. On a salt-poor diet she lost 1.5 kg. in six days. Then came some emotional stress, connected with getting a divorce, and in five days the weight ran up 1.7 kg. while the total urine dropped from 1,550 to 980 c.c. She was quieted with bromids and under increased diuresis the weight dropped back again in two days by 1.7 kg. These fluctuations were the more remarkable as the patient was too worried to eat.

His experiences teach that the conception of obesity will have to be broadened to take in more factors than those hitherto accepted. In three of his cases the thyroid seemed not to have reached full normal development, although the women were 40 to 52 years old. Each had borne healthy children. On food rich in albumin with normal salt content, the weight remained constant or increased. With muscular exercise also the weight increased. On the other hand, a milk diet and repose increased the total output of urine and the patients lost in weight. This occurred also when the food contained little albumin or salt. The weight declined also under thyroid treatment plus repose.

47. **The Blood and Problems in Heredity.**—Hirschfeld has been applying the Mendelian laws to the inheritance of the characteristics of the blood. The results justify the hope that study of the blood of different peoples may throw light on their racial history, migrations and intermarriages.

49. **Prophylaxis of Tetanus.**—Supplementary to the usual antitetanus serum treatment, Arnd and Krumbein advocate copious use of phenol, either by the Baccelli subcutaneous injection method or by administration by the mouth of salol, or both. By this means the entire organism is kept under the influence of the phenol. Experiments on several dozen white mice showed that the Baccelli injections retarded and attenuated experimental tetanus. It is a simple and harmless matter, they declare, to take 1 gm. of salol every four to six hours after a wound in which tetanus is liable to develop. The animal experiments confirm the value of this as a preventive measure. Sahli has long advocated salol in treatment of tetanus.

52. **Disease of the Hypophysis.**—Csepai describes in detail three cases of acromegaly and two of adiposity plus genital dystrophy. In one of the cases of acromegaly there was an adenoma of the glandular part of the hypophysis, the histologic structure of which corresponded to the normal structure of the hypophysis. Among the other glands of internal secretion, marked pathologic changes were found in the thyroid, thymus and ovaries. In one of the cases of the dystrophia adiposo-genitalis there was an adenoma of the anterior part of the hypophysis. It showed an active tendency to spread and its structure was completely different from that of the normal hypophysis. The direct cause of the disease was apparently the degeneration of the pars intermedia of the hypophysis. The thymus, the parathyroids and the ovaries also showed pathologic changes. His research indicates that the cause of hypophyseal diabetes insipidus is hypofunctioning of the pars intermedia. This is shown by the fact that in one case injection of epinephrin caused a fall of 40 per cent. in the daily output of urine, and also by the fact, which has never yet been sufficiently emphasized, that diabetes insipidus is often combined with the syndrome of adiposity plus defective development of the genital organs. In all of the five cases there was leukopenia, with relative mononucleosis. In one of the cases of acromegaly there was also marked eosinophilia. In the first and second case of acromegaly, carbohydrate tolerance was very much decreased. In the other case of acromegaly and in the two of dystrophia adiposo-genitalis it was normal or increased. He suggests two new methods for functional diagnosis in disease of the ductless gland system: 1. The reaction of the conjunctiva to epinephrin. Under normal conditions three drops of 1 to 1,000 solutions of epinephrin cause a slight or moderate blanching of the conjunctiva that lasts for ten to twenty minutes. If, when the solution is instilled, the reaction is exaggerated, this indicates hypofunctioning of the epinephrin-producing system. 2. Study of the quantitative and qualitative blood changes after injection of epinephrin. Injected subcutaneously in a normal individual, epinephrin causes leukocytosis with increase of neutrophils and decrease in the number of eosinophils and mononuclears. If there is any variation from this effect it indicates disease of the ductless gland system. (Compare with editorial in The Journal, Dec. 2, 1911, p. 1840.)

67 Improved Rulings for Blood-Count Chamber. (Meine Netzteilung für die Zählkammer.) N. Goriaew.

61. **Intestinal Disturbance Resembling Dysentery.**—Leschke reports eight typical cases to show that what seems to be true dysentery may prove on bacteriologic examination to be a harmless and transient intestinal trouble, not requiring isolation. He treats it with bed-rest, fluid and soft foods, moist heat to the abdomen, with or without some magnesium preparation, but the main reliance is on charcoal tablets which are taken frequently up to fifteen, twenty-five or more during the day. The finely pulverized charcoal, especially blood charcoal, absorbs the toxins and products of putrefaction, and in a few days as the stools become normal the ordinary diet can be resumed.

64. **Protective Action of Diphtheria Antitoxin on Reinjection.**—Hartoch and Schürmann treated guinea-pigs with both diphtheria antitoxin and toxin—aiming to induce conditions as in a case of human diphtheria given antitoxin treatment. Then as the animals were in a kind of sensitized condition, a subcutaneous injection of antitoxin was given and the blood tested for the amount of protection thus afforded. It was found from eight to thirty-two times less than in the previously untreated animals. At the same time, if the condition of anti-anaphylaxis is induced by subcutaneous injection of small doses, then the subcutaneous injection of antitoxin following confers the same protection as in the previously untreated animals. They think that these experiences explain why the second injection of antitoxin in the clinic sometimes has proved ineffectual. The most important lesson learned from them, however, is that Besredka's suggestion of preliminary subcutaneous injection of small doses of antitoxin not only protects against danger of anaphylaxis from reinjection but it also protects the antitoxin against being rapidly inactivated.

66. **Sleeping Sickness.**—Reichenow remarks that trypanosomiasis of the blood does not become sleeping sickness until the trypanosomes get into the cerebrospinal fluid. They can be reached by drugs when they are in the blood, but this is a more difficult matter when they are ensconced in the cerebrospinal fluid. He has been giving neosalvarsan in intraspinal injections, and also experimenting with alcohol which we know passes into the cerebrospinal fluid. The number of trypanosomes in the fluid markedly declined after the patients had taken by the mouth 200 gm. alcohol on three successive days. He never succeeded by this means, however, in clearing out all the trypanosomes from the fluid, but some drug may yet be found which diffuses into the fluid and will kill off all the trypanosomes.

86. **Rheumatism Among the Soldiers at the Front.**—Schmidt has had a number of cases of acute articular rheumatism, myalgia, neuralgia, etc., among the sick soldiers sent back home. In almost every instance he was able to learn of some preceding tonsillitis or rheumatic affection. In many cases of intestinal trouble or dysentery he has seen swelling of several joints, as also with suppurative colitis, demonstrating that the intestinal mucosa serves as a portal of entry for general infection more frequently than is ordinarily recognized. In other cases the joint swellings were evidently a symptom of septic conditions as the spleen was enlarged and there was high intermittent fever, with albuminuria and sometimes migrating pneumonia. The portal of entry here was evidently the gunshot wound, although this had healed in the interim. He learned further that from one-third to one-half of the rheumatism patients had already had attacks of rheumatism before the campaign. The legs are affected much more than the other joints and the men ascribe this, as well as the rheumatism in general, to the wet and cold in the trenches, but Schmidt thinks that the strain of the long marches is a more plausible explanation. In many cases an obstinate "rheumatic affection of the foot" turned out finally to be a "march fracture" of some metatarsal bone, or flat-foot derangement. His experience has continued to confirm the benefit liable from injection of salt solution or 0.5 per cent. solution of novocain. With myalgia, he makes the injection at the point where the pain is greatest. With neuralgia, at the point most sensitive to pressure; with more diffuse pain, as with bilateral sciatica, severe lumbago or migrating myalgias, the injections should be given by the epidural or lumbar intraspinal technic.

Therapie der Gegenwart, Berlin

91 *Inflammation of the Mucosa of the Mouth. (Mundschleimhautentzündungen.) F. Williger.
92 *Treatment of Chronic Constipation. (Obstipation.) G. Rosenfeld.
93 Cure of Inflammatory Pelvic Tumors by Weak Galvanic Current. (Ueber Heilung entzündlicher Beckentumoren mittels galvanischer Schwachströme.) H. Schmidt.

91. **Inflammation of the Mucosa of the Mouth.**—Williger devotes a word in passing to the amazing resisting power of the lining of the mouth, in such marked contrast to mucosa elsewhere. But when there is damage from a broken tooth or general febrile disease, the secondary stomatitis that may develop is depressing and measures to cure it are imperatively needed and give great relief. Even when there is no actual inflammation, proper care of the mouth may ward off secondary parotitis, besides its effect on the appetite and spirits. Not only the teeth, but the gums and tongue must be wiped off with the finger wrapped in a thin layer of cotton. The best way, he says, is to cut a piece about 4 by 10 cm. out of sheet cotton and then peel off a very thin layer to wrap around the finger, and dip the finger in a mouth wash. By using plenty of the fluid the mouth can be thoroughly cleansed without hurting. The patient can do this himself when perseveringly trained until he does it right. Three times a day is as often as it should be done, merely rinsing out the mouth after eating at other times. He regards it as the criterion for good nursing when the patient's mouth is found clean at the doctor's visit. With contagious diseases a wad of cotton held with forceps must be used instead of the finger. The mouth wash must be such as softens up rapidly phlegm and thick coatings, and nothing seems to be better for this than a heaping teaspoonful of sodium bicarbonate stirred into a glass of warm water, supplemented by hydrogen dioxid not stronger than a teaspoonful of the latter to a glass of warm water. Medicated chewing gum also promotes the natural self-cleansing of the mouth. He emphasizes that before beginning mercurial treatment the teeth should be put in good order and all tartar removed.

Ulcerative stomatitis he treats by swabbing with undiluted hydrogen dioxid, repeating this until the fetor has disappeared. The tartar is then removed, not too forcibly, and then the ulcerations are swabbed and rubbed quickly with an 8 per cent. solution of zinc chlorid. The patient rinses his mouth every hour with the warm, weak hydrogen dioxid solution, and cleans out the mouth besides three times a day with the cotton-wrapped finger. Then the rest of the tartar is removed and by the third day the ulcers are healing and by the end of a week the cure is complete. Instead of the zinc chlorid, a mixture may be used consisting of a little iodoform and a few drops of alcohol with enough of an 80 per cent. solution of lactic acid to make a thin paste. The tooth brush hitherto used must be burned. Aphthous stomatitis requires just the reverse—avoidance of every irritating substance, and merely warm sodium bicarbonate or boric-acid solutions to hold in the mouth for five minutes, the mouth thus rinsed out six times a day. The aphthae can be touched with 3 per cent. boric-acid glycerin; children like this. Drug stomatitis may range from simple edema to blisters and necrotic patches. It requires mild treatment.

92. **Chronic Constipation.**—Rosenfeld has been remarkably successful in curing constipation of years' standing by simple dieting and having the patient stay alone in his room for a day or two, all visitors excluded, and go frequently to the water closet, not waiting for desires. The aim is to train the patient to become aware of and heed the faintest impulses toward defecation. This will bring his bowels under his control again. The simple oatmeal, rice, cocoa and chocolate diet, no meat, butter, milk, fruit or vegetables, is kept up for three or four days. Then to this is added a little poultry or boiled ham for two days; then the same plus roast fowl for two days; then the same plus boiled cream by the tablespoonful, and the sixth menu adds boiled cream by the cupful. This diet outline is the typical antidiarrhea diet, but it seems to regulate conditions just as well in the constipated. The dieting course lasts two or three weeks, finally including cauliflower and asparagus, then spinach, potatoes and green peas, with fruit the last to be resumed.

95. **Treatment of Umbilical and Postoperative Hernia.**—Schottelius has applied the *Menge-Pfannenstiel* technic in 11 cases, as he describes in detail, with illustrations. The

special features of it are the transverse section of the fascia and the freeing of the muscle until it is mobilized enough to suture the lips together. Favorable results with it are being reported from various quarters. Menge has applied it in 75 cases with no fatalities since the very first, when he lost three patients. Recurrence has never yet been observed. Schottelius' last patient succumbed soon after the operation to pneumonia and heart weakness. There was no actual hernia in this case, but the rectus muscles gaped far apart and the huge pendulous abdomen between caused intense discomfort. The reduction of the abdominal contents was a difficult matter, and this crowding of the bowel back inside evidently contributed to the fatal outcome. The case teaches the necessity for a preliminary systematic effort to reduce the abdominal content and accustom the heart and lungs to the altered conditions of pressure before attempting the operation on the abdominal wall.

96. **Ligation of Vena Cava with Puerperal Pyemia.**—In the case reported by Fromme a woman of 24 aborted at the third month of her second pregnancy. After the uterus had been cleared out, febrile puerperal endometritis followed for nearly two weeks and then came four afebrile days. Thrombosis in the right pelvic vessels then developed, with thirty-eight chills during the nearly three weeks of this phase. The vena cava was then ligated, and there were no further chills for nine days although the patient had developed pneumonia. Then came a new pyemic phase with twenty-one chills, with death the third week. Necropsy disclosed that if, besides the vena cava, the sound common iliac vein had had a ligature thrown around it too, just before it entered the vena cava, this would certainly have shut off the region of the thrombosis from the rest of the circulation. The thrombosis had involved the common iliac vein although it was evidently sound at the time the vena cava had been ligated. The case demonstrates the feasibility of ligating the vena cava, and that it is a comparatively simple operation.

99. **Functional Gynecologic Disturbances.**—Mosbacher tabulates under nine headings the details of ninety cases of various disturbances in the genital sphere, all of purely nervous origin. He classifies them in seven groups, those with pure painful menstruation, those with leukorrhea with or without dysmenorrhea, those with nervous exhaustion or neuralgia or smarting at micturition, tenesmus or sacral pain, four cases of amenorrhea, six of climacteric disturbance, and twenty-five of merely functional uterine hemorrhage. All organic causes had been painstakingly excluded. All the patients exhibited numerous signs of abnormal excitability on the part of the vagus or sympathetic nervous system. Most of them presented an intense reaction to subcutaneous injection of 1 c.c. of 1 per cent. pilocarpin, and only comparatively few developed glycosuria under the influence of 1 c.c. of 1 to 1,000 epinephrin. The patients further all had their vitality depressed by sorrow or worry—in some cases dread of a pregnancy—or they were women inclined to psychoneuroses.

102. **Early Diagnosis of Pregnancy by the Antitrypsin Test.**—Adachi obtained a positive response with 97 per cent. of the thirty pregnant women examined. He used Rosenthal's method of "antitrypsin titration."

103. **The Proteolytic Ferment Test of Pregnancy and Gynecologic Disease.**—Lohmeyer's tests for the proteolytic ferment confirmed its constant presence in pregnancy and for two weeks after delivery. The proteolytic power of the leukocyte ferment is increased in all febrile conditions and also with cancer, tuberculosis, and suppurative processes of all kinds. Positive findings are the digesting of the culture medium on a Löffler plate when droplets of blood are placed on the plate. The resulting dimples in the Löffler plate coating demonstrate the activity of the proteolytic ferment, according to Müller and Jochmann who introduced this test.

December 5, XXXVIII, No. 49, pp. 1465-1480

105 *Retention of Scraps of the Placenta. (Behandlung retinierter Placentarreste.) O. Hoehne.

105. **Retention of Scraps of Placenta.**—Hoehne relates 29 cases of this kind from the Kiel clinic in the last seventeen years, the delivery at term. In 6 the gap in the placenta was recognized at once, and the part left behind was immediately extracted. The hemorrhage was promptly arrested and the involution of the uterus proceeded normally. In 8 other cases the placenta seemed to be whole although part had been retained. It was expelled spontaneously in 3 cases within eleven days, with transient fever in 2. In 5 cases continuous or sudden hemorrhage attracted attention to the retained scrap, within one to nearly eleven weeks after delivery. Febrile endometritis followed in only one case. Of the 15 women brought to the hospital not until after delivery, 7 with retained scraps had fever and one thrombosis. Two died in this group. These experiences emphasize anew, he reiterates, the importance of detecting any defect in the placenta and the necessity for extraction at once after delivery of any scraps that may be retained.

If the placenta seems complete, any unusual loss of blood, with delay in involution or gaping cervix, should warn of a retained scrap and call for immediate clearing out of the uterus. When fever is already installed, he advises to wait unless there is much bleeding. The waiting time can be utilized for bacteriologic control; the greater the virulence of the germs found, the more necessity for caution and conservative measures. If active treatment is indispensable, sharp instruments should not be used but the uterus should be thoroughly cleared out. Fever, fetid lochia and defective involution alone are never an indication for digital examination of the puerperal uterus; only a profuse hemorrhage calls for this. If the puerperal infection has spread beyond the uterus and there are profuse hemorrhages, it might be better to consider removal of the entire uterus, with or without ligation of veins, protecting the peritoneum by preliminary stimulation before the operation.

109 Sterility in Women. L. Dozzi.
110 Alcoholic Extract of Beef Tonsils Alleged Superior Antigen for the Wassermann Reaction. A. Vattuone.

108. **The Urochromogen Reaction.**—Balduzzi and Ballero report considerable research with the Moritz Weisz potassium permanganate test applied to the urine. They obtained a positive reaction in 23 and a negative in 100 examinations of the urine of 113 scrofulous children, the sexes about equally divided. The reaction was positive in 10 tuberculous adults, but it was also positive in 25 of 43 non-tuberculous affections including cases of echinococcus or pneumococcus disease, cholelithiasis, acute articular rheumatism, malaria and Malta fever. The reaction is thus not restricted to tuberculosis. They explain it as due to albuminoid putrefaction with elimination of the products oxidized from the indican generated wherever there is putrefaction of albuminoids. This assumption explains the apparently capricious occurrence of the reaction; it is positive when there is fever or the oxidation processes are increased from any cause. It is thus of frequent occurrence in tuberculosis while it is absent in the healthy and with torpid lesions. The test is merely the addition of three drops of a 1 per thousand solution of potassium permanganate to one of two test-tubes, both half full of a mixture of urine with two parts of water. If the reaction is negative, there is no appreciable change in tint. With a positive reaction, the fluid turns a distinct yellow. With a negative response he repeats the test with urine diluted one-half with water. A persisting pronounced reaction is an unfavorable sign. The alternation of positive to negative responses corresponds to phases of improvement and aggravation in the clinical condition, especially with pulmonary tuberculosis.

117 Adenomas of the Sweat Glands. (Adenomi delle ghiandole sudoripare.) G. Frattin.

111. **Familial Laryngeal Tuberculosis.**—Bilancioni has noticed that certain families seem to display a special susceptibility to tuberculosis and, in particular, that certain organs seem to be predominantly affected in certain families. This special topography of tuberculosis in such families may be due to inherited characteristics or to the special environment in the family. He relates the details of three families in which two brothers or two sisters presented tuberculous laryngitis as the earliest and in one instance long the exclusive clinical manifestation of tuberculosis. The patients were 21 and 23, 9 and 11. In the third family two brothers and the son of one all had pulmonary tuberculosis accompanied by lesions in the larynx so severe that the father and son soon died from inanition owing to the progress of the throat trouble.

112. **Enlargement of Stomach as Early Sign of Ileus.**—It is not always that a case of ileus presents the four unmistakable symptoms of obstruction of the intestines, namely, abdominal pain, tympany, fecaloid vomiting and complete retention of feces and flatus. Before all of these are apparent it may be possible to diagnose the ileus by merely the abdominal pain and tympany, vomiting, small and rapid pulse and pronounced dilatation of the stomach. The acceleration of the pulse may be the result of reflex action from irritation of the abdominal sympathetic. This may also be the explanation of the dilatation of the stomach which occurs early in such cases and which is of great differential importance. He describes in detail four cases in which this gastrectasia was the only symptom which seemed to exclude other affections and pointed to ileus as the cause of the disturbances noted. The patients were adults between 33 and 58, and the large stomach protruded as the patients reclined. In some of the cases the bowels had moved up to twenty-four hours previously, and appendicitis seemed more probable than ileus, but the course of each case confirmed the reliability of the gastrectasia as a sign of ileus.

113. **Means to Influence Growth and Functioning of the Thymus.**—Sabatini reviews some recent research by Fiore and Franchetti in which they apparently have demonstrated that it is possible to accelerate the involution of the thymus by injecting serum from adults of the same species, and also to accelerate the growth and postpone involution by injecting the serum from young of the same species. The adult serum, they argued, must contain substances favoring involution, while the serum from the immature must contain substances with the opposite action, and their experiments on laboratory animals apparently confirmed this view.

114. **Tuberculosis of the Kidney.**—Marogna's patients were between 20 and 36 except one man of 46. There were evidences of some focus elsewhere in every case. Unduly frequent passage of urine at night was the first and most constant symptom in all, long preceding any sensation of pain. The pollakiuria developed into incontinence in some of the cases, both at first only at night, and later also during the day. There was slight hematuria in only three cases. The symptoms from the secondary cystitis were what brought the patients to the doctor at first. The history of some of these cases shows anew how practitioners are too apt to regard the cystitis as the primary, or at least the main trouble, and overlook the kidney affection.

115. **Cavity in Thyroid Plugged with Iodoform Filling.**—Scalone's patient was a woman of 56 who had had the thyroid enlarge at times during her earlier pregnancies but it always returned to normal size afterward. At about the age of 50, during convalescence from typhoid, there was extensive suppuration in the thyroid and a fistula was left which refused to heal and caused great discomfort. After six years of this, Scalone operated on the still discharging fistula and found that it led into a large cavity with calcified walls. Attempts to clear away the lime deposits caused such pain and disturbance in neighboring organs that they had to be abandoned. After sterilizing the cavity with iodin, he injected about 25 c.c. of the Mosetig iodoform filling, and sutured the mobilized skin to cover the opening. At first some scraps of the filling were cast off, but then everything healed smoothly and the patient was cured of all trouble from this source. In connection with this case he reviews the literature on the subject of iodoform fillings, paraffin fillings, Beck's bismuth paste, and adipose tissue used as filling for cavities in bones and to compress the lung (Tuffier's extrapleural filling), quoting the details of about thirty-five cases in which these various technics have been applied.

119. **Leukemia.**—Martelli records the details of twelve cases of leukemic myelosis, five of leukemic lymphosis, two of leukanemia and five of what he calls preleukemia, comparing the findings and previous history. He inoculated numbers of laboratory animals with blood and tissues from the patients but never succeeded in reproducing any affection resembling the original leukemia, etc. These negative results and the fact that contagion is not known or any focus where the disease is prevalent, all speak against the assumption of a specific germ for it. On the other hand, in nearly every one of his cases there was a history of some preceding infection or the patient was in a septicemic condition. Tuberculosis, syphilis, malaria, streptococcus or staphylococcus affections were known in most of the cases. There was also a predisposition evident in most, manifested by adenoids, unstable nervous system, or defective development. An additional factor was evident in some cases from a trauma, overfrequent pregnancies, etc. An ordinary toxic infectious affection occurring in the predisposed may lead to the changes characteristic of leukemia. Treatment and prevention should aim to restore normal conditions throughout, and thus counteract the tendency to abnormal metaplasia of the tissues involved. Benzol and Roentgen treatment do not act on the cause.

123. **Indications for Artificial Pneumothorax from New Standpoint.**—Livierato cites numerous instances of benefit from bilateral pneumothorax even when the lungs were compressed very slightly and the intrathoracic pressure was persistently negative. Analysis of these cases shows that the benefit must have been from the interruption of the lymph current from the lungs to the pleura, thus cutting off the passage of toxic substances from the lungs into the blood. Still another factor in the benefit is the resulting damming up of the lymph in the lung which causes a number of biologic and pathologic-anatomic changes. From this point of view, artificial pneumothorax need not be restricted to uni-

lateral cases nor to foci with cavities. It offers a chance to benefit even the extensive cases, involving both lungs, if the affection is not very intense or destructive. The aim in such cases is not to compress and cause the collapse of the lung, but merely to interpose a layer of gas between the sheets of the pleura and interrupt the circulation of lymph and dam it up in the lung. The lymph thus backing up in the lung acts by a kind of autoserotherapy, modifying the virulence of the germs or at least rendering the environment less favorable for their development. The damming up of pus and other toxic substances aids in this, and the fact that these substances are thus kept out of the blood explains the subsidence of the symptoms of the toxemia. The procedure has been extensively applied in this way in his service at Genoa, and the results have been encouraging, but the interval since has not been long enough for a decisive judgment.

131 *Case of Apoplectiform Myelitis. A. Britto.

128. **Electric Treatment of Aneurysms.**—Valladares has somewhat modified the so-called Brazilian method of treating aneurysms by application of the positive pole of a continuous or galvanic current. Instead of relying exclusively on the coagulating action of the positive pole, he enhances the action of the electricity by magnifying the interpolar transcutaneous voltaisation, as he calls it. Both electrodes should be of the same size and as large as the aneurysm to be treated. The electrodes can be changed about so that the skin does not suffer at any point from too long application. As the electrodes are of equal size, this permits the use of stronger currents. Electric treatment of aneurysms is regarded as a triumph of Brazilian medicine, and it is hoped that this modification of it will deprive it of all its previous drawbacks.

131. **Apoplectiform Myelitis.**—In Britto's case a man of 50 with a history of syphilis began to experience pain in the spine and after a few days there was sudden and total paralysis of the legs but no flaccid paralysis. The spine was painted with tincture of iodin, while vigorous mercurial treatment was instituted and by the fifth day the man was taking a few steps and soon was able to return to business.

134. **Skin Tuberculin Reaction with Human and Bovine Tuberculin.**—De Lange reviews the more important literature on this subject and reports her own experience in 150 cases. She thinks that only by combining the two tests do we get a reliable insight into conditions in children. Her experience at the large Emma Children's Sanatorium indicates further that pulmonary tuberculosis is not so prevalent among children as many imagine. Numbers of cases diagnosed as such are in reality cases of chronic pneumococcus infection, and it is cases of this kind that form the majority of those in which the children recover when living an out-of-door life. The course of chronic pneumococcus infection of this kind is generally favorable in the long run, except as it may render the children more susceptible to tuberculosis. (Another article on comparative human and bovine tuberculin tests was reviewed in these columns June 13, 1914, p. 1932.)

141 Post-Mortem Findings in Adult Dwarf. M. S. Davidoff.
142 *Stab Wound of Pregnant Uterus. V. L. Brown.

140. **Staining Technic for the *Treponema Pallidum*.**—Drosdova has been testing and comparing eighteen different methods of staining spirochetes. In her judgment, the Giemsa two-minute stain and Reitman's method, slightly modified, are superior to all others. With the latter, after fixation for ten minutes in absolute alcohol, the specimen is acted on by 2 per cent. phosphotungstic acid for two minutes. This is then washed off with water and alcohol, as with the original Reitman method.

142. **Stab Wound of Pregnant Uterus.**—In Brown's case the *nine-months pregnant* uterus had been stabbed with a knife. The wound was two inches wide, and through it the membranes of the fetus could be seen. Brown decided to abstain from cesarean section and closed up the wound with interrupted silk sutures. In spite of the fact that six hours later labor began, with delivery in five hours, there were no complications on the part of the uterus and the patient was discharged eleven days later in perfect condition.

144 *Solitary Blood Cyst in the Kidney with Hematuria. (Om solitære Blodcyster i Nyrerne med Hæmaturi.) O. Wulff.

143. **Spinal Cord Tumor.**—The patient was a man of 66 previously healthy except for three attacks of acute articular rheumatism. In September, 1913, he began to experience severe pain radiating into the left side from the spine, and his legs gave way under him and there was a little incontinence of the sphincters. By the fifth month he was unable to move his legs; the tendon reflexes were exaggerated and there was some contracture, but the spine was not tender. Lumbar puncture showed considerable pressure, opalescence and positive Nonne-Apelt in the fluid, but no lymphocytosis, and there was no sensation below the umbilicus. The dura was opened and an ovoid fibro-endothelioma an inch long was found on the right side at the eighth and ninth dorsal vertebral arches. It was adherent to both cord and dura, but the cord seemed normal otherwise except for being compressed, and the man's recovery since the tumor was shelled out has been remarkable. He walks with a cane but can go up and down stairs. The cicatrix is not tender, there is no paresthesia in the feet, and sphincter functioning is normal.

144. **Solitary Blood Cyst in the Kidney with Hematuria.**—Two men, 32 and 34, noticed blood in the urine, but there were no pains and no disturbances in urination. The hematuria kept up profuse for a week although the men stayed in bed. They felt somewhat weak but nothing objective could be found to explain the hematuria. One of the men had had gonorrhea eight years before. The other had no morbid antecedents except pneumonia at 11 and 23. The blood came from the right kidney in both cases, and on suspicion of malignant disease the kidney was removed in each. Even after the kidney had been exposed it was impossible to

exclude cancer, and consequently the organ was removed. In both cases the trouble was found to be a single benign cyst filled with blood. There are only a little over sixty cases of a solitary cyst in the kidney on record, and only fourteen in which the cysts contained blood, and of these only a few were accompanied by hematuria. Most of the cases of solitary kidney cysts were in children. This renders the more remarkable the fact that Wulff's two cases were in young men and were encountered within four months of each other. The hematuria also was much more severe than in other cases on record, compelling early operative treatment to save the men's lives. In both cases the cyst was in the upper pole of the kidney and the size of a walnut. It lay so deep that resection was out of the question.

No. 22, pp. 1249-1311

147 Mental Disease and Internal Secretion. (Sinnessjukdomarna och den inre sekretionen.) B. Gadelius.

145. **Hernia and Workmen's Compensation.**—The companies in Sweden insuring against accidents have been distributing since 1908 a question-blank to physicians to be filled out for each case of hernia claimed to be the result of an industrial or other accident. The question-blank states that 5 kronor, a little over a dollar, will be paid for each blank authentically filled out and received by the central office, a cheque to be sent each quarter to the physicians who have thus contributed. The question blank is reproduced here; there are about seventeen questions to be answered. Akerman states that about 170 workmen applied to the authorities for compensation for hernia, which they claimed was the result of an industrial accident, during the last six years. Their application was rejected in 56 cases; 80 were given free operative treatment and sickness indemnity; 26 were awarded compensation for disability, but only 8 were indemnified for permanent disability. During this period about 600,000 workmen were insured, and about 25,000 operations for hernia were performed in the public hospitals in the country.

The data collected, and increasing experience have demonstrated that hernia is of three types, the first of which is hernia from direct violence. This is so rare as scarcely to be taken into account. The second type is hernia from strain, the typical traumatic industrial hernia; the third type is constitutional hernia, a slowly developing and late appearing deformity; he calls this "hernia malady." He declares that it is impossible to decide, without an operation, to which of these groups the hernia belongs. Hence he urges great liberality in respect to the expense of an operation. If the hernia is of the first type, workmen's compensation should always be granted, but not if it is of the third type, the "hernia malady." Among the hernias of the second type, some will be found conferring permanent disability for which the industrial accident was responsible, but the majority will show conditions which exonerate the accident. When an indemnity was allowed, it ranged from 10 to 20 per cent. of the previous wages, an average of 15 per cent. Akerman's own view is that great reserve is necessary in awarding indemnities for permanent disability from hernia, but that, on the other hand, means should be provided generously for operative treatment in all cases, even if it proves merely an exploratory operation.

156. **Lime in Treatment of Tuberculous Bronchial Glands.**—Wersen administered calcium lactate systematically to twenty children with tuberculous processes in the bronchial glands and examined them repeatedly with the Roentgen rays, as also twenty other children with approximately the same findings in the bronchial glands, but who were not given lime in any form. About 6 to 12 gm. of the calcium lactate were given during the day for two months and the glands showed calcification in 8 cases and possibly also in 4 more, while the control cases examined over a period of seven months showed evidences of calcification in only 1 and possibly in a second case. The shadow of the hilus became more distinct also in 12 of the lime-treated children and possibly in an additional 2, while among the control children this occurred in only 2 instances. This clearing up of the shadow may be the result of healing of the tuberculous process or possibly of the direct action of the lime on inflammatory changes in the hilus. The clinical symptoms also improved materially in the lime-treated children and none seemed to have been injured in any way by these large doses of lime. It seemed to act just as well alone as when combined with cod liver oil or sodium tartrate, as was done in some cases. In 2 long febrile cases, the fever subsided almost at once after the lime treatment had been started, without any other change in the treatment.

157. **Bladder Cyst Preventing Voiding of Bladder.**—Ekehorn relates the case of a farmer of 54 who entered the hospital on account of complete retention of urine. The case seemed to be of the ordinary type of prostatic retention, although the prostate was not palpable, and the bladder was opened by a suprapubic incision. No attempt at cystoscopy had been made, as no difficulty had been experienced with catheterization. On opening the bladder the whole trouble was found to be a small, round tumor on a long stem, growing near the mouth of the urethra. This tumor had dropped into the funnel opening of the urethra and thus obstructed it like a ball valve. It was easily pushed aside by the tip of the catheter and consequently offered no obstacle to catheterization. It was then learned that the man had been in the hospital for the same trouble twice before, in 1910 and 1911. Each time the retention came suddenly and for four days the man was unable to emit a drop of urine although catheterization proceeded without difficulty. Then the ability to void the urine returned as suddenly and as completely as before, and there was no further disturbance for another year. The cyst must have been burst by the catheter; as soon as it collapsed there was no further obstruction until the cyst grew again and again started its valve action. The urine at all times had been normal and there were no evidences of cystitis. Ekehorn compares with this the cases of bladder cysts on record. In one case the pedicle was so long that the cyst appeared in the vulva of the little girl.

VOL. LXIV, No. 5 CHICAGO, ILLINOIS JANUARY 30, 1915

SOCIAL INSURANCE AND THE MEDICAL PROFESSION *

I. M. RUBINOW, M.D., PH.D.
Chief Statistician, Ocean Accident and Guarantee Corporation, Limited;
President, Casualty Actuarial and Statistical Society of America
NEW YORK

It is seldom that I have accepted an invitation to speak on social insurance with such enthusiasm and alacrity as the one that came from your committee. For over ten years I have devoted my leisure hours to propaganda in favor of social insurance measures in this country, and I look with a great deal of satisfaction to the change of public attitude toward what when my studies began was considered an idle dream or a revolutionary measure, but has now reached the dignity of an immediate program for most progressive organizations. During all these years it has been my hope that the interest and enthusiasm of the medical profession might eventually be enlisted in the cause. It is not only because I am the proud possessor of a medical diploma, although its use has long been discarded, but mainly because of a deep-seated conviction that there is no other class in this country which might contribute so much to the sound development of social insurance as the medical profession. Unfortunately, the practice of medicine is so exacting that the busy practitioner finds but little time to devote to the study of social problems. In the initial stages of the development of social insurance the medical profession did not play any significant part. But the fact that inquiries are beginning to come in represents a very hopeful sign of the times, even if it be true that those inquiries have been largely started by the economic effects of social insurance measures on the physician's own well-being.

Within the limited time at my disposal it would be unwise to try to present the economic theories which underlie the modern movement for social insurance, but its social significance can be made plain in a few words. Its purpose is no less than abolition of destitution in modern society, not at some distant future, but under the very conditions in which we live at present. It is but a large part of the broad world movement for conservation of human health and happiness, for which the medical profession has done so much in the past and will do so much more in the future.

That the insurance method is well adapted to prevent human distress resulting from certain unfortunate occurrences is an idea quite familiar to the American public. Life insurance has done a great deal to mitigate economic results of death of the bread-winner in the middle classes, and fire insurance has almost abolished that vast amount of human suffering which conflagrations cause, especially to society of lower economic levels. But the greatest amount of human destitution, with which perhaps no other group of people is so familiar as the ordinary every-day practitioner of medicine, is not caused by fire and not even by normal death. Physicians need not be told what the usual causes of human destitution are. They meet them in their every-day experience of visits to the homes of working men and women: widowhood and orphanage on account of premature death resulting either from accident or disease; enforced idleness due to acute diseases or lingering chronic ailments, or permanent deterioration of physical vigor due to old age, and finally all those economic disturbances of our social fabric which make it impossible even for the perfectly healthy and able man to obtain a purchaser for his labor. These are the complaints that must necessarily reach you day in and day out, and all of them are conditions in which you must be interested not only as citizens but also and very largely as members of the medical profession.

Without reading any sentimental descriptions of how the other half lives, the average physician knows that the standard of the wageworker's family is often on the margin of poverty; that the surplus in the weekly or annual balance sheet is but a rare exception and is very readily absorbed by the very first emergency arising from any cause. Without taking any courses of study on labor problems, physicians know that the housing conditions and the working conditions are in most cases unsatisfactory and present predisposing factors toward poor health with all its resulting economic effects; that in the vast majority of families their savings, if any, are so small that the first case of lingering illness or unemployment may bring even a seemingly prosperous family on the verge of destitution. In short, the pressure of the high cost of living on one side and the natural, inevitable desire for a higher standard on the other have destroyed any substantial margin between the workman's income and outgo. The resulting economic equilibrum is so unstable that any unexpected happening may throw any workingman's family below the poverty line.

NATURE OF SOCIAL INSURANCE

Social insurance as it has developed throughout the civilized world within the last three decades is an organized movement to prevent the destruction of wage-working families as consuming units by any of the ordinary emergencies of modern day existence. It recognizes that through the method of insurance, or the method of distribution of individual losses through larger numbers of individuals, the effect of such acci-

---

* Address delivered before the Associated Physicians of Long Island at Long Beach, L. I., Oct. 31, 1914.

dental occurrences may be very largely alleviated. As fire insurance, by dividing the loss from fire among thousands of its insured, may prevent any one of them from becoming impoverished, so accident insurance may help those who suffer from industrial accidents, and sickness insurance may take care of families afflicted by chronic or acute illness.

So far the theory of social insurance does not by one iota differ from the general scientific principles of insurance as a whole. The one substantial difference is the recognition that the importance of some sort of provision is very much greater when we are dealing with the masses of wage-workers, that insurance here ceases to be a matter of individual concern and becomes the concern of organized society or the state. Whether or not all the handsome suburban homes of Garden City or Long Beach are to be insured against fire may be something for the individual owners of those homes to decide for themselves. We know quite well that ownership of valuable property carries with it the necessary recognition of the advantages of security and insurance as well as the ability to pay for such security. I take it that the burning of a private mansion does not represent a serious social problem beyond the individual suffering that its owners might be subjected to. But whether the millions of wage workers in this country are or are not to be insured against consequences of industrial accidents or occupational disease is a matter of the gravest importance to society at large.

The millions of wage-workers are often unwilling and still more frequently unable to bear even the distributed alleviated burden which insurance represents. Social insurance, therefore, means a good deal more than simply social concern in popularizing the insurance methods created by independent effort. It means the establishment of national or public institutions to help and encourage the various forms of insurance which the workman needs for protection against the various hazards of his existence. It means even more than that. It means the willingness of the social body to assume a substantial part of the cost of insurance, to assume a part of the burden which otherwise the wage-working class must carry on its own shoulders. It frequently means that disregarding the time-honored notions of personal responsibility and freedom, the social organism may compel and enforce insurance even against the desires of the individual so that he and his family may be protected against his own poor judgment.

Briefly, this has been the theoretic basis on which social insurance has developed in this country and to a much larger extent in Europe. If you try to imagine the difference between the German or British workmen definitely protected through some system of insurance against loss from industrial accidents or disease or invalidity or old age, and the American workmen to whom any one of these dangers means total breakdown of the economic status of his family, except for industrial accidents in a few of the states during the last two or three years, you will appreciate what social insurance has accomplished in some countries and what it may accomplish in all others, and that even the higher wages of American labor do not sufficiently compensate for the absence of these systems in this country.

So much public attention has been attracted by the recent compensation movement since 1911 that perhaps few physicians have failed to learn of its existence. In Europe accident compensation has been in actual practice for the last thirty years, and it may be safely said that by this time there is no corner of the civilized world left, with the exception of possibly some twenty American states, where some system of compensation for industrial accidents has not been established. Important as this movement has been, another one of much greater interest to the medical profession is arising — that for some systematic organization of sickness insurance, of which in the very next few years undoubtedly a good deal more will be said than has been said in the past. That, too, is an accomplished fact in most of the important European countries. Germany, Austria-Hungary, Great Britain, Norway, even Russia and Servia, have had for some time national systems of compulsory sickness insurance for the wage-working classes, and in other countries in which progress perhaps has not been so great, substantial subsidies are given from the national treasury or from the municipal funds to encourage and stimulate voluntary sickness insurance among wage-workers.

In all of the countries enumerated it is an accomplished fact that not only the wage-workers themselves, but also the employers and the public at large share in the cost of curing and alleviating illness. Some countries have gone far beyond that and have established compulsory systems of insurance against old age and invalidity, while others, such as Denmark, Great Britain, and many of its colonies, have tried to meet the problem by granting gratuitous old-age pensions to persons over a certain age, in recognition both of the economic need of the superannuated men and women and the social justice of providing for persons in the declining years following a life of useful toil. The technical methods used in organizing this vast body of remedial legislation are varied and complex. Technical experts may go on discussing the details from the point of view of legislative efficiency, but experts have never created the force which must exist behind every broad social movement. In America we have made only the first few weak steps on the road toward systematic treatment of such social diseases as poverty and destitution. Important as the gathering of accurate information may be, I have always felt that the great need of the times is to create a general recognition of the serious aspects of the problem and the possibility of meeting it by appropriate means. If we can only get enough enthusiasts clamoring for social insurance, the careful experts to work out the detailed problems will not fail to appear. We have accomplished something in that we have succeeded in passing compensation acts in twenty or twenty-five states of this Union within the short period of three years, but it is necessary to remember that perhaps half of the country still remains unconverted, and that far more important than the question of accidental industrial injuries which represent a serious economic danger in only a comparatively slight number of industries, there is the entire problem of the economic losses through disease, old age and unemployment.

I have heard one of our prominent sociologists, who is also a firm adherent of the Darwinian theory, argue that the policy of social insurance as advocated by us, resulting in assistance to and preservation of the unfit, would lead to deterioration of the human race by abolishing natural selection; but what the prominent sociologist has disregarded is the enormous preventive value, the improvement of general health conditions which may be accomplished by abolishing economic want, and furthermore, that the wasteful method of natural selection of improving the race by sacrificing thousands is utterly inapplicable to present conditions of existence of the human race, which gives us scant surplus for the action of the selective process. Argue as much as we may against neo-Malthusian theories, the plain fact remains that future improvement of the race is possible only through the preservation of the individual rather than his sacrifice to the type.

WORKMEN'S COMPENSATION

The discussion until now has been rather abstract and general. It is inevitable because of the broad outlines of the subject that I am asked to treat. Coming down to the specific aspects of the movement as it is known to Americans at present, one large branch of social insurance has left the domain of theory. The accident compensation movement affects the medical profession in a great many different ways. It has created a great many different problems which many physicians are forced to face. In meeting a member of the medical profession, I quite naturally expect to have questions in regard to accident compensation thrown at me. Now, there are two ways or rather two points of view from which this question may be discussed before physicians, and these two points of view may be characterized briefly as the economic and the social ones. I am forced to state regretfully that as yet the economic problems, or rather the way in which accident compensation affects the economic interests of the physician, have been paramount. Far be it from me to deny the complete right of the medical profession to protect its economic interests, to further the economic standing of the profession or the trade. I have been too long affiliated with the labor movement of this country to deny any profession or trade the full right to aspire to a fair remuneration for its efforts. But it seems to me that nevertheless this is not or should not be the only point of view from which accident compensation should interest the medical profession; that not only as citizens should they retain a general interest in the social results of this new type of legislation; not only should they balance these social results at least to some extent against their own trade interests, but that they should go even beyond that and study and help in the solution of the social problems of compensation just because they are representing the one profession which is most capable of doing so.

In short, the relation between compensation and the physician may be studied from two points of view, first as to what the compensation has done or will do for the medical profession, and second as to what the medical profession can and will do for compensation.

ECONOMIC POINT OF VIEW

Let us begin with the first aspect of the case, the professional or trade interest, which is simpler and more easily disposed of.

Compensation has created a large additional demand for the services of the physician and surgeon. Perhaps two millions of accidents of greater or lesser severity occur annually in this country. Almost all of them require some medical or surgical aid, from first aid only to very prolonged treatment in some cases. Before the advent of compensation, comparatively few workmen could afford to command all the necessary medical aid.

As the accident meant the loss of wages, most of them were forced to crowd hospitals and dispensaries in quest of gratuitous treatment; a good many applied questionable home remedies of their own, and others went to their family physicians, swelling the percentage of uncollectable bills.

With the recognition of the employer's duty to furnish medical aid (which holds true to a greater or lesser degree in all the compensation acts, except those of Kansas and Washington, as far as I remember), all this has changed. Moreover, not only has the amount of work increased, and the amount of gratuitous work and uncollectable bills decreased, but the rate of remuneration has also materially improved.

Try as you may, it it difficult to disassociate wholly the terms of pay for medical practice from the principle of "what the traffic will bear." It is based on the elemental fact that medical aid is not a luxury but a prime necessity—all must have it and all cannot afford to pay the same or even a fair price for it. To put it bluntly, the traffic may bear a higher charge when employers, or industry, or in the final analysis the entire community has been charged with the burden.

That is what compensation has done for you, gentlemen, and being practical Americans you will admit that it is not a small matter for you. How are you going to react to these new conditions?

This new demand for your services, this new source of income, has placed new duties on you, some of a negative, and others of a more important constructive character. There is one great "don't" that must be announced emphatically, though, perhaps, it is not altogether a delicate or pleasant subject to dwell on. The physician must not make the mistake of trying to "make a good thing out of it." Because I happen to be employed by a casualty company writing compensation insurance, my statement concerning this should not be misunderstood. I beg to point to a decade of work for true standards of social insurance before I ever dreamed of any connection with the casualty business.

It is true that in the vast majority of cases your bills for treatment of injured wage-workers are paid by casualty companies, and in the remaining cases by more or less prosperous employers, that neither the casualty company nor the employers will be brought to financial ruin by an unreasonable medical bill. But the force of economic tendencies is great. The cost of medical aid, as the entire cost of compensation, is not borne by the casualty companies who must collect in premiums what they are required to pay out in losses, and who necessarily compute the entire cost of medical aid and add it on; it is not even borne by the employers who will necessarily endeavor to shift this cost on the consuming public. Not for a moment will I dispute the claim that the medical profession is entitled to a fair remuneration for the services it renders. I am not here to protect the interests of casualty companies, or even of the public or the community at large, which still continues to put a higher valuation on the services of prize fighters and baseball players than its educators or healers. But I do plead for the rule of reason in medical bills, because in the final analysis the interests of the toiling masses demand it. The provisions of American compensation laws, in regard to medical aid, are bewildering in the variety and the extent of liberality, from total denial of it in Washington and Kansas, as already stated, up to full treatment for ninety days without limit of cost, as in Wisconsin; limit two weeks in Massachusetts, to four weeks in Illinois, and so on.

In interest of proper care, all time limits are undesirable; but they have been brought about by a fear, let us hope exaggerated, of the figure to which medical bills may grow. It is the usual size of medical bills charged to casualty companies, for minor cases, which has caused very limited and unsatisfactory provisions for medical aid in several states. There can be no question that the physician is worthy of his hire, but it is also true that the injured workman is still a workman and that the standards of payment derived from practice among prosperous families, with its accompanying waste in waiting for visits, should not be applied to the treatment of injured wage-workers.

A fee schedule agreed on after proper consultation with physicians is absolutely necessary, and should receive the cordial support of the profession.

There is perhaps another "don't" of lesser importance which may be mentioned. It fortunately does not apply to the entire medical profession but only to a few on the fringe, and that is in regard to the physician's part in the development of malingery.

Even before the compensation movement had resulted in many acts in this country, the cry of malingery arose. I was not one of those who raised it. Repeatedly on the pages of the *Survey* and elsewhere I protested against the implication that the effort of society to do some modicum of justice to the injured workmen and their families would result in making the American people a people of cheats and liars. Nevertheless it is useless to deny that a certain stimulus to malingery and fraud lurks hidden in the provisions of the compensation act. It is wrong to exaggerate it, but it is equally wrong to disregard it altogether. In my own experience I have met a few cases of this kind, though not so many by far as some enemies of compensation would want us to believe. Physicians in Europe have done a good deal to call public attention to this evil; perhaps they have exaggerated its extent. In telling these often unpleasant truths the medical profession has performed a valuable public service. But it is impossible to disregard the fact that in almost all cases of flagrant malingery a share of the responsibility falls on some member of the medical profession whose crime in the worst cases, and these fortunately are few, is that of deliberate collusion and fraud, and in many cases a certain weakness and misapprehension as to the moral duties of the physician toward his patient.

Not for a moment should this sense of professional duty rise above the duty to the social organism as a whole, and surely it is not socially desirable that the tremendously important step toward constructive social policy should suffer from a charge of destroying the workingmen's sense of self-reliance and independence. Even beyond the temptation to outspoken malingery, there is the danger of encouraging the excessive neurotic diathesis.

Far more important than compensation of a week or two to the injured wage-worker is the preservation and stiffening of his moral backbone. It is the duty of the medical profession as a whole to take a very definite attitude against those few of its members who are forgetful of their social duty.

In many more cases this encouragement of exaggeration by the physician is entirely involuntary. Workman's compensation has put new requirements on the physician. In addition to the surgical and medical judgment a new economic judgment is required. The healing of the injury is often an entirely different matter from the entire restitution of earning capacity. Many years' experience with accident reports and physicians' certificates have convinced me that this economic judgment is largely lacking, and that expert medical opinion in the important problem as to the exact time of permissible return to work is often highly unsatisfactory.

As a matter of fact, the judgment is too optimistic more frequently than otherwise. In perhaps 75 per cent. of the cases the physician's estimate as to the probable duration of disability falls far short of the actual duration of disability. Compensation has done away with many legal technicalities of the liability law which were a valuable asset to hundreds of attorneys, but in its stead it has created a large demand for expert medical opinion which I fear is not as yet always met with uniform degree of success. Nor is an unbiased diagnosis and prognosis all that the physician must furnish.

The acceleration of economic recovery has acquired a definite commercial value. The work of Zander institutes in Germany is an indication of how much the medical profession can contribute to the cause of human conservation.

An indirect result of compensation is the stimulus it must give to the work of prevention, a line of endeavor largely neglected in this country until now. As far as accident prevention is concerned the field is open for the inventive genius of the American engineering profession. For many years our engineers were too busy constructing gigantic buildings and intricate machinery to pay much attention to reducing the toll in human life and limb.

Even so it has been suspected that physicians took more pride in inventing new operations, rather than in preventive work. But while the causation of industrial accidents is not within the province of medical science, there is an equally important field of inquiry in connection with industrial diseases. Already in one or two states these diseases have been included under the compensation act by judicial decisions, and thus have opened a large field for diagnosis, prognosis and prevention. But as yet the American medical profession has paid comparatively slight attention to them. The splendid work done by many physicians in the domain of industrial hygiene must not be disregarded. But it still remains true that similarly important work was done by non-medical investigators.

Compensation is to-day an accomplished fact. Only five years ago it was but a hope. To-day the first steps are taken in this country for a system of sickness insurance. I venture to make the prophecy that once started, the movement will proceed at even a greater rate of speed.

In December, 1912, the American Association for Labor Legislation, encouraged by the progress made with accident compensation, provided for a special national committee on social insurance. During the greater part of two years this committee of leading authorities on the subject has been working on a plan for compulsory health insurance in America. The work has progressed to the point where it may be confidently expected that a bill will be introduced in some of the state legislatures in 1915.

The economic ravages of industrial accidents are picturesque and attract attention, but ordinary prosaic every-day sickness presents a still greater problem. If a dollar and cents measurement is required, it is enough to point out that the cost of sickness insurance in Germany is $100,000,000 a year as against $40,000,000 spent for accident relief. On the same basis a national system of sickness insurance in this country would represent an annual amount of about $300,000,000. Of this amount, it may be confidently expected that nearly one-half will be spent for medical aid, medical supplies and hospital treatment, and yet I venture to hope that this will not be the only point of view from which the American medical profession will consider sickness insurance.

SOCIAL POINT OF VIEW

It scarcely seems worth while to argue the social significance of a comprehensive sickness insurance system to an assembly of physicians. It is not only that the medical profession knows from its own observation the amount of destitution that exists; it is not only a sentimental appeal for relief of human suffering, but it is because no one is better able to judge than is the physician what an important factor poverty represents both in causing disease and in preventing its proper treatment and cure. Whether in dispensary practice or even in the homes of the tenement population, the physician simply cannot fail to feel the entire hopelessness of medication and advice unless supported by substantial improvement in the general hygienic conditions and economic well-being of the family. One might as well try Christian Science or absent treatment as to advise good nourishment, fresh air or rest where the illness of the wage-worker also means the complete stoppage of income and perhaps an immediate dropping below the line with necessary appeals to public or private charity. No one better than the physician knows how totally unnecessary is the largest share of illness surrounding us, how easily it could be met by proper conditions of living or working, and what a depressing effect these conditions must have on the development of the human race. Sickness and poverty stand in a relation of a vicious circle to each other; sickness causes poverty through the interruption of income, and the cost of medical treatment. Poverty causes sickness through lack of good food, good lodgings, through ignorance and neglect of personal hygiene, through destruction of mental rest. Only with the help of a strong shears can this circle be cut, and of its two blades, one spells sufficient medical aid, and the other necessary economic assistance.

I shall not venture to make any guesses as to which of the two blades is of greater importance. Affluence alone will not cure pneumonia or an ingrown toe-nail, but no one better than the attending physician knows the utter futility of drugging the sick man when other conditions are unfavorable.

If the medical profession is at all conscious of its social function, its unqualified support of the comprehensive plans for sickness insurance should be a matter of course. Experience has shown, however, that this has not always been its attitude in the matter. American physicians have heard of the attitude of the British medical profession during the introduction of the British national health insurance act (perhaps the greatest piece of constructive social legislation that Great Britain has passed as yet), and of the constant quarrels between the German physicians and their sick-insurance funds.

So far as the arguments between the British medical profession and Lloyd-George concerned the financial terms for rendering medical service, or the strikes of the German physicians aimed at exacting a somewhat higher rate of pay, I will cheerfully admit that the views of the physicians deserve a hearing. After twenty years' active participation in the labor movement, I am not here to deny to any trade or profession the right of organized effort to improve conditions of employment. Even here, however, the peculiar social character of the medical profession must guide at least its methods of trade-union attack. Above all it must not be forgotten that the employer in this aspect of the labor struggle is the working class with its own low standard, that in distinction to accident compensation, the largest part of the burden falls on the workers themselves. Workingmen seldom deny the necessity of a higher standard than their own for the physician who serves them, but they can hardly be blamed if they are not ready to admit that this normal standard includes automobiles, a retinue of servants and membership in exclusive clubs.

Even in this financial fight the medical profession may be misguided. The famous British economist Sidney Webb points out, for instance, that as yet the physicians were the greatest beneficiaries of the insurance act, having a guaranteed source of income as against the speculative character of private practice among the poor. Moreover, this aspect of the problem need perhaps cause less worry to physicians in America than in any other country. The American people are used to a liberal scale of medical fees. Nothing illustrates it better than the medical fee schedules adopted in some compensation states. It is true that the conditions of remuneration as established by numerous lodges in the East, or by the so-called 10-cent medical organizations, appear as a threat of what a further extension of collective medical aid may bring. But the medical profession may meet these undignified forms of contract in one way only—by supporting and cooperating with the rapidly growing movement for organized sickness insurance, rather than opposing it.

Far more harmful is the tendency shown by British physicians, and which may be noticed here, to fight this movement in principle. Most physicians look with apprehension on any inroads into the field of private practice; hence the silent opposition to extension of hospital facilities and the noisy opposition to dispensaries and 10-cent doctors.

In this the medical profession is hopelessly behind the times. In its worst phase private medical practice is medically from twenty-five to fifty years behind the present status of medical science and surgical skill. In its best phase it is a luxury, which like automobiles or private yachts can be purchased only by the selected few.

The socialization of medical service has been wofully delayed, as compared with many other functions of far lesser importance, but at last it is on its way. The purpose it must accomplish is twofold—improvement in quality and cheapening of cost. These purposes cannot be easily accomplished in face of an obstinate opposition from the medical profession.

PROBLEMS

The technical problems arising in connection with the relation between a sickness insurance system and the medical profession are many and complex. It is quite impossible for me to treat of them in detail in the present article. I can do no better than recommend the splendid monograph by an English student, Mr. I. G. Gibbon, entitled "Medical Benefits," to the consideration of any one interested. Whether the millions of individuals protected by the sickness insurance system be granted the right of selecting their physician (on the preposterous theory that the patient may be the proper judge of the physician's ability, a theory retained from private practice because individual successes have often been built on it) or whether the physicians be selected by persons qualified to judge, as are physicians of hospitals, or members of other professions of equal importance; whether the remuneration of the physician be in the form of a regular salary, as is done in some German cities, and in the so-called Zemstvo medical service of Russia (perhaps the greatest organization of medical aid that the civilized world has seen as yet), or whether it should be computed in proportion to the visits the doctor succeeds in making, as in Leipzig, or in proportion to the number of permanent clients he succeeds in attracting as in England, or whether he should perhaps be remunerated in inverse proportion to the amount of medical aid he is forced to give, as the Chinese are supposed to do — all these are questions in which the medical profession should and will be heard. No one of the advocates of sickness insurance in this country for a moment intends to force an entirely new system of medical aid organization down the throats of the American people. It is recognized that habits and customs of the people change but slowly. But the unmistakable tendency is toward better organization. The present methods are admittedly inefficient and wasteful. An exclusive curio shop on Fifth Avenue may profitably wait a whole day for a single customer and make him pay all the overhead charges for that day. A popular department store must be built on a more economic utilization of capital and labor.

The workingman cannot afford to pay for the time the physician wasted as well as the time he worked. The workingman needs the expert specialist, not the expensive one. It is admitted that the active physician should work at least as hard as does the engineer, the teacher or the statistician. The preposterous charges for expert surgical aid are sometimes defended on the grounds that operations are few and far between. At the same time there are thousands who must be pauperized because operations are too costly. With proper organization of medical aid, such as only a national system of sickness insurance can give, when a physician has a normal working day and does not waste his time in senseless waiting or useless riding, and will command only reasonable but certain remuneration, when the antiquated pretense of omniscience will be abolished and the physician will not be ashamed to admit his ignorance of some things, or prohibited from announcing his expert knowledge of others, then and only then will the medical profession cease to be a speculative profession with splendid prizes to a few, very few, and sad disappointments both financial and ethical to the majority.

For what are the plain unadorned facts? The recent report of the United States internal revenue office disclosed the existence of about 357,000 incomes over $3,000 a year in this country. Let us allow for a certain amount of tax dodging. The preliminary estimates of the federal government assumed about 425,000 taxable incomes. Let us add incomes over $2,500 and assume an entire million families over that level. It still remains true that these represent less than 5 per cent. of the twenty odd million families in this country. And outside of that small group the cost of efficient medical aid (that is, the only kind worth having) in a case of serious illness is either prohibitive, or ruinous, or at least a serious hardship. The fortunate individuals who furnish medical and especially surgical aid to the selected few may prosper and pocket their handsome fees without any throbbing of their heartstrings. But the conscientious physician who is forced to cater to the millions cannot help recognizing that frequently the fee which he should receive is required by the patient for the purchase of necessary food or care. If he happens to know, as he often must, that his visits are altogether ineffectual except for the moral effect, that knowledge for any one with a social conscience must be very bitter. That he needs the fee to meet the bills does not seem to me to be any social answer at all.

There is only one way to meet this economic and ethical problem which has as yet been devised; a system of insurance which meets the economic loss of illness at least half way, and a system of organized medical aid which reduces its cost substantially without pauperizing the patient or degrading the physician. Social insurance against sickness meets both these problems and it has therefore become a world-wide movement. The medical profession can fulfil the time-honored glorious oath of Hippocrates by giving to it a modern broad social content and by helping instead of hindering the development of social insurance.

My brief experience with the practice of medical arts, though discontinued over a decade ago, has left me with sufficient professional pride to make me hope and believe that such will be the attitude of the American medical profession.

The American people have been criticized as suffering from the childish conceit of the half-grown. European institutions have been ridiculed or discarded, sometimes with what seemed insufficient cause. The American physician was perhaps the first to recognize how young and inexperienced we were here, and how much we could learn from Europe. Within the last twenty years or so the childish American conceit has fortunately given way. Slowly at first, and faster as time went on, we learned to see ourselves as others see us, and have found wherein we were deficient. In a great many things we are still behind, but in some things our progress has been almost phenomenal. Our New York compensation law, for instance, will bear comparison with the best in Europe, and is vastly superior to that of England. Our great American universities may be equaled by few outside of Germany. Our children's courts have been imitated everywhere throughout the world. In many lines of social legislation, as in mothers' pensions, we are teaching a lesson to Europe. Our theory and practice of scientific social work is vastly superior to similar European efforts.

A solid foundation for a new national pride is rapidly developing. Let us hope that in the development of social insurance we shall find in the American physician not the stubborn opponent that the British medical profession has been, but an enthusiastic ally, and thus once more prove that in social ethics we are able and willing to rise above European standards.

Making a Peaceful Life.—Remember that in life you ought to behave as at a banquet. Suppose that something is carried round and is opposite to you. Stretch out your hand and take a portion with decency. Suppose that it passes by you. Do not detain it. Suppose that it has not yet come to you. Do not send your desire forward to it, but wait till it is opposite to you.—*The Encheiridion.*

A METHOD OF OBTAINING DENTAL SERVICE IN HOSPITALS BY THE APPOINTMENT OF INTERNS[*]

HERBERT L. WHEELER, D.D.S.
NEW YORK

In 1901 and 1902, the first dental department of a clinic or hospital in New York City was established in St. Bartholomew's Clinic at 215 East Forty-Second Street. This has had a continuous existence up to the present time. The organization and direction of the dental service was carried on by Dr. J. Morgan Howe.

Shortly after this Dr. John W. Brannan, the president of the Board of Trustees of Bellevue and Allied Hospitals, suggested the establishing of a dental service in Bellevue Hospital. This seemed a good suggestion. In the first place, it appeared that a weak point in the chain of resistance to the inroads of disease was the lack of intelligent care of the mouth and teeth, and the opportunity to be associated with this great emergency hospital offered excellent conditions for putting into execution plans which might show that no satisfactory attempt could be made at prevention of disease without considering and including the oral cavity and its contents. With the cooperation and assistance of Dr. Brannan, we set about securing a staff for Bellevue Hospital. In arranging for a permanent dental staff we tried as far as possible to avoid the conditions that seemed sure to arise, and did arise within a short period. The dental profession was divided into two camps: those who favored all dental service of this type being paid for by some one, either the city, institution, or through charitable donations, and those who favored the dentists giving their services as the physicians did. It seems probable that those who favor the payment of the dentist for his services in this charitable work are largely in excess of those who do not; and feeling that this question would arise sooner or later, we endeavored to steer a middle course.

Our plan was as follows: In hospitals in which physicians gave their services the dentists should do likewise, but in turn the dentist should receive due recognition and be appointed on the same basis and with practically the same title as the physician in a corresponding department in medicine or surgery. The dentists had their titles conferred as in the surgical and medical departments. For instance, there was a director of the dental service at Bellevue. There was created a staff of visiting dentists, who represented the older and more experienced men, and a staff of assistant visiting dentists, who represented the younger class more recently graduated; and these were appointed with the understanding that they serve a specific time, weekly or monthly. It is usual for the visiting dentists to come every two weeks or once a month, and for the assistant visiting dentists to serve one or more afternoons per week; besides this, there was eventually, after two years or so of experiment, established a dental intern who lives at the hospital, associates with the medical and surgical interns, and is retained on exactly the same conditions as the other interns, receiving a certificate at the end of his service.

I have had those interested in other hospitals approach me in regard to establishing dental departments for them, but with the exception of Bellevue I have not found those who were willing to give a man the full honor and position due him unless he had the M.D. as well as the D.D.S. This attitude would prevent dental service in most hospitals.

The plan adopted at Bellevue was extended to the Allied Hospitals, one by one; first to Harlem, then to Fordham, then to Gouverneur, with the exception that up to the present time there has not been an intern appointed at any of these Allied Hospitals. Gouverneur is, however, at present, actively engaged in the attempt to secure an intern. It seems probable from our experience at Bellevue that the addition of an intern to the other hospital staffs will double, or more than double, the efficiency and quantity of service that can be obtained from a dental staff in a given time. This is due to the fact that there is somebody at the hospital at all times not only to attend to emergency cases as they come in, but also to arrange and so distribute the work that there is a greater conservation of time and less waste in waiting and arranging for various things. Last, but not least, in this plan of service is the question of a nurse assigned to the dental department.

At the original inception of the dental service, social service nurses, who were under no particular authority, were furnished, but this proved decidedly unsatisfactory and undesirable. Later one of the regular nurses in the hospital was appointed to serve in this department. Practically all of the regular nurses who have served have been deeply interested in the work, and they are enthusiastic, with the result not only that their service in the department of cleaning instruments, caring for the patients, sterilizing implements and arranging supplies has been of the very greatest assistance, but also that their assistance in obtaining patients from the wards with the least expenditure of time, and the keeping of the accounts and records has been of such a character as to entitle the nurses to a good share of the credit for the success of the dental service.

To establish and obtain a successful dental service in an organized public or private hospital the following things are necessary: the dentists must be men willing to sacrifice some of their time in public service and who have a sincere belief in the usefulness and beneficence of their work. They must be regular in their service. The managers or board of directors of the institution must be in sympathy with the work, willing to assist in every way possible and willing to overlook the many shortcomings that are bound to develop on the part of the dentists from lack of experience. There should be also general medical directors or superintendents who are sympathetic with and desirous of using the dental service to the limit of its possibilities for the welfare and upbuilding of the hospital.

An idea of the value of the dental service to Bellevue may be given in instances of record. The service is arranged so that those who shall be first received are the children of the various wards; and it is within the province of the dental department to retain the patients in the hospital until such service as they deem necessary shall have been obtained by the patient. There are at present on the staff of Bellevue and Allied Hospitals no less than twenty-eight or thirty dentists. A goodly part of these serve comparatively regularly, as may be seen from the following report of the services rendered last year.

---

[*] Read before the Section on Stomatology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

At Bellevue Hospital there was given, in time, by the staff, 1,998—practically 2,000 hours. There were attended to in this one hospital alone by the dental department, 1,161 children and 1,142 adults. There were performed altogether, including major and minor operations, which run from mere treating of a carious tooth with an inflamed pulp to operations for necrosis and carious bone, and the setting of fractured mandibles—5,956 operations. In Harlem Hospital, where the work is carried on entirely by a staff of women dentists, in charge of a woman dentist, there were 231 children attended to and 19 adults. The operations here represented something over 600. At Fordham Hospital, where the staff is comparatively small, there were 154 children attended to and 78 adults. The number of hours put in by this staff was 141, and there were performed a total of 874 operations. The dental service at Gouverneur had not been organized fully a year at the time of this report, Dec. 31, 1913—and yet here, with a comparatively small staff, there had been attended to altogether 451 individuals, and there had been performed, from April 1 to December 31, 700 operations—a pretty good service for part of a year.

As an economic proposition, let us see what Bellevue has accomplished in one department only of the dental service as a money saver for the city of New York. Fractures of the jaw, and major treatments of this kind, run about 100 per year in the dental service. Previously all fractures had to be sent elsewhere or else put in the ward and the patients bandaged; there had to be a nurse in regular attendance and the patient had to be cared for, housed and fed for a period extending from five to ten weeks. One may estimate for oneself the cost per patient to the city under these conditions. After the establishment of the dental service there was equipped a dental laboratory sufficiently complete to make vulcanite and metal splints for fracture cases and for doing various other mechanical things that might be demanded in the dental service of any well-equipped office. When patients are sent to Bellevue now with a fractured jaw, they are as soon as possible taken to the dental department, an impression is taken and a splint is made and placed in the mouth. This can usually be done in from one to three days. As soon as the splint is in place, if the injuries are not such as to make it impossible for the patient to go about his usual vocation, he is permitted to return to his occupation at once, coming back to the hospital two or three or four times a week for observation and cleansing. The difference between keeping a patient from five to ten weeks, with a nurse in constant attendance, and keeping one three or four days and allowing him to leave, in the matter of expense is very great, and the economy must be credited to the dental department. I venture to say that the city of New York has been saved considerably more on its fracture cases alone by the dental department than the entire dental service has cost from the beginning to the present time, to say nothing of the improved conditions that have obtained for the patient and the amount that has been saved to patients because of their ability to return to their occupations, within a very few days. Add to this the probable certainty that the dentist will set a fractured jaw so that there will be a proper occlusion after the bone has healed, and you have a very simple but strong argument in favor of the establishment of dental service in a hospital. But this subject would require a paper in itself and I will confine myself to the executive part of the work.

I think that the foregoing statement has shown that if the dentist is given due consideration and authority equal to the responsibility placed on him, it is not impossible to establish a useful and successful dental service in a general or emergency hospital.

There are of course conditions and circumstances which make it impracticable to obtain dental service on this basis, and there are arguments on the side of the men who advocate that dentists shall be paid for their service wherever it is rendered, by somebody or in some way, and experience leads me to believe that circumstances alter cases and that one has to use judgment as to which of these methods one will apply to a given case. At Bellevue and Allied Hospitals the methods described have worked out extremely well. I do not consider that the dentist as yet realizes the necessity of being responsible and regular in his service to the extent that he should, but conditions are improving in this direction.

At St. Bartholomew's it was impossible to get a dental staff on any other than a paying basis. Even then, under the direction of a man who was not recognized by the dental profession, the service gradually ran down and became a failure. Later the service had to be reorganized, and it was found necessary to continue the practice which had been established of paying for the dental service. The payments are not high, in fact they are ridiculously small, but they are sufficient to assist young men who are anxious to spend part of their time in establishing a practice and willing to spend the other part to secure enough to give them a small income as a certainty. Therefore it is not hard work to secure a fairly high class of young men in this service.

If a salary is paid, we can demand certain hours, that the dentist practice along the lines that those in authority wish, and closer supervision and a greater authority can be exercised. The result is that the work can be greatly expedited and the energies utilized may be and are greatly conserved. Although comparisons are invidious and often misleading, the following will show what I mean:

At Bellevue the intern may be said, in a sense, to receive at least some return for his services. None of the visiting or assistant visiting dentists, or the director of the service, receives anything, so that if a man feels, for any reason, that it is impossible for him to be at the hospital at the time he is supposed to be, without much compunction he fails to appear. It requires considerable effort sometimes to impress on them the necessity of appearing regularly. Patients are often brought into the dental department ready for dental service, only to find that the expected assistant visiting dentist does not appear. This is annoying to everybody, besides being a great waste of energy, and costing in loss of time and inconvenience.

At Bellevue, with a staff of twelve, it has been pointed out, the operations performed last year totaled 5,956, which is without doubt an unusually good showing, as evidenced by the number of hours, practically 2,000, which were put in by the staff of Bellevue Hospital alone.

At St. Bartholomew's clinic, with but two men on the staff besides the director, who does no work at the chair, one working every afternoon from 2 until 5, and one two evenings a week, they attended to 5,000 persons and performed over 7,500 operations. This was because the men had to be there, furnish a substitute, or lose their salary, which acts as a strong incentive to keep a man at his work. I am satisfied with both methods that have been described, and believe that, with discretion, either may be used successfully.

I have frankly told those desiring to establish dental service in a hospital, who were unwilling to appoint dentists on the same basis and give them the same standing as the medical attendants, that I saw no other way but to pay a salary. I myself would advise any dentist against serving in a hospital where his recognition was not as complete as that of physician, unless he serves for pay, and that is his own affair. I am not sure but that a small stipend or salary paid to a man (and this would perhaps hold good in the medical and surgical departments) would enable us sufficiently to control those giving the service, so that the work might be directed in a way to save time. It is not impossible that this might serve to make it cheaper in the long run to have a paid service.

This is not intended as an argument either way on this subject. It is a matter that will have to be worked out by experience. I am, however, of the opinion that whether or not it be a paid service, some method whereby it is possible to insist on men's serving the time they say they will is essential in order to obtain the most efficient and desirable results.

560 Fifth Avenue.

ABSTRACT OF DISCUSSION

Dr. W. C. Fisher, New York: This paper proves conclusively what I contended two years ago was necessary in order to get proper dental service in hospitals. Dr. Flanagan of Springfield, Mass., read a short paper before this Association in 1912 on the need of a dental staff attached to hospitals, and in the discussion the question was constantly asked, how could this best be accomplished? Dr. Brown of Milwaukee did not believe proper services could be obtained in a hospital of any size except through internships, and that dental service should be paid for the same as medical service is paid for; that the real work of the hospital was done by men attached to that hospital, under the supervision of more experienced men, and that the dental intern should be there constantly also.

Dr. R. H. Ivy, Philadelphia: In 1900 an oral surgical staff was appointed at the Philadelphia General Hospital. There were four men appointed, two of whom held the dental degree, the other two both medical and dental degrees, and they were all received on equal footing with the medical members of the staff of the hospital. One year later, in 1901, two interns were appointed in that hospital on an equal footing with the other interns of the hospital and under the direction of the visiting staff, and it was decided at a meeting of the medical staff that all cases of mouth conditions and many cases in which the mouth was responsible for the general condition, should be turned over to them for treatment. This plan worked so well that there have been two dental interns on the hospital staff continuously since that time, the dental men working always in harmony with the medical men and belonging to the society of the residents of the hospital. This year the same plan is being carried out in the Episcopal Hospital. A resident dental surgeon on an equal footing in every way with the medical residents has been appointed and has been given a splendid equipment to perform all kinds of dental and oral surgical operations. It is now being contemplated to increase the number of dental interns in the Philadelphia Hospital so as to have two on duty to care exclusively for the tuberculous patients, it being deemed desirable to keep these patients separate from the others in regard to dental treatment.

Dr. M. H. Cryer, Philadelphia: I would like to add to what Dr. Ivy has said, that the four members who form the oral surgical staff give clinics for eight months in the year on Saturdays, and they for some reason have the largest clinics given in the city of Philadelphia. The average attendance for the past winter from the various dental and medical schools was 350. On some occasions we had as many as 450 students and practitioners at these clinics. The city of Philadelphia also gives a certificate to those who attend 80 per cent. of the clinics, and these certificates are signed by the oral surgical staff, the Director of Public Health and Charities, and the city seal of Philadelphia is placed on the certificates. These certificates have become so popular in foreign countries that they stand higher to-day than the university degree, because they are signed by an official of the city and bear the seal of the city. When a graduate goes to a European country, he is asked where he has attended his lectures and what degrees he has. When he answers that he has the University degree, the Philadelphia Dental College degree, or the Medico-Chirurgical College degree, they ask, "Have you a certificate from the Philadelphia General Hospital? We consider that better than any other degree." That is what we have been doing in Philadelphia since 1900.

The dental interns in the Philadelphia General Hospital (Blockley) are appointed in this way: At the clinics and lectures announcement is made that two interns will be appointed each year, and that Dr. Roe, Dr. Russell and myself will be glad to receive applications from students wishing these positions. The students making application are specially watched during the senior year of their course. These men are required to make a certain class of splints and do other operations up to a certain standard, after which they are passed on by the faculty of one of the three schools, and then passed by the state board. Then the applications are gone over by Dr. Roe, Dr. Russell, and myself and we decide which men we will appoint as interns. They are then recommended to the Director of Public Health of the city and he makes the appointments. These men serve one year, and if their service is satisfactory and they wish to continue, they are allowed to serve another year. The dental interns belong to the Intern Society which has been in existence for many years, and they are received on an equality with the medical interns, and the oral surgical staff members belong to the medical board of the hospital. This has been going on since 1900, and the plan has been adopted by other countries—France, Italy, Spain and others—and in 1904 the government of Spain sent Dr. Aguilar to Philadelphia especially to see what we were doing there in taking care of the mouths of some five thousand patients in the City Hospital.

Dr. T. L. Gilmer, Chicago: I have been a member of the medical board of St. Luke's Hospital, Chicago, for twenty years, and Dr. Black is also similarly connected with the same hospital. We are there on exactly the same basis as are the other members of the staff. We are designated as oral surgeons. I think this is a good time to work for extension of the service to include dental interns in hospital work, since it is now recognized by physicians in general that the mouth infections play an important part as a primary factor in the etiology of infections in different parts of the body. The mouth foci must be eradicated before patients can be cured of heart, joint, or other lesions, which may be secondary manifestations of the mouth focus. Much of the work, especially the strictly dental part, may be done by the dental interns, relieving the oral surgeons of much of the less important service which is imposed on him at the present time.

Dr. M. I. Schamberg, New York: It is gratifying to hear the report of the appointment in Philadelphia of interns as a matter of priority over New York. However, in Philadelphia you have one hospital which has interns, while in New York, through the efforts of Dr. Wheeler, we have many which have adopted the internship plan. While hearing this paper it has aroused my desire to ask for a dental intern in our institution, for the reason that I frequently request that many of the fracture cases be put through the so-called prophylactic treatment prior to treating the mouth, so as to avert, if possible, any secondary disease that may occur. In this way I believe the proportion of cases of necrosis and abscess conditions that follow fractures would be materially reduced. I feel confident that the addition of an intern in our institution will raise the efficiency of our work 100 per cent.

Dr. G. V. I. Brown, Milwaukee: I am on the surgical staff of the Children's hospital in Milwaukee just as all the other surgeons are. We have recently had a visiting dentist appointed on the staff. In order that we might outline the work he and I have made a complete examination of the children's mouths in the hospital, and as simple as that may sound, we found it difficult to do, for we found it impossible for us to do it all in one day, and between visits the children would come and go. As the result of our work, the dentist has just sent in a recommendation which will call for a mouth examination as part of the regular intern's examination for each patient. For example, when the history of the case is taken, the general physical examination will include an examination of the mouth with sufficient accuracy to warrant calling in a dentist or otherwise. At least there will be a mouth record of every case the same as the physical record. There has not been any mixing of medicine and dentistry on that; we consider that it is a matter which pertains to the welfare of the patient. We found an appalling state of affairs in the hospital. We found that little patients were lying in bed for months, being treated for joint diseases when they had anywhere from one to five diseased teeth in their mouths. In view of the recent investigations and demonstrations, the importance of this will be understood. We are to blame for that as much as the surgeons; it is a question of wrong routine. In the other hospital with which I am connected I have not had the courage to have a dentist intern appointed. I did not care to have the matter disturbed and have other questions arise which I could not meet. I am there simply as an oral surgeon. When Dr. Wheeler gets this work on the right basis, and when somebody has shown me exactly what should be the relation of the dentist in the hospital, then of course I want to appoint interns. In the meantime, however, I do not care to take the responsibility.

Dr. A. D. Black, Chicago: It is only necessary for a person familiar with mouth conditions to spend a few minutes in a hospital to see the necessity for this work. The greatest difficulty in establishing the work heretofore has been the lack of appreciation of the physician of it and the difficulty of placing dentists in the service on the proper basis, because we cannot get the kind of men we want to do this work under the conditions which have heretofore presented in most of the hospitals. I wish to emphasize that there has been enough published in the medical literature of the past two years, to say nothing of any other work, to have attracted the attention of every physician on every hospital staff to the importance of the mouth as they have never appreciated it before, and there should be no difficulty at present in presenting to any hospital one or the other of the plans which Dr. Wheeler has outlined and have them accept a plan and appoint dentists for the service. In St. Luke's Hospital in Chicago, as Dr. Gilmer has said, we have done many things that are not expected of us, because of the crying need for it. I know I have many times sacrificed time which I was not expected to give because of the need for dental service among the patients and because under the hospital arrangement there was no other way to get the service. There is another feature to this work that I would like to speak of, and that is that there is opportunity in the establishment of these internships in hospitals for the dental profession to get credit for the service or to be embarrassed by the service given, in accordance with the type of men who are selected for this service. We need to be extremely careful of the men we put in because the contact with the medical men and the patients in that service is of tremendous importance. We have the opportunity there to impress on them the value of this dental service as we have in no other way.

Dr. T. F. Tholen, Los Angeles: In the Los Angeles County Hospital we have an oral surgeon who visits the hospital and who confers with the men in the surgical section as to the treatment of oral surgical cases. We have had very good results from this method, but Dr. Wheeler's method seems to be so much better that I think I will do what I can to induce them to introduce his method.

Dr. E. A. Bogue, New York: It does not seem to have been recognized by the medical world at large until lately that the mouth and nose, which are connected by one passage, constitute the entrance for all that we take in to support life, and almost all that we take in to destroy it, and that the condition of the teeth has much to do with the general health. It seems to me that Dr. Wheeler has pretty nearly put us on the track of developing our section and placing it in its proper position in the medical world. I hope he will persevere until all of our hospitals establish the intern system for dental practitioners. As I understand it, all these interns have to be graduates?

Dr. Wheeler: At present they not only have to be graduates, but also have to pass the state board.

Dr. Bogue: In England there is a practice of extracting all temporary teeth, if one happens to be bad enough to come out, but we are rapidly getting away from such practices. In several of the European countries the governments are appointing dentists to take care of the teeth of the children, and in this country, the Forsyth Infirmary in Boston, of which you all know, is doing an enormous amount of work in the way of caring for the teeth of the poor children of the city.

Dr. H. L. Wheeler, New York: There is just one way to get dental service in the children's hospital, and that is to appoint dental interns and let them live there with the medical interns. The service cannot be had in any other way unless it is paid for, and if this scheme is adopted trouble arises because the medical men also want to be paid. This subject in New York City has had a good deal of discussion, not only in the profession but by the laity, and only recently the committee of the Board of Estimate and Apportionment decided to recommend that dentists be put in the same classification as medical men in every department where dentists are to be appointed. They have decided to have first class interns, both medical and dental, men who have graduated from college but who have not yet passed the state board unless they wish to. They may be appointed intern for one, one and a half, or two years, and receive a certificate from the hospital when they finish their service. They are to receive besides as spending money, $240 the first year and $360 the second year. Any man who has served as an intern for one year, or served in the dental clinic for two years, which clinic requires of him three hours' service each week, may be appointed to the second grade which is known as the junior grade. The junior grade is to receive from $900 to $1,380 and is on the same basis as the physician in the Department of Health. After he has served two years in that department he may be advanced to number three grade, which starts at $1,560, to any price that he may be worth, and that is where he has an advantage over the medical man, because the medical man can only advance to the third grade. That is what we are doing in New York. The only satisfactory way to do this is to have the dental men put in the hospitals on the same basis as the medical men and use a little precaution as to who is selected for the dental staff, because one dental man who is a little too aggressive can wreck the whole thing, and the dentist who uses due discretion will make it possible to get the support of the city fathers and get the necessary means to carry on the dental service in any city. The final result of this in New York is going to be that in all clinics which are supported by the benevolently inclined public and charity organizations, these young men will be employed to go into the classified service, which is under the regulation of the city Department of Health, and that will be the only way that one can get into the classified service.

A Guide to Contentment.—Seek not that the things which happen should happen as you wish; but wish the things which happen to be as they are, and you will have a tranquil flow of life.—*Epictetus.*

ANKYLOSIS

AN EXPERIMENTAL STUDY*

NATHANIEL ALLISON, M.D.
Associate in Orthopedic Surgery, Washington University
AND
BARNEY BROOKS, M.D.
Assistant in Surgery, Washington University
ST. LOUIS

This experimental study was undertaken for the purpose of investigating the changes that take place in the joint structures during the process of ankylosis. In a previous study[1] on the mobilization of ankylosed joints, it was observed that there was a marked difference in the reaction to injury between epiphyseal and diaphyseal bone. In the experiments reported there was fibrous union between two denuded joint surfaces at the end of sixty days. At the end of this period of time there was no evidence of bony ankylosis. A further study of this process was carried out in the experiments here reported with the belief that the facts gained will aid in the surgical treatment of ankylosed joints.

Hoffa[2] has defined ankylosis as the condition in which two or more joint surfaces become bound together and immovable. He distinguished three types; an intercartilaginous fibrous ankylosis, an interosseous fibrous ankylosis and an osseous ankylosis. True bony ankylosis, according to Hoffa, may be produced in two ways. Sometimes there is transformation of the connective tissue of a fibrous ankylosis directly from a cartilage metaplasia. At other times following the destruction of cartilages from inflammatory diseases, bony union develops from the bone marrow and periosteum.

Nichols and Richardson[3] from the study of sixty-seven cases of non-tuberculous arthritis, divide this condition into two types; namely, a proliferative type and a degenerative type. In the degenerative there is a tendency to destruction of joint cartilage with deformity and no ankylosis.

An arthopathy, such as a Charcot joint, is typical of this class. In the proliferative type there is destruction of joint cartilage leading to ankylosis of adjacent joint structures. In this type the earlier change is a proliferation of the synovial membrane at the insertion of the joint capsule. This leads to a pannus growth which advances over the cartilage, at times uniting the two joint surfaces and destroying the underlying cartilage. Accompanying this process there may be destruction of the joint cartilage on its epiphyseal surface by granulation tissue from the marrow spaces. These investigators believe that the destruction of cartilage by the pannus growth predominates, though either process leads to fibrous ankylosis. True bony ankylosis, according to Nichols and Richardson, may be produced in three ways. In certain instances there is a proliferation of the perichondrium, which is readily transformed into cartilage or bone. In other instances new bone production results from osteoblasts which have their origin in the bone marrow. Finally, in rare instances, there is a direct transformation of fibrous tissue into bone.

Axhausen and Pels[4] and Kroh[5] have described joint changes resulting from injury in experimental studies of arthritis deformans. In the literature above referred to various joint changes have been described, but the sequence of these changes and the duration of the ankylosing process have not been made clear.

The object of these experiments was the study of the nature, sequence and duration of the joint changes which lead to bony ankylosis. In these experiments the knee joints of dogs were used. All experiments were done under complete ether anesthesia. All operations were done under a careful aseptic technic. Postoperative care of the animals used was such as to insure as little suffering as possible. All animals were sacrificed with chloroform. Four experimental methods were used.

I. Partial excision of joints......	8 experiments
II. Destruction of joint cartilage..	3 experiments
III. Injury to joint cartilage........	2 experiments
IV. Direct infection of normal joints	7 experiments

I. PARTIAL EXCISION OF JOINT

The knee joint was opened by a lateral longitudinal incision, the patella and its tendon were displaced medialwards, the cruciform ligaments were divided. The knee was completely flexed and 1 cm. of the lower end of the femur and 0.5 cm. of the upper end of the tibia were removed with a saw. The joint was then closed with interrupted fine silk sutures and held fixed by a plaster-of-Paris dressing.

SUMMARY

In these experiments in which the joint was partially excised and the cancellous bone surfaces of the epiphyses were approximated, there was produced the simplest experimental condition for the study of the development of bony ankylosis. The condition is the same as that which is produced in a surgical operation for the mobilization of an osseous ankylosis.

These experiments show that ankylosis by bone is a slowly developing process.

At the end of six days (Experiment 10) the apposed bones were united by a fibrous exudate into which is growing granulation tissue from the bone marrow. At the end of nineteen days (Experiment 3) the bones are united by connective tissue. In Experiments 4, 8, and 2 of fifty, sixty-four, and eighty-six days respectively, the connective tissue uniting the bones became progressively more fibrous in character. At the end of 146 days (Experiment 7) the fibrous ankylosis was being changed into an osseous ankylosis by a direct transformation of the fibrous tissue into bone. In Experiment 5, after 180 days with close approximation of the bone surfaces, the ankylosis was by bone.

II. DESTRUCTION OF JOINT CARTILAGE

The knee joint was opened by a lateral longitudinal incision, the patella and its tendon were displaced medialwards. The semilunar cartilages were removed from the head of the tibia, and the joint cartilage was curetted from the joint surfaces of the tibia, femoral condyles, and patella. The joint was closed with inter-

rupted fine silk sutures. The limb was held fixed in a plaster-of-Paris dressing.

SUMMARY

In these experiments in which the articular cartilage was destroyed the condition produced was essentially the same as that in which partial excision was done, except that the normal contour of the bones was unchanged. This condition is the same as that which follows a surgical operation for the mobilization of an ankylosis in which the bones have retained their normal shape—such as is found in fibrous ankylosis.

These experiments show that after destruction of joint cartilage there is union of the joint surfaces by connective tissue which is slowly transformed into bone.

In Experiment 22, actual union by bone was not complete at the end of 334 days.

III. INJURY TO JOINT CARTILAGE

Experiment 23. Knee joint opened in the usual manner. With a curet small areas of cartilage were removed from the inferior surfaces of the femoral condyles and from the outer surface of the tibial head. The joint was closed as usual. No plaster-of-Paris dressing was applied.

SUMMARY

In this experiment the injury to the joint cartilage was comparatively slight. Fourteen days after the destruction of a small area of joint cartilage there was an inflammatory process in the joint which was destroying the cartilage in a manner exactly similar to that which follows infection of the joint cavity. In Experiment 27, in which the joint injury was limited to a transverse patellar fracture, there were after 365 days definite pathologic changes in the joint cartilage and synovial membrane.

IV. DIRECT INFECTION OF NORMAL JOINTS

In these experiments the organisms were injected directly into the knee joint cavity with a hypodermic syringe. The organisms used were a *Staphylococcus aureus* obtained from a fatal case of pyemia in man; and a bacillus tuberculosis of the human type, which had been grown in the laboratory for several years. Of the *Staphylococcus aureus*, twenty-four-hour broth cultures were used for injection. Of the tubercle bacilli one-month glycerin-agar cultures were suspended in normal salt solution.

SUMMARY

In these experiments, in which bacteria were introduced directly into the joint cavity, characteristic pathologic changes resulted. The joint changes in the experiments in which tubercle bacilli were used were the same as those observed in the experiments in which the staphylococcus was used. The extent of the joint changes and the general reaction to the infection varied widely in the different experiments.

Immediately after the introduction of the infectious agent into the joint cavity there was a marked local reaction evidenced by swelling, heat and tenderness. There was a fibropurulent exudate in the joint cavity, which produced adhesions between the capsule and the condyles, resulting in a marked diminution in the size of the joint cavity. The destruction of the joint cartilage was always the result of absorption by granulation tissue. Granulation tissue arising from the proliferating synovial membrane destroyed the cartilage at its margin and granulation tissue from the bone marrow destroyed the cartilage from below.

GENERAL SUMMARY

From the experiments in which the joint cavity was infected with tubercle bacilli or staphylococci, or in which a slight injury was done the joint cartilage, we are led to believe that any inflammatory process within a joint which is of sufficient severity to result in the formation of granulation tissue will destroy the joint cartilages. The cartilage is absorbed at its margin by granulation tissue arising from the synovial membrane and at its base by granulation tissue from the bone marrow.

By the experiments in which the cartilage was removed by operation, or the joint partially excised we have shown that ankylosis by bone is a slowly developing process which consists of the following stages: 1. There is union by granulation tissue; 2, there is union by dense fibrous tissue; 3, there is a metaplasia of fibrous tissue into cartilage and a direct transformation into bone. The shortest period of time in which complete bony ankylosis was observed experimentally was 180 days. In man the duration of the process is equally prolonged.

The long duration of the process of osseous ankylosis we believe explains the following: After arthroplasty a joint may allow motion for some weeks and subsequently become stiff. Fractures of the epiphysis unite by bone slowly. It also suggests that the conclusion reached by certain investigators that the interposition of soft parts prevents bony ankylosis is misleading in that many of their experiments were of insufficient duration.

The long duration of the fibrous stage of ankylosis also shows conclusively that any method of arthroplasty should have as its object the prevention of fibrous ankylosis rather than bony ankylosis; also that the insertion of an irritative substance into a joint should be avoided.

ABSTRACT OF DISCUSSION

Dr. J. Torrance Rugh, Philadelphia: Perhaps neither Dr. Allison nor Dr. Brooks has read a paper that I presented before the American Orthopedic Association four or five years ago; but Dr. Allison used almost the same words that I used at that time. My paper was a purely clinical one, based on a study of a series of cases of excised knee-joints; and the work that has been done by Dr. Allison carries out exactly the statement that I made then, which was based on clinical observation; that is, that bony union between the epiphyses of the long bones after excision does not take place under from six months to two years. I also made a plea, at that time, for the longer fixation of a joint after its excision, because of the great danger of deformity resulting from absence of bony fixation. I am extremely glad to-day to find the clinical observations that I made at that time proved correct by the experimental work of Dr. Allison.

The Proper Correlation of Experience.—When memory pictures have a faulty setting, they may influence behavior disastrously. The old man thinks all this talk about impure milk killing infants and infected water causing typhoid fever is nonsense, because all his life people, both young and old, have been drinking dirty milk and polluted water. . . . He has always connected these bereavements with the world-old belief that disease could not be prevented nor death delayed. . . . Many reason post hoc ergo propter hoc. This faulty logic is still a strong support of charlatinism in its many survival forms.—Victor C. Vaughan, *Science*.

THE BLOOD-PRESSURE DURING PREGNANCY

BASED ON OBSERVATIONS ON 450 CASES FROM THE RECORDS OF THE COMMITTEE IN CHARGE OF THE PRENATAL WORK CARRIED ON BY THE WOMEN'S MUNICIPAL LEAGUE OF BOSTON *

FRANKLIN S. NEWELL, M.D.
BOSTON

The patients (450 in number) on whom this report is based were referred to the prenatal committee of the Women's Municipal League of Boston for care during pregnancy, either by institutions which have no facilities for prenatal work, although equipped to care for the labor and convalescence of their patients, or through the personal application for prenatal care made by the patient herself. The length of time that the patients were under observation varied from a few days to six months, according to the period of pregnancy which had been reached when the patient first sought prenatal care, and averaged about two months or a little longer. As long as no abnormal symptoms developed the patients remained under the observation of the prenatal committee, but the care during labor was provided by the institution referring the patient or by the patient's private physician, and all abnormalities discovered during pregnancy were immediately reported to the medical adviser, the prenatal work being confined to close observation of the patient's condition and such advice as is suitable for a nurse to give.

The routine of the work is as follows: As soon as a patient is referred to the prenatal committee for care she is visited at her home by the nurse, who gives her practical advice, suited to her circumstances, in regard to the hygiene of pregnancy, diet, clothing, exercise, etc., takes the blood-pressure and examines a specimen of urine for albumin. This visit is repeated at ten day intervals, or oftener in doubtful cases, until the time of labor. All abnormalities are reported at once to the proper persons, so that in case of need the patient shall receive more adequate attention. This system is not, perhaps, ideal, since for the most satisfactory results the clinic in charge of the prenatal work should be in a position to provide adequate care for the abnormal cases which it meets, and there should be no division of responsibility, as inevitably occurs under this system, but it certainly results in giving these patients much closer observation than they would ordinarily receive.

This report is based on the records of blood-pressure thus obtained and is made with the feeling that although it shows nothing of startling interest, it will prove of value, even though the facts which it develops only serve to corroborate the work of previous observers. It has been recognized for some years that the estimation of the blood-pressure during pregnancy furnishes evidence of considerable value in determining the condition of a patient during pregnancy, an abnormally low pressure suggesting that the patient is likely to react unduly to the strain of labor and should be saved all avoidable shock and suffering, while a high pressure is not infrequently the initial symptom of a toxemia and should call for increased watchfulness on the part of the attending physician, even though no other abnormal symptoms are to be discovered on a thorough investigation. The average blood-pressure during pregnancy is commonly stated as 118, and it is also commonly stated that the pressure tends to rise toward the end of pregnancy in perfectly normal patients, a statement which in this series appears to be true for only a limited number of patients. The normal variations of the blood-pressure may be considered as from 100 to 130, and although the observations in this series are too infrequent to show what transitory changes may occur in the normal patient, only one patient in whom the pressure remained within these limits developed any abnormal symptoms. This patient developed postpartum eclampsia and had several convulsions, but made a good recovery. In this case the last visit of the nurse had been made eight days before delivery, and the blood-pressure had presumably not been taken during or immediately after labor so that we have no information as to the development of the toxemia, but in all probability a toxemia of low grade was brought into prominence by the exhaustion of labor. A closer observation of the patient before labor might or might not show the impending danger in such a case, but such an occurrence suggests that the pressure should be estimated in all cases during labor and soon afterward as well as during pregnancy.

If the blood-pressure remains persistently under 100 it is fair to assume that the patient's general condition is below par, and steps should be taken to improve it. At the time of labor the patient should be watched carefully and guarded as far as possible against exhaustion, since the patient with an unduly low pressure not infrequently develops shock and collapse to a marked degree following labor. If the pressure is over 130 the patient should be kept under close observation even in the absence of other symptoms, and a rising pressure should receive most careful attention. A pressure of 150 has been commonly called the danger line, but a persistent rise of pressure from a low point, even though it may never reach the arbitrary danger line, calls for most careful attention.

Of the 450 cases, 421 patients showed a blood-pressure that at no time was either below 90 or above 130; in other words the 421 patients showed what can be properly classed as absolutely normal blood-pressures. Of these 421 patients, 78 at some time during the pregnancy showed a pressure slightly below the normal, ranging somewhere about 90 and 100. In none of these patients, however, was the low blood-pressure persistent, it only being noted on one or two examinations, and in no instance did any uncomfortable symptoms develop in labor afterward referable to the low pressure, showing, therefore, that a temporary low blood-pressure is of no significance during pregnancy. Of these 421 patients, only the above mentioned patient who had postpartum eclampsia had any uncomfortable symptoms. The remaining twenty-nine patients showed at some time during their pregnancy a pressure which was above the normal limits, that is, above 130. There were four patients who ran a constant pressure of 140 at each examination and one patient who ran a constant pressure of 145 through the pregnancy. In none of these patients did any trouble occur, and the high pressure seems to have been due to other conditions rather than to changes taking place during pregnancy. In the remaining twenty-four patients the blood-pressure showed marked variations, running as high in one instance as

---

* Read at the Fifth Annual Meeting of the American Association for the Study and Prevention of Infant Mortality, Boston, November, 1914.

195. This patient developed eclampsia in spite of treatment, and there were several other patients in whom threatening symptoms developed, but in whom the conditions yielded to treatment.

In the 450 cases the examination of the urine showed albumin persistently or temporarily fifty times. Eleven of the fifty patients who showed either transient or persistent albuminuria also showed a blood-pressure of over 130, and every case of toxemia, except the postpartum one mentioned, developed among these patients. The rise in blood-pressure preceded the finding of the albumin in every instance except one, suggesting definitely the fact that a rise in blood-pressure is apt to be followed by albuminuria and other symptoms of toxemia, and that a high blood-pressure plus albuminuria are symptoms which call for immediate attention. The recognition of the high blood-pressure plus albuminuria was immediately followed by proper treatment, which was successful with one exception in checking the process before it became serious, showing the value of frequent observation of the patient during pregnancy. The occurrence of albuminuria in more than one-third of the patients who show an abnormally high blood-pressure as compared with its occurrence in less than 10 per cent. of the patients who did not show a high blood-pressure, is definite proof of the value of the estimation of the blood-pressure during pregnancy.

The fact that in 421 of the 450 cases the blood-pressure was within normal limits and that in only one of these patients did any sign of toxemia occur, certainly tends to show that as long as the blood-pressure remains normal the presence of slight traces of albumin in the urine (which were noted in 39 of the 421) is negligible.

I have attempted to tabulate the observations in this series with the object of learning, if possible, whether any particular group of cases showed constant variations in blood-pressure, either within the normal limits or not.

Race.—The patients in the series were of many different nationalities as follows:

American	159	Russian	16
Jewish	81	Scotch	12
Canadian	47	Swedish	7
Irish	43	Italian	7
English	20	German	6
Colored	19		

The remainder were either divided in small numbers among many different races or the nationality was not given. The examination of the records shows, as would be expected, that there are no characteristic variations in blood-pressure in the different nations.

Age of Patients.—The patients ranged from 16 to 45 years of age. Sixty-seven were under 20 years of age; 271 between 20 and 30; 80 between 30 and 40, and 7 were over 40. The age of 15 patients is not given. In line with the fact that the blood-pressure is apt to be considerably elevated in persons of above 50 years of age in whom arterial changes are common, it seemed fair to expect that a rise in arterial tension might be expected in the women in the latter part of the child-bearing period. Contrary to expectations there was no such tendency evident on examination of the records. On the contrary, in the one case of eclampsia which occurred during pregnancy the patient was only 18 years old. It is, therefore, fair to assume that in women during the child-bearing period a high blood-pressure is due to some individual peculiarity or disease and is not to be expected. The more or less constant rise in pressure which is observed in later life seems, therefore, to begin at or after the menopause and is evident during the child-bearing period.

Number of Pregnancies.—In this series there were 218 primi-parae; 99 II-parae; 46 III-parae; 34 IV-parae; 17 V-parae; 9 each VI-, VII- and VIII-parae; 5 IX-parae, and 4 who had had ten or more pregnancies. It might well be expected that the increased strain thrown on the whole organism by repeated pregnancies would be reflected by a rise in pressure to a greater or less degree, but the observations made on these patients show no constant change, two of the three women in their twelfth pregnancy having a blood-pressure of 120 or less throughout. In studying the series as a whole, however, it would seem that after the second pregnancy there is a slight tendency upward in the pressures. This tendency is not sufficiently marked to be significant. The average in the seventh pregnancy as compared with the first is between five and ten points higher. In other words, it would seem that repeated pregnancies, in the absence of complications, have little or no effect in producing an increase in arterial tension, and that in the absence of complications a normal pressure is to be expected in a pregnant woman irrespective of her age or the number of the pregnancy.

Relation Between Albuminuria and High Blood-Pressure.—The urine was examined for albumin in conjunction with the estimation of the blood-pressure. The specimens examined, however, were not catheter specimens, and, as is well known, albumin is found much more frequently in non-catheter specimens, some observers placing it as high as 40 per cent.

In this series 50, or about 11 per cent., showed albumin at one or more examinations, an extremely low percentage, but since the urine was only examined by an expert when large traces of albumin were present or when other symptoms developed, it seems probable that small traces may have been overlooked, and the percentage really may have been considerably higher. In 37 of the 50 cases the albumin was found at one examination only and the blood-pressure showed no change, nor did other symptoms develop. In 2 cases the albuminuria was more persistent but no other symptoms developed. In 11 cases the presence of albumin was accompanied by a rise of blood-pressure to over 130, in 5 of which patients the albumin disappeared and the pressure dropped as soon as appropriate treatment was instituted.

In the six others the albumin and high pressure persisted until after delivery. Four of these patients also developed other definite symptoms of toxemia, but spontaneous labor ensued, with relief before the more serious symptoms developed. In one patient only did convulsions occur and this patient made a good recovery on being delivered. This patient had a persistently high pressure for the six weeks she was under observation, but the albumin did not appear till eight days before delivery, from which time it increased rapidly in amount, the blood-pressure rising to 195 shortly before the convulsions developed.

Another patient had a blood-pressure of from 150 to 180 for a month before delivery, with a slight amount of albumin constantly present. She did not develop convulsions, but gave birth to feeble twins at seven months, one of which lived only a few hours. One patient referred to previously had postpartum convulsions, no abnormality having been noted during the four and one-half months she was under observation. Six patients ran a persistently high pressure of between 135 and 145, but at no time showed any other symptoms and were delivered safely. With one exception all of the patients who developed toxemic symptoms showed a rising blood-pressure as the first symptom, but in one case the appearance of albumin preceded the rise in pressure. Although the number of cases is too small to form the basis of any definite conclusions this would point to the conclusion that a rise in blood-pressure even in the absence of other symptoms should receive serious consideration as possibly being the initial symptom of an impending toxemia.

Results.—In the 450 cases there were four maternal deaths following delivery. One patient died of pneumonia; one of hemorrhage from placenta praevia; one of heart disease, and one of septic infection. Neither the blood-pressure nor urinary examination showed anything abnormal in any of these women.

There were nine still births in the series. Four were due to difficult operative delivery; two to placenta praevia, and one each to premature detachment of the placenta, congenital syphilis, and fetal monstrosity. In each case the pregnancy was normal as far as shown by the urine and blood-pressure.

There were four premature births, and three of the babies died, one at 7 and two at 8 months. In two of these cases the mother showed an abnormally high blood-pressure, one of the patients developing a definite toxemia, though without convulsions, the maternal condition accounting directly for the death of the child.

CONCLUSIONS

The study of the records of these cases shows definitely that a considerable number of patients have a temporary rise in blood-pressure during pregnancy without the development of other symptoms, as is found in patients under other conditions. The significance of this rise in blood-pressure can only be ascertained by a frequent study of the blood-pressure in a large number of cases. In other cases the rise in blood-presure was followed by the appearance of albumin, a combination of which has been shown to be a definite indication of the development of toxemia. In only one case, however, did convulsions develop, the other cases yielding to treatment. Thirty-nine cases showed slight traces of albumin in the urine, but no changes in the blood-pressure. As the urine was not obtained by catheter, the source of the albumin is unknown, but in the majority of the cases it was probably due to contamination of the urine by leukorrheal discharge. To judge from these cases, the presence of a slight amount of albumin, if not accompanied by a rise in blood-pressure, is negligible. Eleven patients showed albumin with a high blood-pressure, all of these being presumably more or less toxemic. Five patients showed a blood-pressure of 140 or over throughout the period during which they were under observation. Only one of these patients developed albumin at any time during the pregnancy and all passed through labor normally, which would tend to prove that persistent high blood-pressure, in the absence of other signs, is not necessarily a dangerous symptom, although it should always arouse suspicion and call for increased watchfulness, whereas, as was shown in other cases in this series, a rise in blood-pressure from a low point is not infrequently followed by the appearance of albumin and the development of symptoms of toxemia, and is more significant than a high pressure throughout.

HYPOPITUITARISM IN CHRONIC HYDROCEPHALUS

LEWIS J. POLLOCK, M.D.
CHICAGO

Disorders of pituitary metabolism may be due to disturbances of the gland itself, organic or functional, as tumors, hyperplasia, hypoplasia, etc., or such changes may be the result of remote factors, such as distant tumors pressing on the gland, and hydrocephalus. In severe hydrocephalus, the third as well as the other ventricles is distended with fluid; it becomes cystic, bulges, and presses on the underlying pituitary gland.

The disturbance of pituitary function resulting from hydrocephalus may manifest itself in two conditions, hyperpituitarism (Neurath, Cushing, Oppenheim), or in hypopituitarism. In view of the frequency of dyspituitarism in chronic hydrocephalus, the literature on the subject is astonishingly scarce.

Marinesco and M. Goldstein,[1] in December, 1909, and Kurt Goldstein,[2] in 1910, described the clinical picture of pituitary body disease as an accompaniment of hydrocephalus. Kurt Goldstein calls attention to the fact that changes in the sella turcica have been noted in cases of chronic hydrocephalus in the cases of Schüller, broadened and flattened, of Fermröhr, a widened entrance, and of Oppenheim, a very deep groove. He further states that in a careful search of the literature he has found cases of chronic hydrocephalus presenting isolated symptoms which were probably similar in character to the symptoms observed in his own cases, namely, obesity (Quincke), amenorrhea (Jollye) and hypoplasia of the uterus and amenorrhea (Moore). Seivert reported two cases which Goldstein states are similar to those reported by himself; two sisters, aged 9 and 15 years, both of whom were fat, had optic atrophy and hydrocephalus, but no genital atrophy. Goldstein reports three cases, in all of which enlargement of the head was associated with a very fat body and undeveloped genitalia; the second patient had some symptoms of bony overgrowth shown by separation of his teeth and enlargement of the ends of his bones. In no case was a necropsy obtained. He makes the diagnosis of meningitis serosa by virtue of the long duration, the remissions, the absence of focal symptoms and the presence of concentric diminution of the field of vision without hemianopsia. He further asks if it is not possible to obtain the symptom complex ordinarily accompanying tumor of the hypophysis from pressure on the hypophysis by an increased amount of cerebrospinal fluid.

Mueller[3] reports a case of tumor of the posterior fossa with secondary hydrocephalus in a girl aged 16 years who showed arrested menstruation, small stature and abundant adipose tissue.

Marinesco and Goldstein report two cases with necropsy, one, that of a boy of 15, who, besides the symptoms of a cerebellar neoplasm, showed enlargement of the head, marked adiposity, hypoplasia of the genital organs, no hair in the axillae or on the pubes. Necropsy showed a cystic tumor of the cerebellum with secondary hydrocephalus, a compressed pituitary body and a broadened-out sella turcica. The second case, that of a girl aged 16, showed a large head, marked adipose deposits, scanty hair, menstruation every three or four months, and small mammae. Necropsy showed chronic hydrocephalus and no new growth of the pituitary body.

[3] Mueller, quoted by Marinesco and Goldstein (Footnote 1).

Cushing[4] remarks on the scarcity of literature and calls attention to twenty preadolescents with tumor cerebelli and chronic hydrocephalus, all being well nourished, and many quite adipose. He likewise reports one case of essential hydrocephalus with hypopituitarism, one case of cerebellar cyst with hydrocephalus and hypopituitarism and one case of endothelioma of the right hemisphere, hydrops of the third ventricle and hypopituitarism, all with necropsy.

He mentions six illustrations of the syndrome of hypopituitarism in chronic hydrocephalus reported by Babonneiux and Poisseau.

Oppenheim[5] states that he has seen two cases of cerebellar cysts with secondary hydrocephalus causing symptoms of acromegaly.

I[6] have reported one case of hypopituitarism in chronic hydrocephalus with necropsy. Because of the inaccessibility of the bulletin wherein it was published, this case will be described along with the others here reported.

The frequency of dyspituitarism in chronic hydrocephalus may be shown by the fact that since the publication of the foregoing report in 1913, twelve additional cases have been observed, ten in institutions and two in private practice. Of these, three will be briefly described.

In all the cases, adiposity was the predominating feature, ranging from that of an overnourished person to that of a monstrosity. Genital hypoplasia was observed but once; all the cases show a delicate, pudgy, tapering hand with broad base. Increased carbohydrate tolerance was found in all of six cases so studied. Not much importance can be attached to this particular feature, inasmuch as it is observed in many conditions and is not well understood. Thermic reaction following the injection of extract of anterior lobe (kindly furnished by Armour & Co.) was observed in none of six cases so tested.

REPORT OF CASES

Case 1.—*History*.—S. D., man, single, no occupation, aged 40, was admitted to the Kankakee State Hospital, Nov. 1, 1905. The family history shows that the patient's father died of "paralysis," probably apoplexy; his mother of hemorrhage of the bowels. There is one brother living and well, and there were three sisters, two of whom are dead from unknown causes. Circumstances of the patient's birth are unknown. At the age of 4 months he developed "cerebrospinal meningitis" and was ill for several months; the condition was associated with opisthotonos and followed by spasmus nutans. After recovery, it was noted that the patient was deaf; he did not walk until he was 9 years old. Mentally he did not develop more than the equivalent of 7 years. At 15 he was taken to the Illinois State School for Deaf Mutes at Jacksonville. He was returned to his home at the end of eight months on account of his inability to learn. It was noted that while a young man he was fat, that his head was somewhat large, that the penis was very small and at the age of 18 the testicles "apparently disappeared." This condition was explained by the relatives as being the result of their being hidden by the excess of fat. He did not develop hair as did other men. A tin-type taken at age 18 shows a very fat boy with a large head. He had never complained of headache, nor did he vomit.

Examination.—On admission to the Kankakee State Hospital, examination showed a man, aged 40, weight 278 pounds, height 5 feet 6 inches. He was very fleshy; the skin was soft and moist, the mucous membranes red and muscles flabby. The hair on the head was dark and thin. In the axillae the hair was sparse and very thin over the pubes. The abdominal wall was protuberant. There was a moderate umbilical hernia and so large an amount of fat that the abdomen hung over the thighs like an apron, concealing the penis. The head was large and hydrocephalic, the tongue negative. Several teeth were missing. Examination of the chest showed the lungs to be negative. Heart action was rapid, the first sound loud. Abdomen showed dilated colon. The genitalia were notable for the atrophic penis and partially descended testicles. The penis was about 1¼ inches long, small in caliber, hidden by fat. Reflexes, deep and superficial, were normal. Pupillary reflexes were normal.

In this case, therefore, the notable features are hydrocephalus, adiposity, lack of hair and genital atrophy. The patient was quiet and tractable, possessed little memory, performed very few functions and even needed assistance in feeding. He was untidy, soiling and wetting himself, and made no effort to attend to the calls of nature. He frequently laughed loudly without cause and took no interest in his surroundings.

Aside from the steady decrease in weight there was noted no change in the condition of the patient after admission. There was no gross change in vision, but he became more and more unsteady in his gait. He was found dead in bed, Oct. 25, 1911.

Necropsy.—Post-mortem examination revealed an umbilical hernia, dilated colon with displacement upward of the thoracic contents, edema of the lungs, moderate general arteriosclerosis, fatty degeneration of the liver, chronic parenchymatous nephritis, colloid goiter, general adiposity, partially descended testicles and an infantile penis. The ossicles of the ear were quite small.

The skull and brain deserve more extended description. The calvarium was easily removed, and showed a marked thinning, each convolution of the brain being lodged in a groove of the skull. When held to the light the places marked by the grooves were found to be exceedingly thin. The dura mater did not bulge and was not adherent to the calvarium; it was quite thin but somewhat opaque.

On removal of the calvarium a large amount of cerebrospinal fluid was observed to be escaping from the brain, and as it was released at the base there was seen a small opening, the size of a pea, in the right orbital lobe from which spurted a clear fluid, of which there was apparently about 20 ounces. As this fluid escaped both sides of the brain collapsed, resulting in a mushroom-like appearance. When the brain was removed it was seen that there was a chronic hydrocephalus which affected all the horns of the lateral ventricles and the third ventricle as well. The latter by its distention produced a cyst-like formation above the optic commissure which was pushed downward and flattened. With the exception of the pituitary body, which was implanted on a very broad and bulging infundibulum, the structures in the interpeduncular space could *not* be seen. (The pituitary body itself was flattened from the pressure above it and was very difficult to remove from the sella turcica, which was broadened.) The cyst-like formation of the third ventricle extended backward to the crura, and on its sides were seen the third nerves. The convolutions were somewhat flattened throughout. The meninges were slightly edematous, the vessels somewhat injected.

After hardening and cutting of the brain into coronal sections it was seen that anteriorly the hydrocephalus was very marked, the brain tissues surrounding the cavity being but 1.5 cm. thick. A section in front of the optic commissure showed the foramen of Monro to be the size of a quarter, the third ventricle was distended to the size of a large walnut, the pillars of the fornix being exceedingly thin and membrane-like. The corpora albicantia were seen in the floor of the third ventricle, but did not make their appearance at the base of the brain. Above this was seen the septum lucidum, which was 3 inches long, 2½ high, and showed marked separation of its two walls, each of which was a delicate membrane with numerous fenestrae. Above this the body of the corpus callosum was very thin and posteriorly, membrane-like and ruptured. The splenium of the corpus callosum was likewise very thin. A section posterior to the midbrain when viewed in its anterior portion presented a broad fornix with the choroid plexus lying on it, which was in general appearance normal. As this was followed down, the hippocampus was seen sharply outlined in the floor of the markedly distended descending horn. The internal capsule with its adjacent ganglia was noted lying free in the cavity of the lateral ventricle on the superior and posterior surfaces, while inferiorly it was seen to be continuous with the midbrain. The ganglia were smaller than usual and flattened from above downward. The fourth ventricle showed a slight amount of distention and the floor was somewhat granular. The central canal of the spinal cord was negative. The pineal gland was compressed, its anterior surface forming a portion of the wall of the distended third ventricle. When removed a marked concavity was noted on its surface.

[5] Oppenheim, H.: Text Book of Nervous Diseases, *1911*, p. 1380.

[6] Pollock, L. J.: Chronic Hydrocephalus with Dyspituitarism, Inst. Quart., 1913, iv, 67.

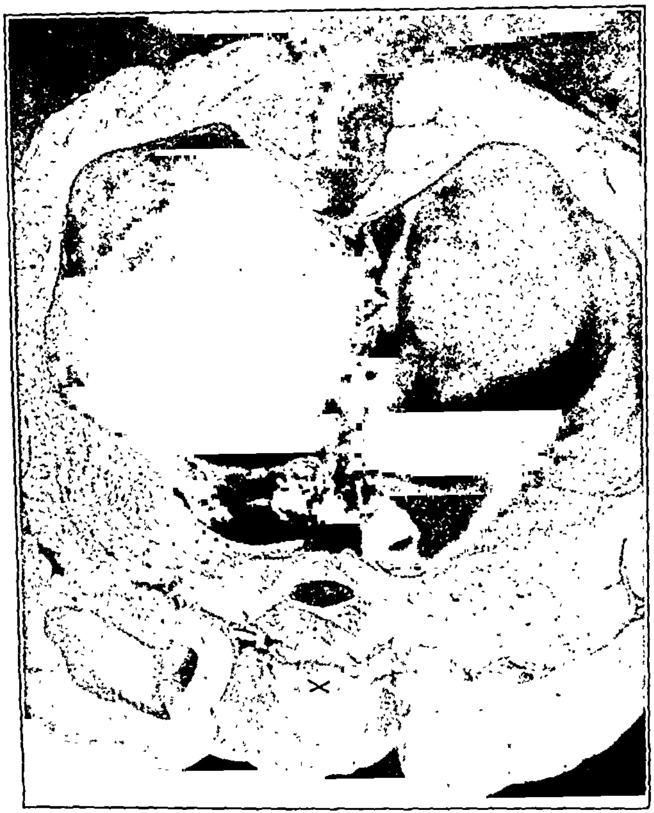

Fig. 1.—Pituitary gland (*x*) beneath the floor of the cystic third ventricle.

Microscopically the findings bear out the gross diagnosis, and only the pituitary body and pineal gland will be described. The pituitary body was flat and the posterior lobe showed an increase of connective tissue. The anterior lobe showed that the part adjacent to the posterior lobe was composed almost entirely of nuclei within cells showing very little protoplasm and no chromophilic granules. These nuclei showed various granules of degeneration; some were distorted, others large, swollen and quite pale; here and there was found a large chromophilic cell. In the remaining portion of the gland, the cells were somewhat crowded, the chromophilic cells being abundant. An increased amount of connective tissue was noted and here and there a small collection of colloid material. The pineal gland was crescentic in shape. There was a marked increase of connective tissue surrounding it. The interior of the gland was divided into compartments in which were seen numerous nuclei contained in cells with little protoplasm, resembling glia cells. Very little gland formation was seen. No ganglion cells were present. In several of the parts of the gland were seen masses of colloid material and in the center a mass which had become calcified (Fig. 1).

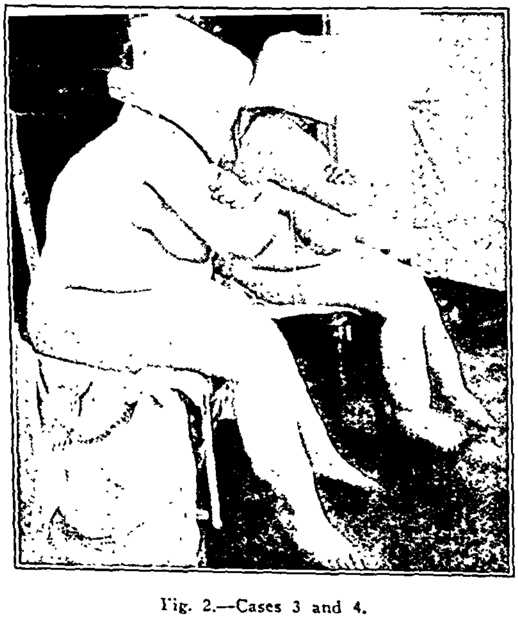

Fig. 2.—Cases 3 and 4.

CASE 2.—Girl, aged 11, height 4 feet 8 inches, weight 127 pounds, an overdeveloped, very obese child with tapering hands; was an idiot who could not talk; the pubic hair was well developed. Roentgenoscopy revealed a normal sella turcica, but a hydrocephalic skull.

CASE 3.— Woman, aged 19, had an attack of meningitis at age of 7 weeks, and has never walked or talked. She has a marked hydrocephalus and spastic diplegia. She has atypical epileptiform attacks, is very obese and has tapering hands. Menstruation is irregular.

CASE 4.—Woman, aged 25, has a marked hydrocephalus. She is an idiot with spastic diplegia, is exceedingly obese and has tapering hands. Menstruation is irregular (Fig. 2).

The specificity of the symptom of adiposity, described as associated with pituitary disease, is not well established. Marburg[7] first formulated the theory that adiposity is present not only in tumors of the pituitary, but in "certain cases of cerebral tumor of embryonic type and of ectodermal structure which cause adiposity, independently of their localization, by virtue of a specific internal secretion." That this is not entirely true is shown by the cases exhibiting pressure on the pituitary from hydrocephalus without tumor, and from tumors of the pineal gland not teratomatous in nature, as in the cases of Nothnagel, Mueller, Pearce Bailey and Smith Ely Jelliffe. Marburg[8] subsequently, in a study of tumor of the pineal gland and metabolic symptoms, described a tumor of the pineal gland associated with hydrocephalus but in which the pituitary was not disturbed, although infundibular hydrocephalus was present. He formulates three groups of pineal gland disturbances:

1. Hyperpinealism — obesity.
2. Hypopinealism — genital atrophy.
3. Apinealism — cachexia.

---

[7] Marburg, quoted by Marinesco and Goldstein (Footnote 1).

[8] Marburg: Zur Kenntnis der normalen und pathologischen Histologie der Zirbeldruse, die Adipositas Cerebralis, Wiener med. Wchnschr., 1908, lviii, 2617.

In a recent article on tumors of the pineal gland, Pearce Bailey and Smith Ely Jelliffe[9] give an exhaustive summary of the literature, in which they collect sixty cases.

It is notable that of sixty cases, thirty showed hydrocephalus, usually marked; of ten cases showing evidence of adiposity, in nine there is mention of hydrocephalus; in one of the other two (Marburg, mentioned above) there was no change in the pituitary. In the other case (Daly) no mention is made of hydrocephalus. The authors state that "the whole situation is in need of more extended study to determine whether pineal tumors alone can produce adiposity, apart from third ventricle hydrocephalus." Speaking of the accompanying hydrocephalus, which is "usually very marked in the third ventricle, and the infundibulum may be swollen and puffed out like a cyst," they state that "such a hydrocephalus can unquestionably lead to adiposis."

From the case here recorded as coming to necropsy no conclusion relative to the cause of the adiposity can be made, inasmuch as not only was the hypophysis compressed, but the pineal gland as well showed disturbances resulting from the dilatation of the third ventricle.

CONCLUSION

I wish to state that the purpose of this report is simply to call attention to the frequency of the association of hypopituitarism with hydrocephalus and by a few illustrations recall to memory many similar cases observed by all physicians.

The similarity of serous meningitis to tumor cerebri is well known and the inclusion of pituitary symptoms may lead to a diagnosis of tumor of the hypophysis, wrongly. The involvement of the pineal gland in the mechanical injury resulting from a cystic third ventricle deserves further study in its relation to cerebral adiposity.

I wish to express my thanks to the State Board of Administration of the State of Illinois for their kind cooperation in enabling me to observe some of the cases.

25 East Washington Street.

Value of Statistics.—Statistics have suffered in reputation because of the seeming truth of the trite statement that one can prove anything by figures. In reality figures are but evidence upon which conclusions may be based. If the evidence is faulty and the faults are not perceived, errors in judgment may result. *But this is true of all evidence upon which opinions are based and is no more true of figures and statistics than it is of other kinds of evidence.—Trask.*

HIBBS' OSTEOPLASTIC OPERATION FOR POTT'S DISEASE *

A REPORT OF CLINICAL OBSERVATIONS WITH RESULTS IN ONE HUNDRED AND FIFTY-EIGHT CASES, AND INTERPRETATION OF EXPERIMENTAL STUDIES IN ANIMALS

BENJAMIN P. FARRELL, M.D.
Attending Surgeon, New York Orthopedic Dispensary and Hospital
NEW YORK

About half a century ago Taylor and Sayre demonstrated the principles of mechanical support in the treatment of Pott's disease. Since that time the routine has been to apply, in the case of ambulatory patients, either a Taylor spinal assistant or a plaster-of-Paris jacket. More recently a Bradford or Whitman frame has been employed whenever the recumbent position was indicated. While these forms of treatment have resulted in a large percentage of cures, they have confessedly left much to be desired. Even the best apparatus is cumbersome and needs constant supervision; and in most cases only imperfect results can be obtained even after years of tedious treatment. In no branch of surgery, perhaps, is the social status of the patient in such close relationship to the possibility of cure. Among the well-to-do tuberculous lesions in the cervical and lumbar regions can be dealt with in a fairly satisfactory manner. The repair, however, of similar lesions in the dorsal region is usually a failure anatomically, although functionally good, because of the impossibility of immobilization. If such is the case under satisfactory social conditions, how much more unfavorable is the outlook for the poor dispensary patient! General recognition of these facts has led a number of men to attempt operative treatment of Pott's disease.

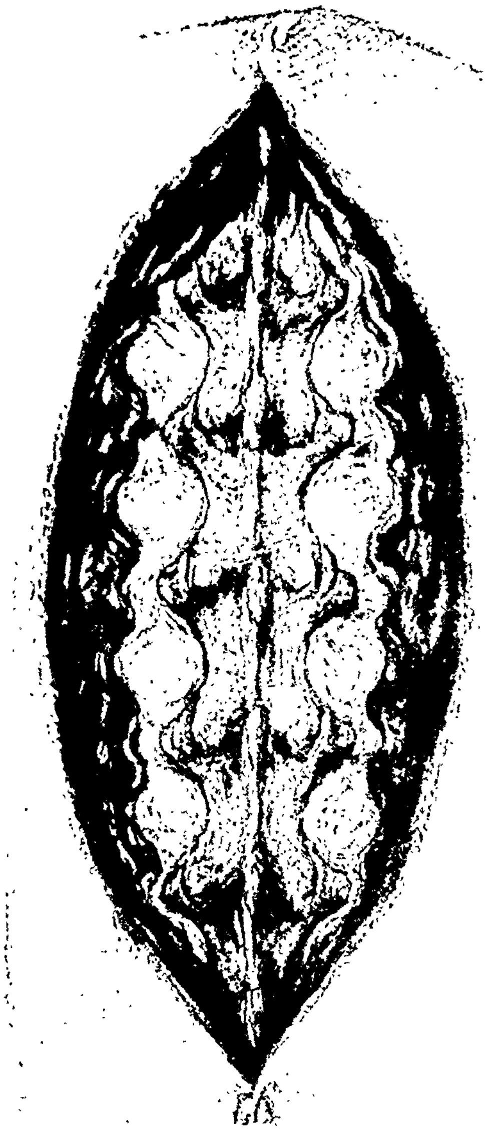

Fig. 1.—The spines and the posterior aspect of the vertebrae are stripped of periosteum, which is shown in circular white areas. The spines have not as yet been cut and imbricated.

Prior to 1908 no definite results were obtained, but in that year F. Lange implanted two tin-plated wire splints with bulbous ends beneath the muscles over the diseased area. These lay on either side of the spinous processes, their ends being attached to them by a silk suture. Two years later[1] the symptoms had subsided, deformity had not increased, and the splints had remained in place.

It has long been known from studies on the healed kyphos that in many instances a fusion of the posterior aspect of the vertebrae through the laminae and spinous processes is the method by which Nature effects repair. Herein, *obviously*, is the key to the situation. If the surgeon could in a few weeks cause the fusion which it took Nature months or years to bring about, he could not well fail to stay the course of the disease and limit the deformity. Thus considered, the question became simply one of determining the best technic for causing arthrodesis of the lateral *articulations* and bridging the intervertebral spaces, thereby fusing the entire dorsal aspect of the vertebrae. Early in the year 1910 it became my privilege to assist Dr. R. A. Hibbs in his studies on the cadaver which led him to devise the technic which experience has shown to be both anatomically satisfactory and surgically acceptable. While it was easily demonstrable that in adult and adolescent life there was always adequate bone *in situ* to make the bridge, it was necessary in the case of very young children to await a verdict which should be based on actual findings at the operating table. It is gratifying to report that adequate bone exists at *all* ages; therefore the use of the autoplastic bone transplant, or any other form of foreign body, is not necessary. The use of such bone transplants had at first been deemed necessary in the case of younger children, but operative experience has demonstrated their uselessness.

* This article is abbreviated by omission of some of the illustrations.

[1] Lange, F.: Jour. Am. Orthop. Assn., November, 1910.

The first account of Hibbs' operation[2] was published in 1911. He also described his method in a paper[3] read before the Section on Surgery of the American Medical Association, at Atlantic City, June, 1912. From this latter paper is taken the author's account of his operation, as follows:

> In performing the operation, a longitudinal incision is made directly over the spinous processes, through skin, supraspinous ligament and periosteum, to the tips of the spinous processes. The periosteum is split over both the upper and lower borders of the spinous processes and the laminae, and stripped back from them to the base of the transverse processes. The spinous processes are then transposed after partial fracture, so that they make contact with fresh bone, the base of each with its own base, and the tips with the base of the next below. The adjacent edges of the laminae being absolutely free from periosteum, a small piece of bone is elevated from the edge of the laminae and placed across the space between them, its free end in contact with the bare bone of the laminae next below it.
>
> The lateral walls of periosteum and the split supraspinous ligament are brought together over these processes by interrupted chromic catgut sutures. The skin wound is closed by silk, and a steel brace applied. Detailed operative and postoperative directions follow.

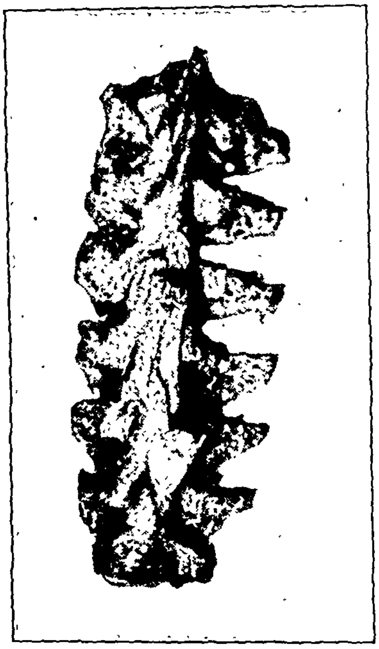

Fig. 8.—Complete fusion after eighty days. The imbricated spinous processes are seen.

The only addition to this technic has been as follows: The lateral articulations are exposed and the cartilage removed by a very small curet. This adds to the extent of the fusion.

We have now had ample opportunity to test the value of this operation. It would be too much of a tax on your time and patience to detail the nearly two hundred cases which have been treated by this method in the New York Orthopedic Hospital; therefore, I will briefly summarize the main features in the cases so treated during the years 1911, 1912 and 1913.

Summary 1911.—There were *twenty-two* cases, ranging in age from 5 years to 25 years; the duration of the disease was from two months to thirteen years; six had formerly worn plaster jackets; sixteen had worn spinal assistants; the range of the deformity was from three to twelve vertebrae; in six cases psoas spasm was observed, psoas abscess in two, and increased reflexes in eight; the number of vertebrae fused varied from five to fourteen.

Summary 1912.—There were seventy-two cases, ranging in age from 3 to 41 years; the duration of the disease was from four weeks to twelve years; six had formerly worn plaster jackets, thirty-seven spinal assistants and one Bradford frame; the range of the deformity was from three to twelve vertebrae; fifteen showed exaggerated reflexes, eight, psoas abscess and nineteen psoas spasm; the extent of the operation varied from five to fourteen vertebrae.

Summary 1913.—There were sixty-four cases, ranging in age from 18 months to 14 years; forty had previously worn spinal assistants, two had undergone bone transplantation from the tibia, and four had previous osteoplastic operations, an insufficient number of vertebrae having been included; the range of the deformity was from six to fourteen vertebrae; in twenty-three cases psoas spasm was observed, psoas abscess in two and increased reflexes in seventeen; the extent of the operation varied from eight to fourteen vertebrae.

Of the 158 patients seven have died, and four required reoperation for the above-mentioned reasons. With these exceptions, the results have been eminently satisfactory, inasmuch as, barring three who were paralyzed when they came to the hospital, all the symptoms of Pott's disease other than the deformity have disappeared; all the patients who have been operated on for a longer period than one year are without apparatus, and are able to carry on the ordinary avocations of life, whether play or business.

Of the seven who died, it should be noted that the cause of death was in every case extrinsic, and not due to the operation. One died one and a half years after the operation; cause of death, miliary tuberculosis; one died six and a half months after the operation, cause of death, tuberculous meningitis; one died sixteen months after operation, cause of death tuberculous meningitis; one died one and a half years after operation, cause of death, miliary tuberculosis; one died a year and ten months after operation, cause of death, tuberculous meningitis; one died three months after operation, cause of death, pyemia, the patient having been infected before he entered the hospital; one died a year after the operation, cause of death miliary tuberculosis.

[2] Hibbs, R. A.: New York Med. Jour., May 27, 1911.

[3] Hills, R. A.: An Operation for Pott's Disease of the Spine, The Journal A. M. A., Aug. 10, 1912, p. 433.

Necropsy on two of these cases showed, so far as the field of operation was concerned, a complete fusion of laminae and spinous processes from the lateral articulation on one side to the lateral articulation on the other side, the fusing bone mass in both instances being thick, strong and efficient, thereby proving that the operation itself had been perfectly successful.

In the four cases referred to in which reoperation was required, because an insufficient number of vertebrae had been included in the original operation, an incision was made through the old scar, the original field of operation was exposed, and the vertebral fusion present was found complete, but too short. After healthy vertebrae were included both above and below, the results were as satisfactory as in the other cases. The bone production is easily demonstrated by Roentgen ray in most cases, but the chief value of the roentgenograms is as a preoperative guide to indicate the number of vertebrae which should be fused.

The experimental series may be classified as follows:

Dog No.	Date of Operation		Date and Cause of Death	Days Old
172	March	23	March 27, meningitis	4
178	March	25	March 27, shock?	2
177	March	24	March 31, meningitis	7
126	March	22	March 25, shock?	3
127	March	22	March 28, meningitis	6
188	April	1	April 10, meningitis	9
189	April	1	Still living	
175	March	24	March 27, nephritis	3
104	February	5	Still living	
167	March	20	Still living	
166	March	20	Still living	

From the above it appears that the majority of the dogs died either of meningitis or shock. One, however, died of unilateral nephritis, based on autopsy finding.

It is interesting to notice the wide difference in mortality rate between the animal and the human series. For seven dogs the average postoperative life was four and one-half days; the total mortality, in a series of eleven dogs being 72.7 per cent. The cause of this high mortality has not yet been worked out, but as, with two exceptions, the skin wounds healed primarily, the inference is that the operative technic was reasonably clean and that dogs tolerate operative procedure of this nature poorly.

Of the recovered dogs, subjected to euthanasia, two, respectively sixty-two and sixty-eight days postoperative, show that while sufficient bone growth had not taken place to fuse the bridged vertebrae, considerable bone was shown in process of formation. Furthermore, these were undergraduate student preparations in which the fragments were found not to have adhered in a position to insure early fusion of the joints. It may be further noted that lamina-fusion in these animals was not attempted, nor were the lateral articulations disturbed, because of an attempt to reduce the mortality by using a less extensive procedure.

Another specimen, eighty-five days postoperative, shows complete vertebral fusion, while in another, over 100 days, somewhat denser bone deposits exist. One may therefore conclude from animal experiments that osteoplastic operations on the spine of dogs, especially if the laminae and lateral articulations are disturbed, is attended with high mortality, and that terminal bone formation sufficient to fuse the vertebrae and destroy all motion does not occur until after the seventy-fifth day.

Good Legislation.—It is the duty of the government so to legislate as to make it easy to do right and difficult to do wrong.—*Gladstone.*

OBSERVATIONS ON BONE TRANSPLANTATION (ALBEE METHOD) FOR THE CURE OF TUBERCULOUS SPINE DISEASE*

CHARLES M. JACOBS, M.D.
Associate Clinical Professor of Orthopedic Surgery, University of Illinois Medical School; Attending Orthopedic Surgeon, Cook County Hospital and Home for Destitute Crippled Children
CHICAGO

Certain principles in the treatment of tuberculous spine disease appear so firmly established that they have been regarded as axiomatic. For 135 years conservatism has been considered the only reasonable and safe course to pursue, whereas it is only recently that operative measures have come into their own in Pott's disease. Hence to replace conservative by operative measures is to run counter to the established conservatism in the treatment of the disease, and naturally there is opposition on the part of those who have not yet accepted radical measures.

In considering the possibilities of cure for Pott's disease by bone transplantation into the split spines of several contiguous vertebrae, or by any other operative method, clinical experience is necessary to form an unbiased opinion of its practical value. At the last session of the *American Medical Association* a paper was presented by the surgeon in charge of the Sea Breeze Hospital, giving his interpretation of the results of fifteen cases of tuberculous spine disease in which operation was performed by the originator of the Albee method at the above-mentioned institution. The report was extremely unfavorable, and the publication of which leads me to present my observations with the hope that other men of experience may carry the discussion farther, thus adding light on a subject of so much importance.

Unquestionably bone transplantation, as advised by Albee, marks a new epoch in the treatment of Pott's disease and is a valuable surgical asset. Surgery shows to better advantage here than in tuberculous joints elsewhere in the body; there is no danger of disseminating the infection into contiguous normal bone; no sacrifice of bone to affect shortening and it is in accordance with orthopedic principles in securing physiologic rest, thereby affecting the pathologic process.

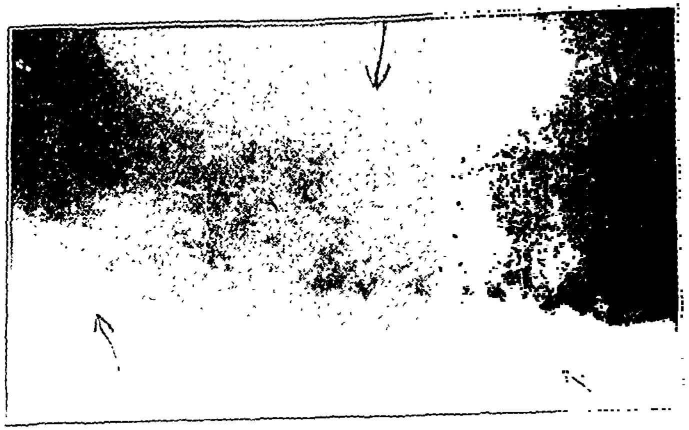
Let it be understood that I do not favor surgical measures in every case of Pott's disease. The value of any plan of treatment in tuberculous spine disease is estimated by its effectiveness in combating ultimate deformity. Under conservative treatment recovery may be anticipated, in an average period of three or four years, with or without deformity, depending often on the region of the spine affected. We know that caries in the middle and upper dorsal region of the spine is frequently associated with great angular protrusion, whereas caries in the cervical or lumbar region, even when extensive, has little or no kyphos. This is explainable by the fact that the superincumbent weight is greatest on the bodies of the vertebrae in the dorsal region because of the normal curve of the spine being concave in front. In childhood, therefore, routine treatment should be protective except, perhaps, in middle and upper dorsal Pott's disease; but in cases in which conservative treatment has been tried and found impossible to control, surgical intervention is then justifiable. In adults operative measures depend on social and ecoonomic conditions. The leisure class is in a position to choose between conservative and operative treatment. On the other hand, the wage earner must regain health in the shortest possible time; therefore, conservative treatment in his case demands a sacrifice justified only by a necessity which I consider no longer exists.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Undoubtedly surgical measures in Pott's disease shorten the period of disability with a presumption of a rapid cure. But rapid cure, in the exact sense, cannot be obtained by any method of treatment in tuberculous spine disease. In comparison to conservative methods, bone transplantation followed by protective treatment shortens the duration of tuberculous spine disease many months. The early relief afforded patients from discomfort and pain following the operation is striking.

It is needless to state that bone transplantation has no direct curative action on the tuberculous process.



Bone transplant extending from first lumbar vertebra to coccyx; bodies of the fourth and fifth lumbar vertebrae destroyed.

The underlying principle is fixation of the vertebrae in order to hold the spine in the extended position so that pressure on the diseased area may be removed, thus arresting and controlling the morbid process. Success thus depends on the efficiency in which the spine is splinted. This is accomplished, primarily, by the bone graft being implanted into the spinous processes of all the diseased vertebrae and at least two contiguous vertebrae on either side. This will effectively splint the spine. A source of failure is almost invariably due to the error of implanting the graft into the contiguous vertebrae of one end only which imperfectly eliminates motion. To obviate this error it is all important that the extent of the diseased area be accurately determined by a good roentgenogram before proceeding to operation. The kyphos alone is not a sufficient guide.

External support, either casts or braces, must not be disregarded for many months following the postopera-

RESULTS OF OPERATION IN NINE CASES OF POTT'S DISEASE

Case	Duration of Disease, Years	Deformity Previous to Operation	Age at Time of Operation, Years	Vertebrae Affected as Shown by X-Ray	Reasons for Operation	Date of Operation	Location of Graft as Shown by X-Ray	Length of Time of Postoperative Recumbency, Months	Length of Time of Postoperative Protective Treatment, Months	Ultimate Results
1............	2⅓	Yes	13	3 to 4 L.	Increasing kyphos	4/13	1 to 5 Lumbar	3	3½	Has no discomfort or pain; lower end of graft stands out prominently; right lateral curve of the spine above the graft.
2............	3	Marked	5	3 to 4 D.	Discomfort and pain on walking	7/13	2 to 5 Dorsal	1½	3	No discomfort nor pain, and walks with ease; kyphos slightly increased.
3............	?	Yes	19	7 to 10 D.	Economic	8/13	5 to 12 Dorsal	2	None	Without symptoms; no increased kyphos.
4............	4	No	7	4 to 5 L.	Pain on walking; discharging sinus.	9/13	1 to 5 Lumbar	2	None	Walks with ease and is without symptoms other than sinus has not closed.
5............	2½	Marked	7	11 to 12 D.	Grunting respiration; increasing kyphos	9/13	9 D. to 3 L.	2	3	Allowed up without any protection, but after one week a cast was applied because of grunting respiration; after three months cast was removed, since which the kyphos has only slightly increased; otherwise without symptoms.
*6............	3	Yes	6	7 and 8 D.	?	4/13	7, 8, 9 D.	2½	None	Four months after operation unable to walk and was placed on Bradford frame.
7............	¼	Slight	20	11 to 12 D.	Discomfort and pain	12/13	10 D. to 5 L.	1½	None	After six weeks, protective treatment became necessary because of a "slight weakness" referred to the abdomen; two months later the cast was removed, and the patient has been without symptoms; no increased kyphos.
8............	1	Yes	32	12 D. to 2 L.	Economic	12/13	10 D. to 4 L.	6	None	Graft became infected and was removed; Roentgen-ray shows beginning bone formation connecting spinous processes.
*9............	3½	Slight	18	6 to 10 D.	Pressure paralysis	3/13	6 to 12 D.	3	1½	Without symptoms for six months following operation; then right knee gradually began to "jerk" and unable to walk; patella reflexes and ankle-clonus much increased; now on Bradford frame.

* Operated on before coming under observation of the author.

tive period of recumbency (six weeks), inasmuch as too early reliance cannot be placed on the strength of the graft. It is improbable that a firm bony union exists between the graft and the split spinous processes in this period of time. Albee, however, states that the graft becomes united by bony union in four weeks. According to Dupuytren and Wieder, there is no permanent callus formation between the ends of the transplant and the bone into which it is to be transplanted before the eighty-fifth to two hundred and fiftieth day.

In the middle and upper dorsal region of the spine, where deformity has developed necessitating a pronounced bending of the bone insert, the strain on the graft is greatest. Unless external support be given, tracings of the spine will almost invariably show an increased, rounded kyphos. In lower dorsal or lumbar Pott's disease the graft is usually straight and the strain is mostly confined to its lower end. Here again it is necessary to use external support; otherwise the lower part of the graft may not remain firmly anchored and then it stands out prominently. I am accustomed to give postoperative protective treatment at least for six months. Clinically no harm can come from too long a protection—other views notwithstanding.

This paper is based on nine cases observed in my private practice and on my services at the Cook County Hospital and the Home for Destitute Crippled Children during the year of 1913. In seven of the cases operation was performed by me and in two (Cases 6 and 9) by other surgeons. No attempt has been made to gather cases for statistics from other sources.

CONCLUSIONS

I feel warranted in stating that:

1. Surgical measures for tuberculous spine disease are a great advance over conservative treatment, but should be restricted to selected cases. Undoubtedly they shorten the period of disability.
2. Not only may existing deformity be prevented from becoming exaggerated, but also deformity itself may be prevented by surgical measures.
3. Too early reliance cannot be placed on the strength of the bone graft. It takes time for the splint to become securely fixed by permanent callus.
4. External support must not be disregarded for many months following the operation; otherwise deformity may ultimately occur.
5. Even with postoperative protective treatment for a period of six or more months, the duration of treatment is much shorter than the average duration under non-operative methods.
6. Success of bone transplantation for the cure of tuberculous spine disease depends on the proper implantation of the bone splint into the diseased and normal contiguous vertebrae. Essential to the success is the *careful protective after-treatment* for a period of months.

I wish to thank Mr. Julius Gillis, private radiologist, and Dr. Edward S. Blaine, radiologist to Cook County Hospital, for their valuable aid with roentgenograms.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. FARRELL AND JACOBS

Dr. W. G. Stern, Cleveland: One question cannot be settled by animal experiments, but only by long clinical experience, and that is, can the bones of one human being be permanently transplanted into another? If the bones of one individual can successfully be transplanted to another, we have before us a means of making transplants of even greater extent and scope than the ones already shown. Hoffmeister, in Germany, for sarcoma of the upper end of the humerus, took the fibula of a cadaver and using the external malleolus as the joint-forming body, implanted the other end into the shaft of the humerus. He was able, by means of this long piece of bone, to put the muscles of the arm under great tension; and the result was eminently successful. Reports have been drifting to America, brought by word of mouth, that some of these splendid operations, done by means of transplants from one individual to another, have not been permanently successful. The bones, which apparently healed in and formed a new joint in Lexer's case, later lost their bony character, and after a year or two, could no longer be identified as bone. If this transplantation from one individual to another will succeed, the method offers a promising field in the large hospitals, from material gathered in cases of amputation, etc. I also agree that in the operation of transplantation for the cure of Pott's disease, the graft should extend a fairly long distance above and below the seat of the disease; and that the case should have mechanical support for a long time afterward.

Dr. John B. Murphy, Chicago: It is pleasing to note tha the position that we have taken is being confirmed, that bone of any size, even to that of the longest bone of th anatomy, can be transplanted from one part of an individua to another part and will survive if it be aseptic. The question is not yet settled whether the periosteum and the compact bony tissue or the medulla plays the most importa rôle in the regeneration of bone. It is fairly well establishe that the autotransplant gives the best results. In somethin over one hundred cases of bone transplants of all sizes, fro 14 inches down, we have removed only one transplant. Thi shows the uniformity with which bone can be healed in. I matters little whether the bone is placed on the surface, i the compact bony tissue, or in the medulla. What we ar interested in, and where we feel that work can be done b this section, is in the treatment of malignant and semimalignant lesions of bone by resections in place of amputations. Our great work is going to be that we shall be able t prevent metastasis by early resection of bone and save th extremity. The epiphyses must be preserved when this ca be done, because they are important for the growth of bone That we are not doing for tuberculosis in all portions of th body the best that we can, is definitely settled in my mind We must do more than merely give mechanical support. Great stress has been laid on the advisability of keeping a patient with tuberculosis in activity. I consider that an error; for it lessens the opsonic index in the extremity as well as in the lung. How well satisfied are we with the management of our cases of tuberculosis of the hip on the former orthopedic basis of mobility?

Dr. Joel E. Goldthwait, Boston: The discussion has shown that bone transplants can be inserted in large pieces and that they will not be thrown off. Conservatism in the treatment of malignant bone and joint disease promises, certainly, as much as any other; because Coley's statistics reported a short time ago, showed that life was not prolonged by operation. The disease goes on, in spite of such radical measures. This method of bone transplantation offers an opportunity to do something early, when the patient is willing.

Dr. M. S. Henderson, Rochester, Minn.: I have operated on five patients by Hibbs' method. Clinically, ankylosis was obtained. The most striking case was that of a young man 25 years of age who had a lumbar Pott's with large psoas abscess, but no sinus. After operation the abscess was aspirated, the patient gained 35 pounds and manual labor was resumed. Later he developed acute miliary tuberculosis of the lungs and died. Three other patients were apparently cured. One is too recent to report. I have operated in over thirty cases by the Albee method. We lost no transplants. In those observed long enough after operation to be fair, it would seem that ankylosis was secured. Dr. Murphy emphasizes the practicability of bone transplantation. In something over seventy transplantations we have only lost one graft.

THE SYMPTOMATOLOGY AND TREATMENT OF SEBORRHEIC KERATOSES *

RICHARD L. SUTTON, M.D.
KANSAS CITY, MO.

Few physicians appreciate the important part played by seborrheic keratoses in the pathogenesis of carcinoma of the skin. A material, if not absolutely essential, factor in the etiology of both basocellular and prickle-cell cancer is a peculiar quality of the skin, a quality which may be inherited but is usually acquired, and which is characterized by harshness and dryness, with more or less evidence of long-standing dry seborrhea. In the production of these cutaneous changes, age is an important, but not indispensable, factor. Long-continued exposure to strong sunlight and to sudden atmospheric changes aids in the preparatory process. The custom of applying a local descriptive term to a skin of this kind is unfortunate, for it tends only to confuse the unsophisticated. The so-called "sailor's skin" is by no means confined to those who follow the sea. Typical examples of the condition are probably far more frequent on the plains of Kansas than on the Newfoundland Banks. In discussing the subject of seborrheic, or "senile," keratoses, these facts should be borne in mind, for it is on a skin of this type that the majority of these lesions develop.

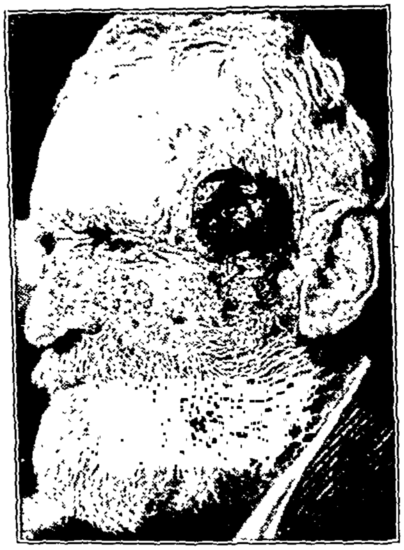


Fig. 1 (Case 4).—Keratoses of the keratoid type, and large prickle-cell carcinoma involving the skin and periosteum.

Clinically, seborrheic keratoses begin as small, round or oval, brownish macules. The sites of predilection are the face, scalp, trunk, particularly the interscapular and sternal regions, and the backs of the hands. When fully developed the growths are flat-topped, papular elevations, usually oval in outline, yellowish, grayish or brownish in color, sharply circumscribed, and covered with a firmly adherent crust which is usually greasy and velvety if the lesions are situated on the trunk or scalp, and harsh, rough and dry if they are located on the face or hands. When the crust is carefully removed its under surface often presents numerous tiny projections which formerly extended into the mouth of the follicles. Not infrequently the location of an involved area is apparently dependent on some preceding slight injury of the skin, such as a nick from a razor while shaving. The tumors never disappear spontaneously, and may persist indefinitely without change, but generally, and especially in those instances in which the growths are exposed to constant or repeated irritation of any sort, the bases of some of them undergo further pathologic change and ultimately become malignant, the resulting carcinomas invariably being of the prickle-cell type.

The histopathology of seborrheic keratoses has long been a matter of controversy. Neumann[1] found thinning and pigmentation of the prickle layer, atrophy of the derma, and hypertrophy of the sebaceous elements, with cystic changes in the hair follicles and their appended glands. Balzer[2] reported the granular layer and stratum lucidum unaffected, the presence of a decided acanthosis, hypertrophy of the stratum corneum, and enlargement of the papillae, with some perivascular infiltration. Otherwise the cutis was normal. Handford[3] found acanthosis, with associated hypertrophy of the horny layer, and there were present throughout the epidermis numerous round and oval spaces, the walls of which were lined with cubical epithelium. Pollitzer,[4] who was first to investigate the condition thoroughly, studied sections from a considerable number of lesions, some of which had been excised from a patient suffering with mycosis fungoides. He found the papillae enlarged and elongated, and containing many epithelioid cells, the majority of which were arranged alongside and parallel to the capillaries. The vessels themselves were unchanged, and the elastic fibers and sebaceous glands also were normal. There was hypertrophy of the prickle layer, with parakeratosis of the stratum corneum. The follicular orifices were filled with horny substance. The coil gland ducts were dilated and cystic, many of the cavities containing large numbers of leukocytes and degenerated epithelial cells. There was much free fat in the cutis and in the interspinal spaces of the prickle layer. Unna[5] examined a series of the growths secured post mortem from eight cases of the disease. The findings were very similar in all, and he concluded that the lesions were true soft nevi which had undergone a peculiar form of fatty degeneration, and differed from ordinary soft nevi only in their containing more fat. Hartzell[6] has recently gone thoroughly into the subject. He found in all of his specimens:

> A marked increase in the thickening of the corneous layer of the epidermis, the nuclei of the cells being still present as fairly well-stained, slender spindles. The greatest increase in thickness was about the mouths of the hair follicles and the sweat ducts, the former being widely dilated and filled with horny plugs. The granular layer had in most places disappeared, but was still well preserved about the hair follicles and sweat ducts. The rete mucosum presented considerable variation in the amount of alteration present. In the newer lesions there was but slight increase in the width of this layer, although there was always evidence of increased cell activity in the basal cells, such as numerous dividing cells and multiplication of nuclei. In the older lesions there were all degrees of increase in the thickness of the rete up to actual invasion of the corium and beginning epithelioma. In a small lesion removed from one of the patients who also had multiple epithelioma, there was a circumscribed down-growth of the rete surrounded and penetrated by a cellular infiltrate composed of numerous mononuclear leukocytes, and in the corium a moderate number of plasma and mast cells. With the exception of a decided flattening out, and in some cases the complete disap-

pearance of the papillae, the corium presented but little alteration.

It is difficult to reconcile the conclusions of these various investigators. Inasmuch as all were skilled and experienced observers, the disparity of the pathologic reports would indicate that the question is as yet an unsettled one.

I first became particularly interested in the condition about two years ago, and since that time I have endeavored to secure some material from every case of seborrheic keratosis that came under my care. The disorder is a common one in the Middle West, but unfortunately the general public has not yet become educated in the matter of biopsies; consequently I have been able to secure only thirty-four pieces of tissue from thirty-one different individuals, all of whom were private patients.

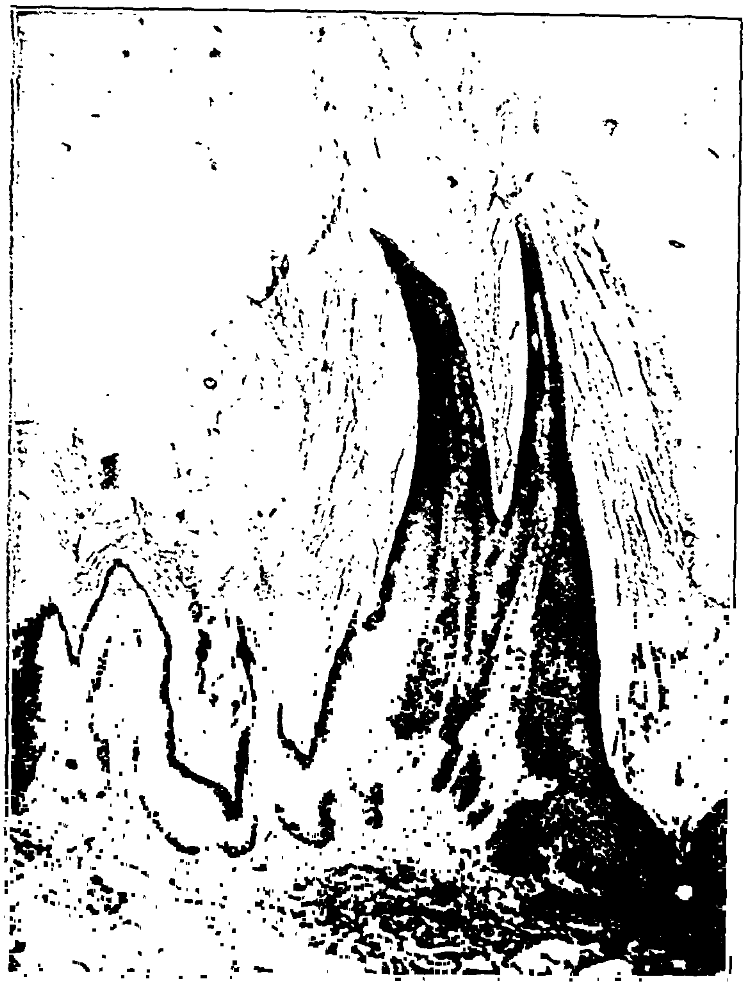

Fig. 2 (Case 7).—Seborrheic keratosis of the verrucose type, showing hyperkeratosis, acanthosis and inflammatory changes in the derma (Leitz, No. 3 objective, No. 4 eyepiece, 20 cm. bellows extension).

A brief summary of the case histories may be of interest:

Case 1.—Retired farmer, married, aged 61, referred by Dr. J. N. Goodson of Kansas City. Lesions on face and trunk. Carcinoma beneath right eye. One growth excised from right temporal region.

Case 2.—Commercial traveler, married, aged 56. Lesions on face and back. One growth excised from left cheek.

Case 3.—Widow, aged 64, referred by Dr. Elmer Twyman of Independence, Mo. Lesions on face, scalp and back. Carcinoma near inner canthus of left eye, involving lid and the left side of nose. One growth excised from forehead, near hair margin.

Case 4.—Farmer, married, aged 69. Numerous lesions on face and trunk. Large carcinoma on left temple (Fig. 1). One growth excised from left cheek.

Case 5.—Lawyer, married, aged 63, referred by Dr. W. M. L. Witter of Milan, Mo. Lesions on face and back. One growth excised from region of right temple.

Case 6.—House painter, single, aged 26, referred by Dr. Edward Asbell of Kansas City, Kan. Lesions on face and trunk. One growth excised from region of right scapula.

Case 7.—Housewife, aged 49, referred by Dr. Jabez N. Jackson of Kansas City. One lesion on scalp, just above right temple. Growth excised (Fig. 2).

Case 8.—Farmer, married, aged 67, referred by Dr. J. Archie Robertson of Kansas City. Numerous lesions on face. One growth excised from left cheek (Fig. 3).

Case 9.—Ranchman, single, aged 48. Numerous lesions on face and trunk. Carcinoma on right side of nose (Fig. 4). One growth excised from right cheek.

Case 10.—Widow, housewife, aged 58, referred by Dr. Sam T. Mead of Slater, Mo. Lesions on face and scalp. One growth excised from right side of forehead, near hair margin.

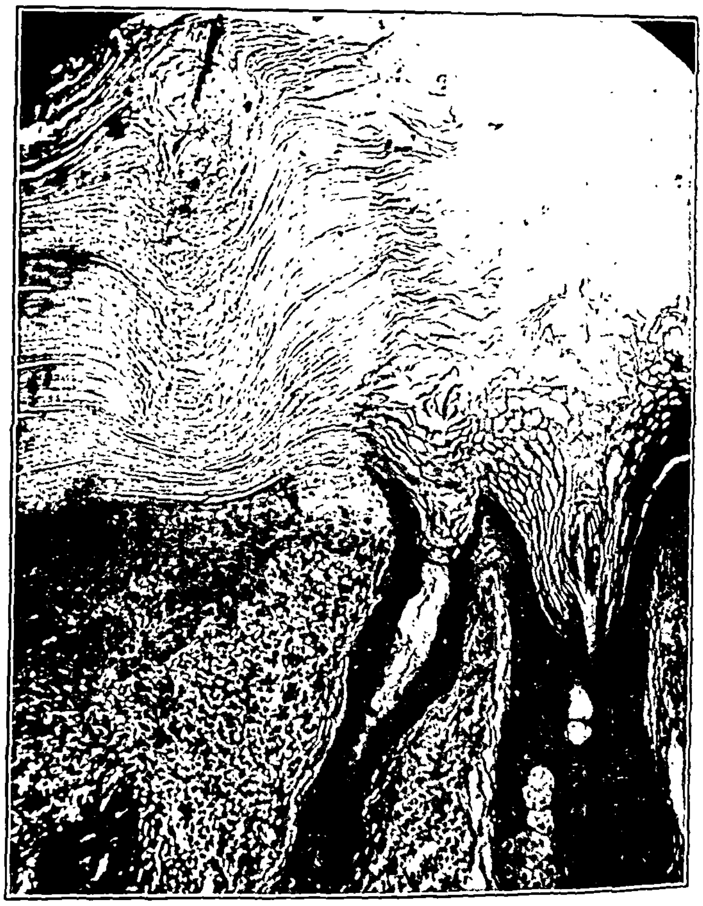

Fig. 3 (Case 8).—A typical keratoid lesion, showing horny plugs in mouths of follicles, hyperkeratosis, slight papillary flattening, and beginning inflammatory changes in derma (Leitz, No. 3 objective, No. 4 eyepiece, 20 cm. bellows extension).

Case 11.—Engineer, single, aged 26, referred by Dr. C. D. Trask of Kansas City. Lesions on face and ears. One growth excised from upper border of left ear.

Case 12.—Rural mail carrier, married, aged 43, referred by Dr. T. S. Blakesley of Kansas City. Numerous lesions on face and one on ball of left eye (Fig. 5). Diagnosis made, and growth excised from eye by Dr. Blakesley.

Case 13.—Physician, married, aged 56, referred by Dr. Roger Brewster of Kansas City. Numerous lesions on trunk (Fig. 6). Two growths excised from scapular and interscapular regions.

Case 14.—Oil operator, married, aged 34, referred by Dr. Frank J. Hall of Kansas City. Lesions on nose, forehead and trunk. One growth excised from side of nose.

Case 15.—Commercial traveler, married, aged 47, referred by Dr. W. T. Reynolds of Kansas City. Numerous lesions on trunk. Two growths excised from left scapular region.

Case 16.—Widow, aged 44, referred by Dr. W. T. Shelton of Kansas City. Lesions on nose and forehead. Carcinoma on right side of nose. One growth excised from forehead.

CASE 17.—Farmer, married, aged 32, referred by Dr. Peterson of Nashua, Mo. Lesions on trunk and left ear. One growth excised from left scapular region.

CASE 18.—Retired teacher, widower, aged 73. Lesions on face, ears and trunk (Fig. 7). One growth excised from left cheek (Fig. 8).

CASE 19.—Farmer, married, aged 43, referred by Dr. W. C. Lathrop of Norton, Kan. Numerous lesions on face and forehead. One brother similarly affected. One carcinoma beneath right eye, and one on right cheek. One growth excised from forehead.

CASE 20.—Electrical foreman, married, aged 27, referred by Dr. Frank Teachenor of Kansas City. Lesions on trunk. One growth excised from left lumbar region (Fig. 9).

CASE 21.—Street-car conductor, married, aged 45, referred by Dr. Will Iuen of Kansas City. Lesions on face and trunk. One brother similarly affected. One growth excised from left side of chin.

CASE 22.—Widow, aged 65, referred by Dr. C. D. Trask of Kansas City. Numerous lesions on face and forehead. One brother and one son similarly affected. Carcinoma on left cheek. One growth excised from forehead, and one from right cheek.

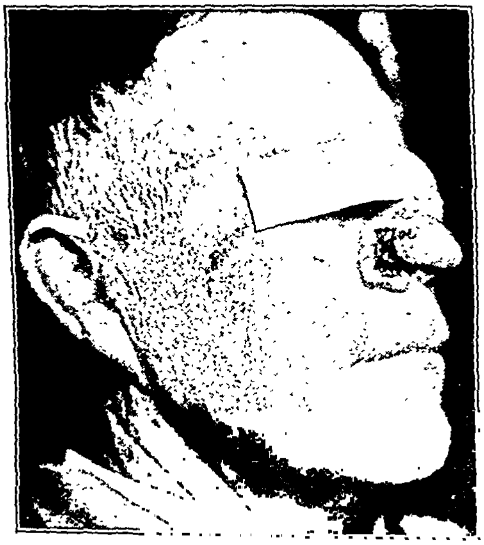

Fig. 4 (Case 9).—Seborrheic keratoses of the face, with prickle-cell carcinoma of the nose.

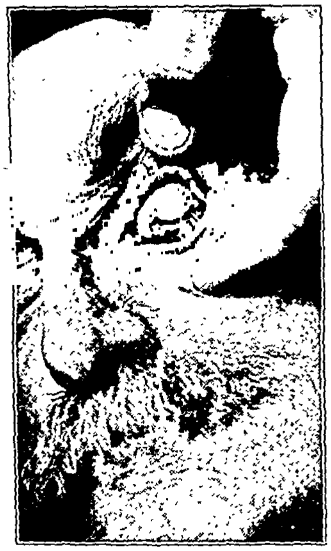

Fig. 5 (Case 12).—Keratosis of eyeball, with numerous keratoid lesions on face.

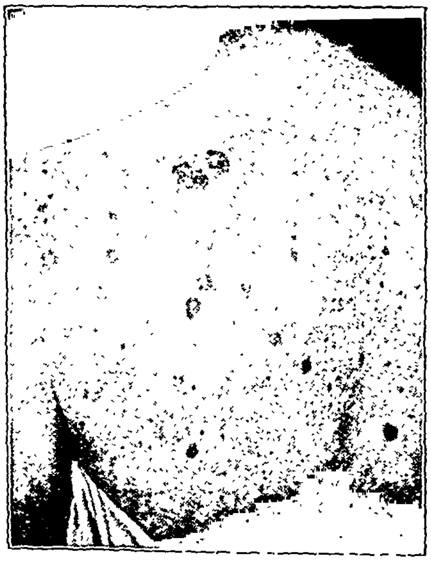

Fig. 6 (Case 13).—Typical example of seborrheic keratoses of the nevoid type.

CASE 23.—Street-railway pay clerk, married, aged 34, referred by Dr. Chas. B. Hopkins of Kansas City. Lesions on trunk. One growth excised from left side of trunk.

CASE 24.—Housekeeper, single, aged 34, referred by Dr. A. G. Swaney of Lee's Summit, Mo. Lesions on face and scalp. One growth excised from left temporal region.

CASE 25.—Farmer, married, aged 64, referred by Dr. N. P. Wood of Independence, Mo. Lesions on face, ear and trunk. Carcinoma on left ear. One growth excised from ear.

CASE 26.—Farmer, married, aged 63, referred by Dr. H. W. Tull of Carrolton, Mo. Lesions on face. Carcinoma on right cheek. One growth excised from right temporal region.

CASE 27.—Cattleman, married, aged 41, referred by Dr. Daniel Ross of Denison, Texas. Lesions on lower lip and on trunk. One growth excised from left suprascapular region.

CASE 28.—Housewife, aged 54. Lesions on face, scalp, trunk and left leg. One growth excised from left cheek, and one from left shin (Fig. 10).

CASE 29.—Telegraph operator, married, aged 31, referred by Dr. Ernest W. Reynolds of Bristow, Okla. Lesions on face and trunk. One growth excised from right ala of nose.

CASE 30.—Salesman, married, aged 57, referred by Dr. A. Comingo Griffith of Kansas City. Numerous lesions on trunk. One growth excised from left subscapular region.

CASE 31.—Stockman, married, aged 37, referred by Dr. Nathan Harrelson of Kansas City. Numerous lesions on face and trunk. One sister similarly affected. Carcinomas on forehead and on right cheek. One growth excised from right temporal region.

In all but three instances (Cases 12, 26 and 30), the biopsies were performed by means of a medium-sized cutaneous punch, under local anesthesia. Liquor formaldehydi was employed as a hardening and fixing agent. About one hundred frozen sections were made. These were stained with either osmic acid or sudan III. The rest of the material was blocked in paraffin, cut serially and stained with hematoxylin and eosin. I am indebted to Dr. W. K. Trimble and his assistant, Miss Blakesley, for much of this preliminary work.

After examining sections from a dozen or more of the lesions, it was apparent that the growths could be roughly separated into three distinct groups: first, and most frequent, a keratoid variety, characterized by great corneous hypertrophy, with some parakeratosis, a moderate degree of acanthosis, slight proliferative changes in the germinal layer, and more or less flattening of the papillary bodies; second, a nevoid type, which was practically identical with Unna's "naevus seborrhoeicus," and third an acanthoid or verrucose form, distinguished by considerable hyperkeratosis, very pronounced acanthosis, signs of exceedingly active proliferative changes in not only the stratum germinativum, but also at numerous other points in the rete, and enormous papillary hypertrophy. In these wartlike specimens the cutis showed inflammatory changes of a subacute nature, with capillary dilatation, extensive perivascular infiltration and small collections of leukocytes and round and plasma cells scattered through the upper derma.

As the studies progressed, the group characteristics of the three types became more obvious, until, toward the end, it was not a difficult matter to foretell accurately the histologic features of a majority of the growths even prior to excision.

Some of the more advanced keratoid tumors bore a distinct structural resemblance to early Roentgen-ray carcinomas (as represented by both comparative specimens[7] and Wolbach's[8] description), although the keratinization of the epithelial processes extending downward into the derma was not so prominent a feature here as in tumors of the Roentgen irritation type. In the earlier keratoid lesions the most noticeable change in the cutis was the dilatation, with occasional development of cysts, in the sweat ducts. The sebaceous glands were practically normal in all three classes, despite the fact that all contained considerable quantities of free fat. The nevoid tumors were richest in this material, the acanthoid less so, and the keratoid least of all.

Of the thirty-four specimens excised, nineteen were of the keratoid variety, eleven of the nevoid and four of the acanthoid. Needless to say, not all were typical examples, but the borderline cases were so infrequent that they could safely be disregarded.

From the point of view of prognosis, the keratoid lesions were by far the most dangerous. Nine of the patients who suffered from growths of this type presented also active manifestations of carcinomatosis.

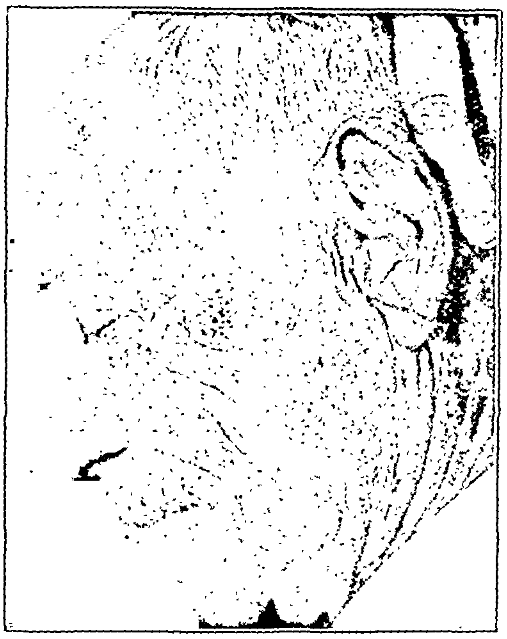

Fig. 7 (Case 18).—Seborrheic keratosis of the verrucose type, showing pigmentation and crusting. The patient's skin is dry, rough and harsh.

Both the clinical and histologic features in Case 12 were unique. So far as I know, a keratosis of this type has never before been reported as occurring on the eyeball. Prior to the removal of the entire tumor, Dr. Blakesley had scraped off a portion of the shelf-like mass and found that it consisted of elongated, cornified cells, many of which retained their nuclei. The base of the growth was exceedingly vascular, and contained many sinus-like, epithelial-lined cavities, as well as old and newly formed capillaries. There were no signs of malignancy, however, and the tumor did not recur after removal. The patient's sight was not impaired by the presence of the growth.

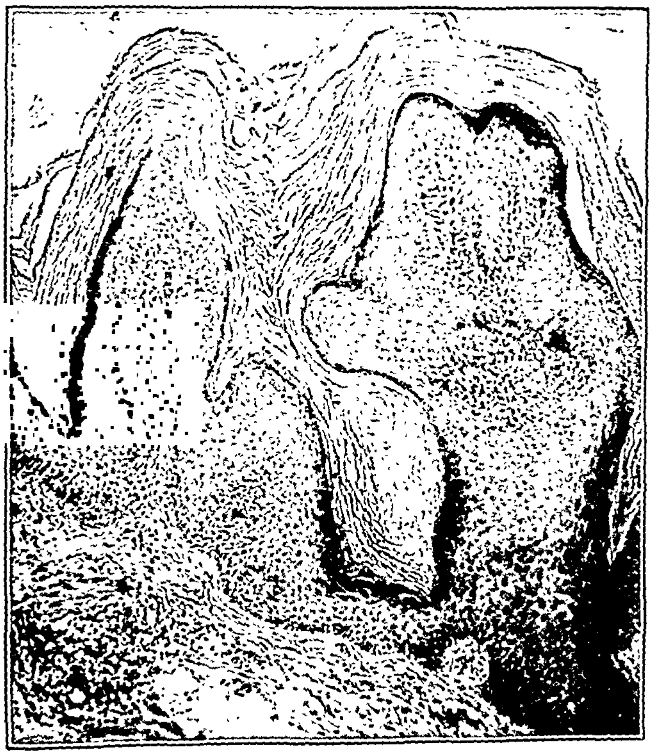

Fig. 8 (Case 18).—*Seborrheic keratosis of the verrucose type, showing hyperkeratosis, acanthosis and decided inflammatory changes in cutis (Leitz, No. 3 objective, No. 4 eyepiece, 20 cm. bellows extension).*

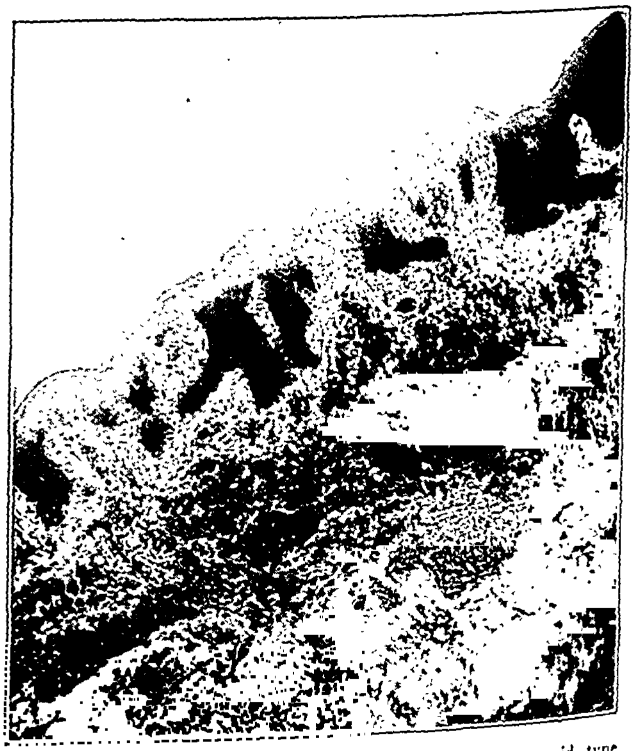

Fig. 9 (Case 20).—Early seborrheic keratosis of the nevoid type, showing slight parakeratosis, *pigmentation and changes in derma* (Leitz, No. 3 objective, No. 4 eyepiece, 12 cm. bellows extension).

For purposes of comparison, sections of a small cutaneous horn from the penis were examined. The lesion was one of three which had developed from a group of acuminate condylomas just back of the glans on a man of 27, and had existed for eight months. The papillary hypertrophy, sharply circumscribed acanthosis and excessive cornification were all suggestive of a possible relationship between cutaneous horns of this character and the verrucose type of seborrheic keratoses. As Unna[9] has stated, "the preference of cutaneous horns for the seborrheic regions of the skin, the scalp, forehead, the nose, the eyelids, the glans and the scrotum is somewhat remarkable; as is the seborrheic history of many of them," and it may be that in the warty form of seborrheic keratoses we have the *link* connecting certain types of cutaneous horns with seborrheic keratoses in general.

In view of the fact that the sebaceous glands are apparently unaffected in all three of the varieties here described, the appellation "seborrheic keratosis" might appear, on first thought, a misnomer. The objection cannot be sustained, however, if we accept the term

"seborrheic" in the broad sense in which it is generally employed. In Unna's[10] "eczema seborrhoeicum," which is essentially identical with Elliot's[11] "dermatitis seborrhoeicum" and Duhring's[12] "seborrhoea corporis," the sebaceous glands show few, if any, changes, and many pathologists are of the opinion that the fatty character of the lesions is due solely to the material thrown off by the coil glands. Consequently, the disease is possibly more of a "syringodermatitis" than anything else. Unfortunately, dermatology is already suffering from an embarrassment of riches in the matter of nomenclature, and the wisest plan now is to stick to those terms which have met general approval and acceptance, even though we should strain a technical point or two in so doing. I, myself, must agree with Schuchardt[13] that an anomaly of secretion of the sebaceous glands is probably the essential and primary trouble in both seborrheic dermatitis and seborrheic keratosis. Otherwise why should the regions which are richest in these structures seldom escape involvement, while other localities, like the palms and soles, which are fairly a network of coil glands, exhibit the lesions of seborrheic dermatitis only occasionally, and of seborrheic keratoses never at all? Montgomery and Culver[14] have called attention to the effect of the ingestion of large quantities of butter fat on these glands, and it is not improbable that many other substances have a similar deleterious action.

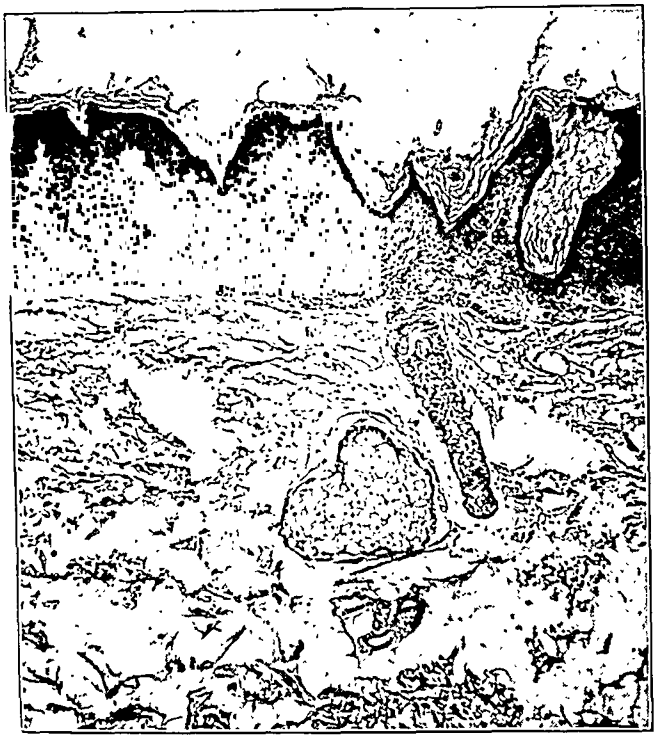

Fig. 10 (Case 28).—Early verrucose lesion, showing slight hyperkeratosis and pronounced papillary hypertrophy (Leitz, No. 3 objective, No. 4 eyepiece, 16 cm. bellows extension).

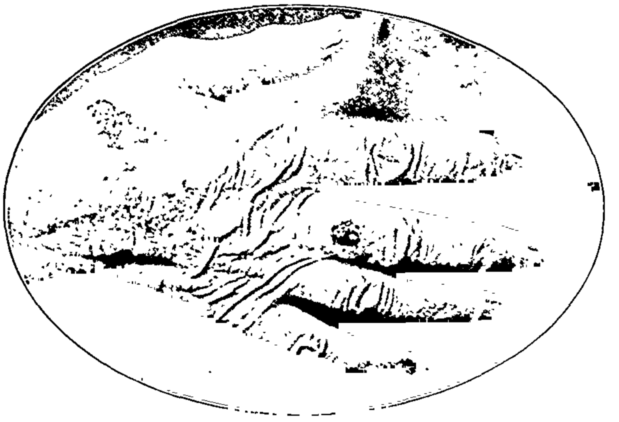

Fig. 11.—A typical example of "sailor's skin" in a woman of 70. The lesions are already showing carcinomatous tendencies.

TREATMENT

The earlier keratoid lesions are readily removed by frequent applications of a bland grease, such as rosewater ointment. Afterward, the occasional employment of a lubricant of this kind will prevent a recurrence, provided care is taken to avoid the use of hard water and highly alkaline soaps. Men whose faces are affected should never shave with a dull razor, and, after shaving, no soap should be allowed to remain on the skin. The nevoid, verrucose and advanced keratoid types are more resistant to treatment, and a salve consisting of salicylic acid (1 part), sulphur (1 part) and petrolatum (30 parts), as recommended by D. W. Montgomery[15] and by Stelwagon,[16] is generally required to remove the outer layers. This ointment may be applied on cloth at night, the patch being covered with a bit of oiled silk, and the whole held in place by a cross of adhesive plaster. As soon as the corneous mass is softened, it may be gently removed with a bit of cotton moistened with benzine. Of all the caustics that have been recommended for use in this condition, none, in my opinion, equals Pusey's carbon dioxid snow. One thorough freezing, with moderate pressure, for a period of from thirty seconds to one minute, is usually all that is required. The lesion is then painted with tincture of iodin, and dithymoldiiodid (thymol iodide, U. S. P.) or a similar antiseptic,

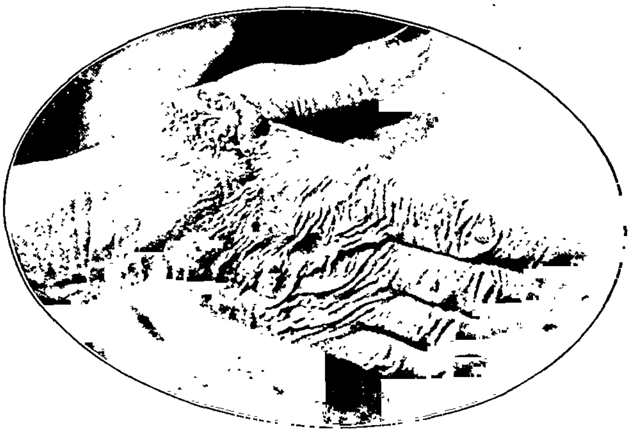

Fig. 12.—Following the use of a salicylic acid and sulphur ointment some of the lesions healed, but the one near the thumb has developed into a typical prickle-cell carcinoma (picture taken four months after first consultation, Fig. 11).

applied. If a bulky dressing is objectionable, a 5 per cent. ammoniated mercurial ointment may be prescribed.

In growths that have already assumed a malignant character, the treatment is that of carcinoma of the skin. On the scalp, forehead, lips, trunk and limbs, radical excision is nearly always to be preferred. On the face, and particularly in the nasal and orbital regions, admirable results can often be obtained by the use of the Roentgen rays or radium.

CONCLUSIONS

Seborrheic keratoses are the most frequent of all forerunners of prickle-cell cancer of the skin. In their production, age and exposure to sunlight and to wind are important factors.

The lesions are of three types, keratoid, nevoid and acanthoid, or verrucose. The keratoid are the most liable to become carcinomatous.

The best plan of treatment is prophylactic. Failing this, the removal of the superficial layers of the growth by means of a keratolytic, followed by thorough freezing of the base with carbon dioxid snow, is the method of choice. Lesions which already exhibit signs of malignancy should be excised. If, for cosmetic reasons, excision is inadvisable, Roentgen therapy or radium may be tried. Under no circumstances should silver nitrate or other superficial caustics be employed.

Every person presenting the symptoms of seborrheic keratosis, particularly if the lesions be of the keratoid type, should be warned of the danger incurred by neglecting treatment. Carcinomaphobia is to be deplored, but wilful negligence is inexcusable.

Lathrop Building.

The Typhoid Epidemic at Barcelona.—An official announcement is quoted in a recent issue of *Siglo Medico* saying that after causing about 4,000 deaths the epidemic of typhoid seems to be dying out, only seven new cases having been reported in the last day or so. This is only 1 per 100,000 inhabitants. It is proposed to have a celebration "to show the gratitude of the populace to chance that has freed the city from this terrible scourge. . . ." The hotels, theaters and stores are deserted and it is hoped that the king will come to the festival and thus break up the economic crisis which is still as serious as at the height of the epidemic." A letter from a leading physician in Tortosa is published in the *Revista Clinica de Madrid,* which laments that the populace in Tortosa is now paying the penalty for the crime of the municipal authorities at Barcelona in allowing typhoid to get such a hold that 50,000 cases were officially recorded, and the only prophylactic measure proposed or employed by the authorities was to advise the people to boil the water!

TRANSPLANTATION OF THE ANTERIOR TEMPORAL ARTERY*

J. SHELTON HORSLEY, M.D.
RICHMOND, VA.

Occasionally defects of the cheek, caused by accidents, or as a result of operation for malignant disease, or from gangrene, are so extensive that plastic correction is exceedingly difficult. The margins of the defect are frequently fixed to the bone and do not permit much stretching. If the flaps are taken from the arm, the character and texture of the skin is so different from the skin of the face that the contrast is very noticeable. Then, too, it is frequently necessary to have an epithelial lining on the inside of the mouth, and though a mucous membrane lining is preferable to one of skin, it is often impossible to secure mucous membrane.

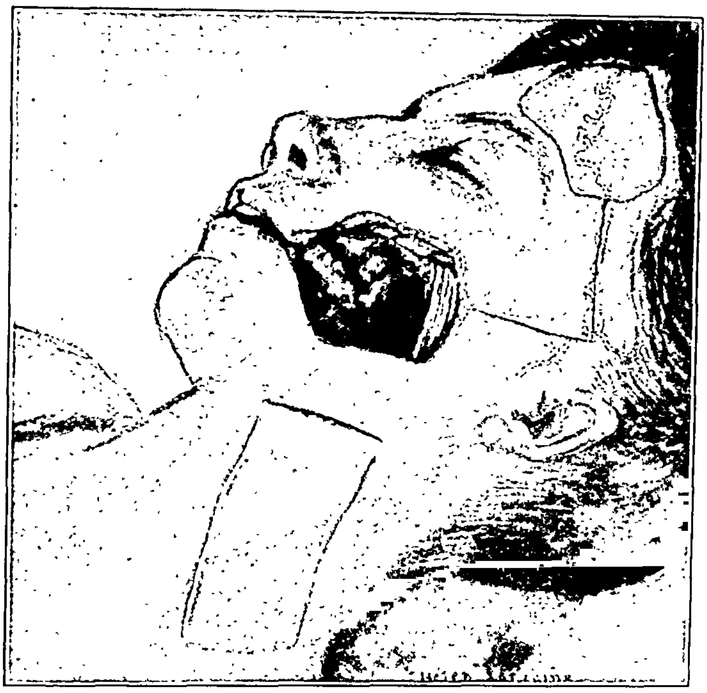

Fig. 1.—First step of transplantation of the anterior temporal artery with a frontal flap. Outlines of the flap on the neck and of the frontal flap, together with the incision for dissecting out the anterior temporal artery, and for burying it in its new location are shown.

Flaps from the forehead are used to remedy these defects, and are taken with the pedicle either from the temporal region or from the middle of the forehead. This, of course, necessitates cutting the pedicle later and returning it to its original position. If the anterior temporal artery is included in the pedicle, the flap is thus deprived of an important blood supply. Frequently flaps that cover defects of the cheek obtain their sole nourishment around the edges, and if a flap has also been turned in to make a lining, there is a still greater demand on the external flap for blood supply. Dunham of New York has met this objection by dissecting the temporal artery from the flap and returning the pedicle minus the artery to its original position. This, of course, is an improvement; but it necessitates two operations, and the dissection of the temporal artery from the transposed and infiltrated pedicle is more difficult than a dissection from the normal tissue at the original operation.

On two occasions I have transplanted the anterior temporal artery, dissecting it free from its origin to the margin of the proposed flap.

The anterior temporal artery presents peculiar advantages for transplantation. It is not essential to the nourishment of the forehead or scalp, which has an abundant anastomosing blood supply. It is tortuous and when dissected free, even with some surrounding tissue, it may be straightened and will reach much farther than before dissection. This permits placing the flap in positions distant from the origin of the artery, and maintenance of an abundant blood supply.

The patient should be prepared for rectal anesthesia according to the method of Gwathmey. The bowels are opened by a dose of oil the night before, followed by soap-suds enemas from two to three hours before the operation. An hour before the operation a suppository of from 5 to 10 grains of chlorbutanol is given. A hypodermic of ¼ grain of morphin and 1/120 grain of atropin is administered half an hour before the operation, and the injection of oil and ether is begun slowly about ten minutes later. The mixture consists of pure olive oil and ether, varying from equal parts in children to three parts of ether and one of oil in patients difficult to anesthetize. In adults, usually two parts of ether to one of olive oil is a satisfactory mixture. The amount injected is 1 ounce of the mixture to every 20 pounds of body weight, but in any case it should not exceed 8 ounces of the 75 per cent. solution of ether in oil. This is given slowly in the room, with the patient turned on his left side, and should take from five to ten minutes. The patient usually goes under the anesthetic gradually. If anesthesia seems profound, especially as indicated by cyanosis and disturbance of the respiration or a bad pulse, some or all of the mixture can be withdrawn through a rectal tube. About five minutes before the operation is concluded all of the mixture is withdrawn, the rectum and sigmoid are irrigated with cold water, and several ounces of pure olive oil are slowly injected and allowed to remain. This anesthesia in my hands has been most satisfactory for surgery of the neck, for plastic work about the face, and particularly for such an operation as transplantation of the anterior temporal artery.

---

* Read at a meeting of the Southern Surgical and Gynecological Association, Dec. 15, 1914, at Asheville, N. C.

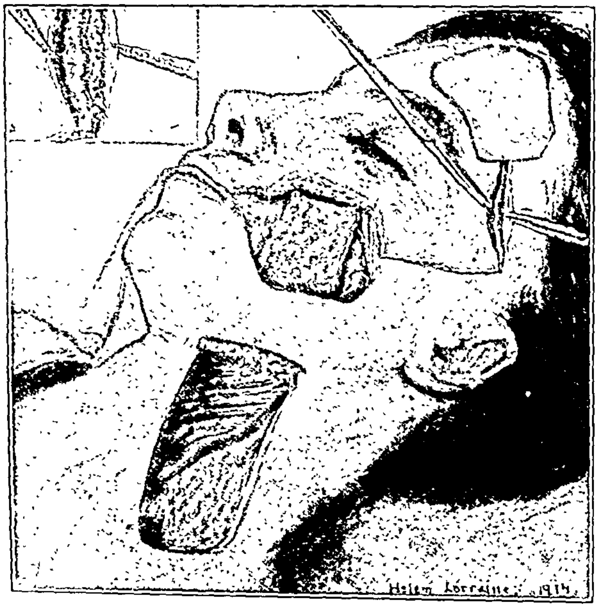

Fig. 2.—The flap in the neck has been dissected free and drawn under the bridge of skin separating its base from the defect in the cheek. The artery has been partially dissected. At *A* is shown a section of the artery with ligation of posterior temporal artery when necessary to secure greater length.

The cheek is prepared for the new flap by trimming away the scar tissue along the margins of the defect and by undermining the skin slightly. The position of the flap to be transplanted is outlined on the forehead with the point of a knife, going as near to the hair line as possible. An incision is made over the region of the anterior temporal artery, extending from its origin to the point at which the artery enters the proposed flap. This incision should be straight, no matter what the course of the artery. Great care is taken not to injure the artery and not to grasp it with forceps. It can be easily handled by picking up the tissue around it with delicate thumb forceps. Considerable tissue is included with the artery in order not only to avoid injury to the artery, but also to preserve its nerve supply. After the artery has been freed, the flap is cut and placed in position. This gives an idea where the artery shall be buried (Figs. 1, 2, 3 and 4). The flap is covered with cloths wrung out of warm salt solution and an incision for burying the artery is made just through the skin. The margins of this incision are undermined freely, but not too deeply. In this way the branches of the facial nerve are not injured. The flap is placed in position and fastened with a few sutures. It should not be sutured too tightly, because the flap has too much nutrition; and unless there is some point where the excess of blood can ooze out for the first day or two, the tension in the flap from the arterial pressure may be so great as to cause partial necrosis. This, in fact, is the chief danger, not too little but too much blood supply. If it is necessary to have an epithelial lining, a flap may be turned up from the neck and sutured with the skin side toward the cavity of the mouth before the anterior temporal artery is transplanted, or mucous membrane from the tongue can be used, as suggested by Willard Bartlett. The illustrations show the manner of doing this.

By the second day the flap is swollen and becomes a dark purple color. If it is too tense, every few hours a sharp knife can be inserted along the edges of the flap to scrape it a little so as to promote bleeding and relieve the tension. After a week the swelling begins to disappear, and new venous capillaries drain away the blood. The efficiency of the artery can be demonstrated months after the operation by pressing on it and noting the change in color of the flap.

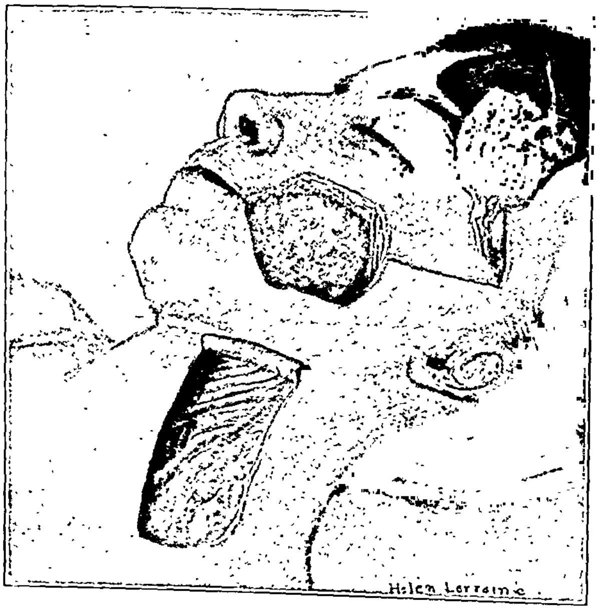

Fig. 3.—The flap from the neck has been sutured in position. The anterior temporal artery and frontal flap have been freed, and are ready to be transplanted.

In two cases in which this operation was done the artery has remained patent and is pulsating several months after the operation. In the first case, all of the flap took. In the second, a middle aged woman in poor health, about two-thirds of the flap sloughed away on account of excessive passive hyperemia.

REPORT OF CASES

Case 1.—Mr. W. H. D., aged 22 years, was injured, Feb. 2, 1914, by a shotgun, while trying to quell a disturbance among the laborers of a mine, of which he was superintendent. The gun was discharged at short range and blew out his left eye, a good portion of the left maxillary bone and the septum of the nose, together with the soft tissues over the cheek. A large cavity was left connected with the nasal fossa. This was closed by transplanting from the forehead a flap with the anterior temporal artery. The technic was as described above. All of the flap took.

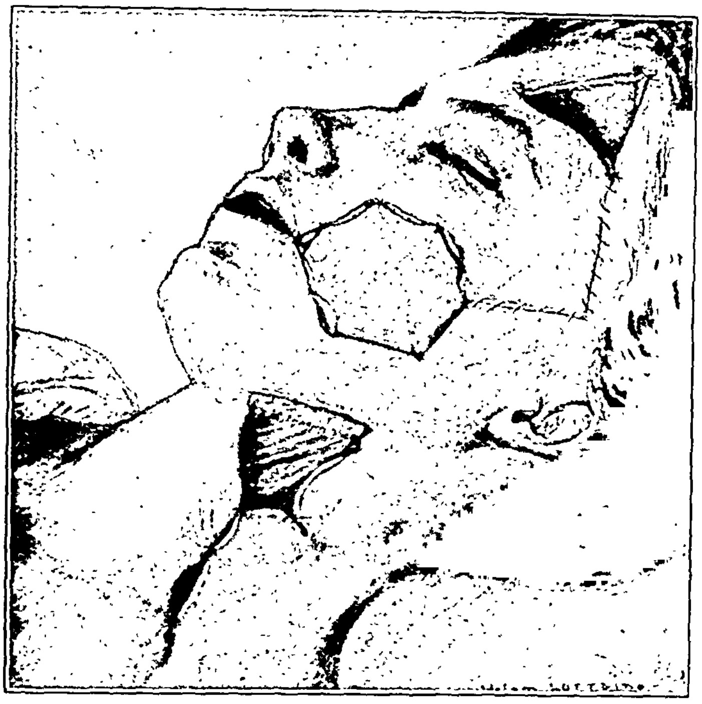

Fig. 4.—The anterior temporal artery with the frontal flap has been transplanted and the flap sutured in position. The raw surface left on the forehead has been diminished by sutures at its angles.

Case 2.—Mrs. S., aged 47 years, was referred to me for a recurrent cancer of the cheek. She had been operated on a few months before by another surgeon, and as recurrence was prompt and the glands of the neck were involved, the prognosis seemed bad. A block dissection was first done on the upper part of the neck, removing glands, fat and fascia in one mass. The cancer in the cheek, which was about an inch and a half in diameter, was then excised with a Paquelin cautery. The defect was, of course, extensive and the deformity great. A flap of skin was turned under as shown in the accompanying illustrations, and sutured to the wound with the skin surface inward. The anterior temporal artery with a flap from the forehead was then transplanted as in the previous case. The flap became purple and tense, but on scraping its edges and letting out some blood, its color would again become normal. The growth of capillaries was poor, and about two-thirds of the flap sloughed off on account of the intense passive hyperemia. To the well-nourished remnant, however, flaps from neighboring tissues were later attached and grew satisfactorily.

Infant Mortality as an Index to Social Welfare.—Sir Arthur Newsholme, the eminent English statistician, says that infant mortality is the most sensitive index we possess of social welfare. And then he adds: "If babies were well born and well cared for, their mortality would be negligible. The infant death-rate measures the intelligence, health and right living of fathers and mothers, the standards of morals and sanitation of communities and governments, the efficiency of physicians, nurses, health officers and educators."—*Bull. Chicago School of Sanitary Instruction.*

THE PYLORUS AFTER GASTRO-ENTEROSTOMY FOR CONGENITAL PYLORIC STENOSIS

A REPORT ON ITS CONDITION TWO HUNDRED AND FIFTY-SIX DAYS FOLLOWING THE OPERATION

DEAN LEWIS, M.D.
AND
CLIFFORD G. GRULEE, M.D.
CHICAGO

There have been but few opportunities of examining the condition of the pylorus at any great length of time after an operation for the relief of the symptoms associated with congenital pyloric stenosis. In many of the cases which terminate fatally, death has occurred as a direct result of the operation or so soon that no regressive changes in the hypertrophied muscle could have been expected. Roentgen findings would seem to indicate that the pylorus never becomes patent, even after successful gastro-enterostomy. If the pylorus is permanently occluded, the indication for surgical treatment becomes imperative, and there should be no attempt at medical treatment. Cautley and Dent state that all patients with true congenital pyloric stenosis die before reaching the age of 4 months unless operated on. Heubner, Starck, Bloch and Bendix have between them reported seventy-one cases treated medically with sixty-six recoveries. To explain the differences in the results of treatment, it has been suggested that there are two types of cases, one a true congenital hypertrophy, the other a spasm of the pylorus, which could be overcome by lavage and diet.

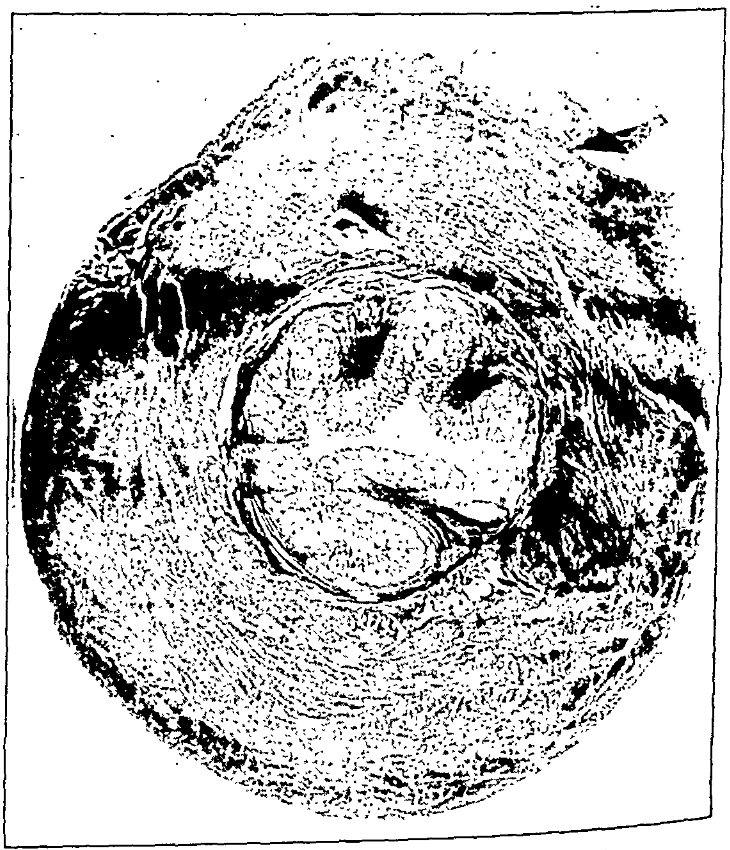

Fig. 1.—Cross-section through the pylorus, showing hypertrophied musculature and connective tissue. Mucous membrane is thrown into folds. It is redundant, and if the pressure of the hypertrophied muscle were removed, the lumen of the pylorus would be reestablished. Pyloric orifice reduced to small slit, through which a small probe may be passed.

This case is reported because it would seem to indicate that the stenosis associated with congenital hypertrophy of the pyloric sphincter persists even after ideal conditions have been provided for rest of the pyloric sphincter by a well-functioning gastro-enterostomy.

L. A., a male baby, aged 2 months, was admitted to the Presbyterian Hospital, Nov. 11, 1913. The child had been breast fed up to a month before admission. Vomiting commenced in the fourth week and has recurred after almost every feeding. The bowels have moved only every second or third day, a glycerin suppository or enema being required. There has been a progressive loss of weight. The baby is small and has a dry, weazened appearance. Nothing especial was found in the general examination. Whenever the child was given water or milk, a distinct enlargement of the epigastrium was noted. Peristaltic waves could be made out, but no distinct tumor at the pylorus could be found. Vomiting occurred soon after the ingestion of food, and was propulsive in character. Examination of the stomach contents removed by a tube revealed a total acidity of 10, free hydrochloric acid 9, combined hydrochloric acid 1. Hemoglobin was 85 per cent., red blood-cells 4,840,000, leukocytes 8,000.

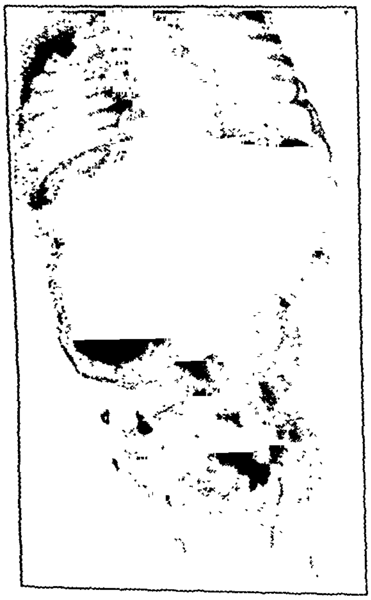

Fig. 2.—Picture taken half an hour after bismuth meal. A small amount of the bismuth has passed into small intestine.

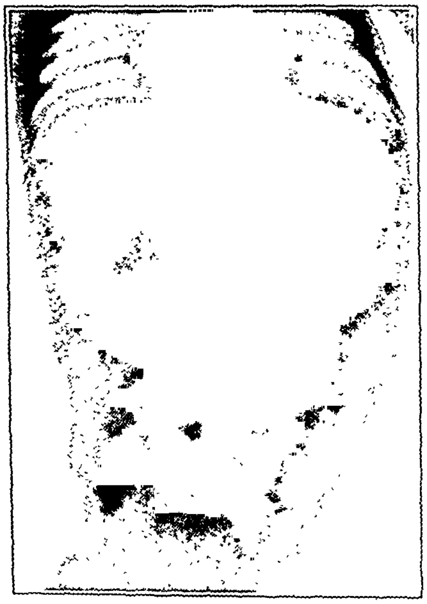

Fig. 3.—Picture taken one and one-half hours after bismuth meal, showing marked retention. Some bismuth has passed into small intestine and the shadows are more marked than in preceding picture.

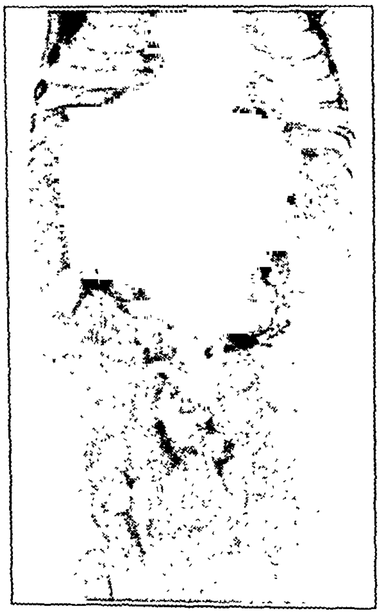

Fig. 4.—Picture taken seven days after operation, showing food passing through gastro-enterostomy orifice.

Urinalysis revealed some nucleo-albumin, but was otherwise negative.

A Roentgen examination of the stomach after a bismuth meal revealed marked retention, although small shadows were seen in some of the intestinal loops.

The findings were typical of congenital pyloric stenosis, and an operation was performed Nov. 14, 1913, three days after the child entered the hospital. Under ether anesthesia a midline incision was made in the epigastrium. When the peritoneum was opened an enormously distended and tense stomach popped out. The pylorus was enlarged — it was the size of the terminal phalanx of the middle finger — and was white, somewhat edematous and hard. It had the characteristic appearance of the enlargement associated with congenital pyloric stenosis. The stomach was so tense that it could not be manipulated easily in performing a posterior gastro-enterostomy, and therefore it was punctured as soon as the transverse mesocolon was cut through. The punctured wound was then closed with a purse-string suture, as it could not be made to come easily in the line of the gastro-enterostomy. The ordinary posterior gastro-enterostomy was performed without any trouble.

Feeding was commenced immediately after the operation, and a progressive gain was noted. The baby weighed 6 pounds and 11 ounces, December 2 — eighteen days after the operation — a gain of 1 pound and 11 ounces. The baby was discharged, December 17, weighing at this time 6 pounds and 12 ounces.

The baby did well after leaving the hospital, but was brought back March 24, 1914. During a few days before admission he had an attack of difficult breathing. Fever, cough and labored breathing had been noted. Vomiting had not occurred at any time. Percussion revealed dulness over the upper lobe of each lung posteriorly. Resonance was more impaired over the right upper lobe. Bronchial breathing and moist and crepitant râles were heard over the area of dulness. A Roentgen examination of the chest over the right upper lobe revealed a shadow, but no pus was found when a needle was inserted.

The baby when admitted to the hospital the second time weighed 9 pounds and 5 ounces. The weight reached 8 pounds and 9 ounces, April 14. Following this there was a rapid gain, and April 24 the baby weighed 9 pounds and 9 ounces. No vomiting was noted, and the gastro-enterostomy opening seemed to be working perfectly, judging from the rapid gain in weight and absence of digestive disturbances. The pneumonia continued from March 24 to April 7, when the temperature became normal. During most of this time the temperature at night reached 104 or 105.8 with a morning remission of 2 degrees. The baby left the hospital April 28, 1914.

The baby was brought to the hospital the third time, July 28, 1914. The symptoms at this time were high fever, cough, difficult breathing, pain in the chest and slight convulsive attacks. Illness began two days before entrance with restlessness, slight cough and rapid breathing. The weight at this time was 10 pounds and 4 ounces. Respirations were labored, rapid and grunting. The breathing was mostly abdominal. Physical examination revealed consolidation of almost the entire right lung and of the left upper lobe. Blood count taken at this time revealed: red blood cells 4,750,000, leukocytes 19,500.

The baby died a few hours after entering the hospital, and at the necropsy the following anatomic diagnosis was made: Lobar pneumonia. Passive hyperemia of posterior portions of the lungs. Left fibrinous pleuritis; hyperplasia of the tracheobronchial lymph-nodes; passive hyperemia of the spleen; moderate edema of the brain; marked diminution of the yellow color in the adrenal cortices; acute diffuse parenchymatous nephritis. Right obliterative pleuritis. Pyloric stenosis; healed gastro-enterostomy.

When the abdomen was opened the stomach was found to be of normal size. At the pylorus an enlargement was found which was of approximately the same size and consistency as that found at the operation. From the duodenal side, the enlargement projected into the lumen of the bowel much as the cervix of the uterus projects into the vagina. When the stomach was opened, the lumen of the pylorus was found to be greatly reduced in size, and surrounded by a rigid wall. A fine probe could be passed through the opening. The gastro-enterostomy orifice was in the pyloric antrum, about 1 inch to the cardiac side of the pylorus. It measured about an inch in length. A linen suture projected into the cavity of the stomach. This had in greater part sloughed through the walls of the stomach, but still remained attached at some points.

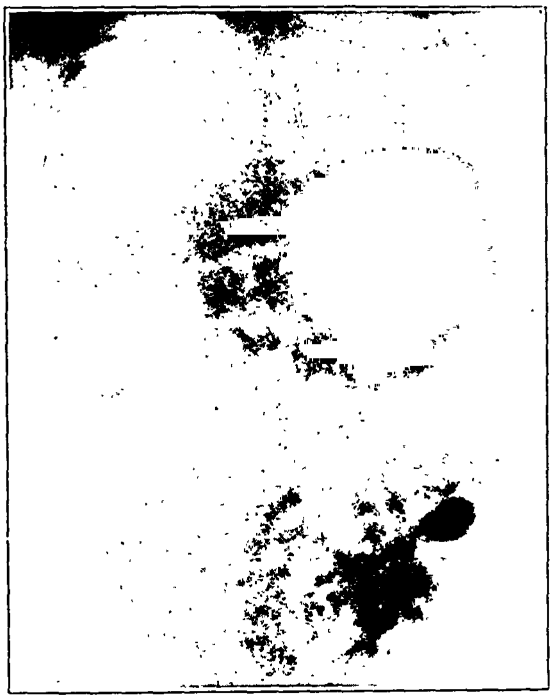

Fig. 5.—Picture taken six months after operation, half an hour after bismuth meal.

Histologic examination of a cross-section of the pylorus revealed enormous hypertrophy of the circular muscular coats. The hypertrophy was not confined to the circular coats alone, for the longitudinal muscles also seemed to have undergone a hypertrophy. The connective tissue bundles were also larger than normal, and seemed to be involved in the process. The mucous membrane was thrown into folds and seemed to be redundant. It was not contracted, and apparently it was merely compressed by the surrounding hypertrophied muscular tissue. If a wedge of muscle were excised and compression removed, the pylorus would undoubtedly become patent. The fact has been taken advantage of in some cases in which the operation which has been performed has merely consisted of excising a piece of the hypertrophied muscle, down to the mucous membrane, to permit of its expansion. In some of the cases in which this procedure has been practiced the pylorus has remained patent and the child has developed normally.

Notwithstanding that a sloughing suture was found in the gastro-enterostomy orifice, food was apparently passing through it freely, for the child had not vomited, except occasionally during the first two days following the operation. There was no induration about the line of suture and no adhesions between the viscera and surrounding structures. Apparently the gastro-enterostomy was functioning perfectly.

A Roentgen examination of the stomach following a bismuth meal five months after the operation was performed indicated that all the food was passing throughh the gastro-enterostomy orifice. This has also been the case in which a study has been made of a large series of postoperative cases observed by Scudder, Richter and others.

This case, with others which have come to necropsy some months after operation, such as those reported by Morse, Murphy and Wohlbach and Walton, show that a congenital pyloric stenosis associated with a hypertrophy of the musculature and connective tissue about the pylorus is permanent, and is not relieved after a gastro-enterostomy which functions perfectly.

The case reported by Morse, Murphy and Wohlbach came to necropsy six and one-half months after operation, and the one observed by Walton seven months after. In both instances the condition of the pylorus was the same as at operation, and in Walton's case the pylorus was water tight.

As the stenosis is permanent and not relieved when the pylorus is put in a condition of at least partial rest by a gastro-enterostomy, it would seem that attempts to relieve this stenosis by gastric lavage and medical treatment were futile. The diagnosis once established, the indication for treatment, which is surgical, is established. The high mortality associated with the early cases was due to the poor condition of the children when operated on. Posterior no-loop gastro-enterostomy is the most satisfactory operation; although excision of a wedge of the hypertrophied muscle down to the mucous coat, permitting of expansion of the mucous membrane, seems to give good immediate and late results.

Gastro-enterostomy is well stood by infants, if performed rapidly and without much trauma. We have had five cases with no deaths. In all cases the children have developed normally.

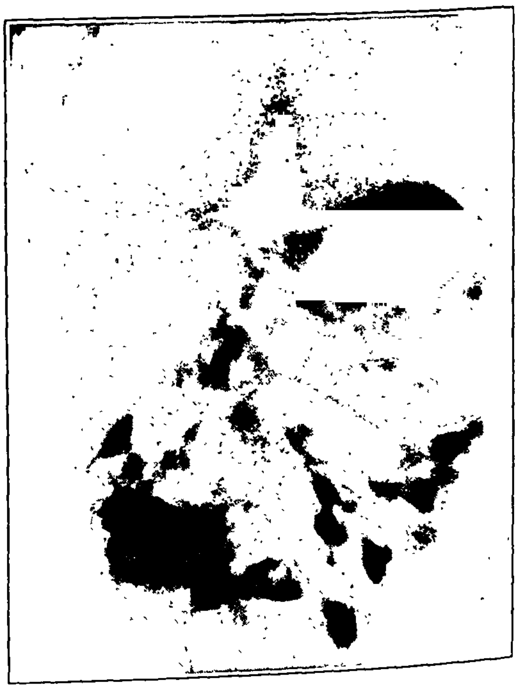

Fig. 6.—Picture taken six months after operation, two hours after bismuth meal, showing amount of food passing into small intestine through gastro-enterostomy orifice.

THE SERUM TREATMENT OF HYPERTHYROIDISM

S. P. BEEBE, Ph.D., M.D.
Professor of Experimental Therapeutics, Cornell University Medical College
NEW YORK

The physiologic and chemical studies of recent years have established the probability that the function of the thyroid gland is to prepare an active substance or hormone which is essential to the health of the organism. This substance probably is protein in character and contains iodin in chemical combination. This active substance probably forms a large portion of the colloid stored in the aveoli of the gland, and its physiologic activity is proportioned roughly to the iodin content. Under physiologic conditions only a sufficient amount of this hormone finds entrance to the circulation to meet the normal needs of the tissues, and recent work in this laboratory indicates that the control of this absorption is, at least in part, a function of the nervous system. When the gland for various reasons, which will not be discussed, becomes overactive, its secreting cells multiply, its circulation increases, the store of reserve material is drawn on in excess and we have a train of symptoms known as hyperthyroidism.

If there is one fact established regarding the disease it is that the thyroid plays the predominant rôle in the production of symptoms. The circulating blood probably contains an excess of the peculiar active protein supplied by the gland, and the tissues react to it. To no small degree the disease may be regarded as a toxemia, and the source of the toxin is to be found in the excess of thyroid secretion excreted into the blood from the overactive gland. The pathologic studies of recent years have indicated that in cases which come to necropsy other glandular structures show lesions, but we have little information to enable us to determine to what degree these may be the cause or an effect of the thyroid disturbance. The pathology of the thyroid is so constant, the clinical symptoms are so closely similar to the physiologic effects produced by overdosing with thyroid secretion, and the therapeutic measures which have secured the most relief all point so strongly to the thyroid origin of the symptoms of the disease that it has been accepted as the basis for the serum treatment. It is not the purpose of this paper to enter into a prolonged discussion as to the nature of the disease; therefore no elaborate attempt will be made to defend the principle just announced. Certain well-authenticated observations point almost incontrovertibly to such a conclusion. These observations may be summarized as follows:

1. The gland is enlarged. It has a much increased blood supply and histologically shows marked evidence of an increase in the total amount of secreting epithelium.

2. The symptoms of the disease, such as loss in weight, increased heart action, weakness, increased oxygen absorption, etc., can be imitated by giving to normal persons large amounts of thyroid preparations.

3. Removal of the gland or a diminution of its blood supply by surgical means relieves the condition, while many observations show that these patients are in most cases more than usually sensitive to thyroid administration.

The gland, therefore, is overactive. The function of the gland is not subserved within itself. The secretion prepared in the gland must reach distant organs and tissues. If the gland is overactive and an additional amount of the active secretion, which is chemically an iodized protein, reaches through the medium of the blood supply the tissues which it stimulates to unusual activity, we have the complex of symptoms which we recognize as exophthalmic goiter. The blood in exophthalmic goiter, therefore, must contain an unusually large quantity of the active secretion prepared in the thyroid gland. When this secretion is present in the blood within normal limits, the physiologic activity alone is served. When, on the other hand, excessive quantities are present, pathologic conditions are produced.

The purpose of the serum treatment is to prepare in an alien species of animals a serum having special antagonistic properties to the human thyroid secretion. The injection of this serum into a patient having exophthalmic goiter provides him with a ready-made antagonist to a complex toxic substance circulating in his blood.

The first preparation of the serum was a direct result of some experiments which I made in 1905. The purpose of these experiments was to determine whether it was possible to prepare an antiserum from the nucleoproteins of an organ which would have a more specific action than a serum made by inoculating an emulsion of the whole organ. (The literature in regard to the specificity of cytotoxic serum is summarized in the forthcoming fifth volume of Forchheimer's therapeutics by Dr. Richard Weil[1], so that only the arguments of particular interest will be given here.)

In 1905 I reported the results of a series of experiments with immune serums developed by injections of nucleoproteins. These experiments gave evidence of specific cytotoxic action, more definite than any which had been published previously. At the Toronto meeting of the British Medical Association, I read a second short paper dealing with the subject. Since these results have been made the basis of a therapeutic method, and since the validity of the observations has been called in question in the minds of many by the experiments of Pearce, I wish to review the situation and present reasons for adhering to the belief expressed in my first paper on this subject, namely, "Such a thing as absolute specificity under all conditions has never been demonstrated and probably never will be, but it is possible to make a serum which will act primarily on a given organ."

Since the publication of the papers referred to above, many experiments with nucleoprotein serums have been made in this laboratory and have confirmed the position originally taken. The method of preparing the nucleoprotein has been practically the same as that outlined in my first paper, with the exception that blood-free organs have been used, and the prepared proteins have been preserved for injection by freezing rather than by chlorofrom or by drying.

If attempts are made to duplicate these results, I suggest that the method I have outlined for preparation of the proteins be followed. Pearce followed what he conceived to be an improvement, namely, the boiling of the hashed organ in alkaline salt solution previous to its filtration. This procedure undoubtedly hastened the filtration time, but it destroyed the biologic character of the protein. It is known that many specific enzymes cling to nucleoproteins in their solution and precipitation; these would be destroyed by boiling. An excellent instance of the destruction of the specific character of a nucleoprotein by boiling may be seen in the case of the nucleoprotein of the parathyroid gland, which, when freshly prepared, is effective in relieving the symptoms of parathyroid tetany, but which is absolutely useless for this purpose if it has been boiled. Since the publication of Pearce's paper, I have made experiments in which the prepared nucleoprotein was divided into two portions for inoculation, one portion boiled and the other unboiled. The unboiled protein was effective, but I have never been able to get an active serum with the boiled protein. With the exception of the means of preserving the protein, the same methods have been employed in the production of the serum as were outlined in the previous papers. I quote from one of the former papers certain observations regarding the difficulties to be encountered.

---

[1] Forcheimer: A System of Therapeutics, v. D. Appleton & Co., New York.

To get the best results the protein should be freshly prepared before each inoculation. Considerable difficulty was encountered in the failure of a large percentage of the animals to produce a highly active serum, even though they had the best of care and were inoculated with satisfactory proteins. For instance, out of a lot of five rabbits inoculated with liver nucleoproteins, only one produced a highly active serum; of four sheep inoculated with thyroid proteins, only one produced an active serum. My experience in this matter has led me to the conclusion that it is more difficult to form antibodies to nucleoproteins than to globulins or albumins.

EVIDENCES OF SPECIFICITY

The evidence on which I draw the conclusions of specificity is based on precipitation, agglutination, absorption experiments and on the effects of animal injections.

The Precipitin Reactions.—These are specific except in high concentration, and here the relative speed and completeness of the reaction shows a decided preference of the serum to unite with its specific antigen.

In Tables 1, 2 and 3 are shown the reactions of different serums made against human nucleoproteins as antigen.

The Agglutination Reaction.—This reaction closely resembles the agglutination reaction which is used so much in bacterial immunity work. The emulsion of fine organ particles is prepared as follows:

The tissue is ground in a fine hashing machine and the pulverized mass suspended in normal saline. This suspension is centrifugated in a high speed machine with the result that the finer particles come down at the top of the sediment. These are removed by a pipet, suspended in salt solution and the suspension filtered through cotton; such an emulsion will be found to be serviceable for the flocking or agglutination reactions. The reaction is highly specific.

* At twenty-four hours the kidney showed a mild positive agglutination, but the others were no greater than controls.

Agglutination reactions of this sort have been obtained by a variety of serums, and with active serums the specific character is marked, as is shown in Table 5. The reaction is more readily carried out than the precipitin reaction, for the success of the latter depends on the use of perfectly fresh nucleoproteins and also on a neutral reaction. If the reaction is too alkaline, as is likely to be the case unless especial care is exercised, no precipitin reaction will be obtained, even with highly active serum.

Absorption Experiments.—In addition to the foregoing reactions, absorption experiments have been tried as follows:

The serum was mixed with finely hashed muscle tissue from the same animal species as the antigen from which the serum was developed; that is, serum developed by the injection of dog kidney nucleoprotein, was absorbed by finely chopped dog muscle. The mixture was allowed to remain in the incubator for fifteen minutes and was then transferred to the refrigerator for three hours. At the end of this time the extract was centrifugated and filtered, and the clear serum thus obtained was used in the same kind of precipitin and agglutination experiments as outlined above, with the result that both reactions still occurred, though they were somewhat weaker than before, but they had a more specific character. The common factors had been absorbed, but the specific ones remained. Such absorbed serum is not hemolytic, but retains its power of acting on the specific antigen.

Animal Inoculation.—The most searching and conclusive method of demonstrating the specificity of the serum, however, is by means of animal inoculation. In my first paper was published evidence to show that serum developed from the selected antigen had a markedly special action on its appropriate organs. The nephrotoxin caused acute nephritis, while the hepatotoxin caused focal necroses and general granular and fatty degeneration of the liver. These lesions were acute, and caused the death of the animal.

In attempting to repeat these animal experiments with an inactive serum which he had prepared by a faulty method, Pearce drew the conclusion that "such serums have mildly toxic properties acting in a general way and affecting especially the principal excretory organ, the kidney." He admits, however, that it is difficult so to explain the severe albuminuria which I described.

I call attention again to the fact that, on the intravenous injection of the serum, an immediate reaction occurs which is much more marked than occurs with the same quantity of normal serum. This general reaction is evidently an expression of the general toxic character of the serum. It passes in a few hours, however, and the next day the animal is normal. The specific effects which prove serious are not manifest for several days, even though the serum has been given in one injection, and although the lesion may go on to a fatal termination.

Another point of interest is to be found in the fact that not all animals react alike to active serum. A serum which causes an acute fatal nephritis in one animal may cause in the same dose a milder lesion in another animal. Two dogs were given the same dose of an active hepatotoxin; one died in eight days, while the second, although severely ill, recovered after a period of two weeks.

The results which have been cited above appear to me to warrant the use of the term "special" or "specific" in their description. It is admitted that the work requires special attention to the technic, but I believe that other investigators can duplicate the results cited.

THE SERUM

The thyroid lends itself to the production of such a serum for the reason that in this gland there is stored in the alveoli a large amount of a protein peculiar to the organ, and with a peculiar chemical structure as evidenced by its remarkable selective affinity for iodin. This protein is, therefore, sharply differentiated from proteins to be found in other organs and should serve as a suitable antigen for the production of a specific serum. The review of the literature on this subject given in the chapter by Dr. Weil shows that special cell products produce antiserum having a higher degree of specificity than can be obtained by other animal antigens. Experiments showed that such a serum had highly specific properties as evidenced by its precipitin and agglutinin reactions. A serum which would agglutinate completely an emulsion of thyroid in five seconds would produce a doubtful reaction in a kidney or liver emulsion at the end of an hour. Because of the biologic specificity of protein it is necessary to use human glands in the preparation of serum for therapeutic use.

The method of preparing the serum is as follows:

Human thyroid glands are carefully trimmed free from all connective tissue, and thoroughly comminuted by a special machine. The comminuted mass is suspended in from three to four times its volume of physiologic salt solution made alkaline by the addition of 5 drops of a 10 per cent. solution of sodium hydroxid to each hundred cubic centimeters of the saline. After shaking on a machine for three hours the extraction is continued in the refrigerator for twenty-four hours additional. The extract is strained through gauze to remove the coarser particles and then filtered through paper. To the filtrate a few drops of 10 per cent. acetic acid is added and the whole heated on a water bath to 44 C. (111.2 F.). Under these conditions an abundant precipitate is formed which is thoroughly washed by decantation with acid physiologic salt solution. The washed protein is filtered out and dissolved in alkaline physiologic saline solution. The protein content is estimated and the solution diluted to 1 per cent. strength. This solution of human thyroid protein serves as the antigen.

Intraperitoneal injections of this solution are given to sheep at weekly intervals with gradually increasing dose until from 125 to 150 c.c. of the solution are given at each injection. After six injections the animals are bled, the serum allowed to separate and prepared for injection by testing its agglutination reaction, and filtration through a Berkefeld filter. The serum is sealed in ampules containing 1 c.c. to preserve it for injection.

GENERAL PRECAUTIONS

Certain precautions must be followed in administering the serum if its beneficial effects are to be fully realized. Preeminent among these are the matters of dosage and frequency of injection. It is true with this serum as with all others used for passive immunization that the magnitude of the dose best suited to afford relief varies with the clinical condition. With some mild cases of diphtheria, 2,000 units at a single injection may be sufficient, while with the others from 10,000 to 15,000 units in successive injections may be necessary. As a rule the first injections of the thyroid antiserum are borne well without local or systemic reaction of any moment. One occasionally encounters a case, however, which is unusually sensitive, and the first injection if not carefully proportioned may cause a very marked reaction at the site of injection, evidenced by a brawny swelling which may extend below the elbow, heat, redness and pain. Some general reaction accompanied by fever, nausea and general malaise is also shown. These cases are unusual, and nearly always are found to occur in neurotic persons only mildly affected by the disease. In the severe toxic forms of the disease I have at times given three injections of 1 c.c. each during the first twenty-four hours of the treatment. However, it is best as a rule to begin with a small dose, not more than ⅓ c.c., and observe its reaction before increasing the dose. A suitable method to follow in beginning the treatment is outlined below. The best site for the injection is a point midway between the elbow and shoulder on the outer aspect of the arm. The injection should be made into the subcutaneous areolar tissue. For the first injection give 5 minims (⅓ c.c.). Immediately after the injection is made apply hot compresses at the site and continue them for one hour. Following this treatment apply a wet dressing of 50 per cent. alcohol. There may be no local reaction, whatever; in the majority of cases there is a localized area of tumefaction, the skin is slightly reddened, hot and sensitive. This reaction develops in from three to seven hours to its full height and then subsides to a normal condition within a few hours. If the local reaction is negative or very mild, a second injection may be made the following day in the other arm, giving a dose of from 7 to 8 minims. The site of injection should be treated as before. The local conditions being favorable, the third injection may be made on the third day of the treatment in the first arm injected, giving a dose of from 10 to 12 minims. With a favorable local reaction the following doses should be of a full tube of the serum every second day, using alternate arms for the site of injection. In the very unusual cases the first reaction is severe and does not subside promptly. In such a case one should wait until the primary reaction has entirely subsided and then begin again with a smaller dose, from 2 to 3 minims of the serum. It is not wise to repeat the injections until the previous reaction is nearly if not entirely subsided. If this precaution is not observed, the reactions become progressively more severe, and not only is there a very troublesome reaction at the point of injection, but the previous reaction areas light up again and both arms become much swollen and intensely inflamed. A somewhat similar reaction has been observed by Gay to follow repeated injections of diphtheria antitoxin.

In some instances the smaller doses of serum are well taken and no disturbing reaction occurs until four or five injections of a full tube have been given. Then each injection causes an increasing reaction, and if continued at the same interval as before, a condition of great discomfort to the patient follows. The arm may show a brawny, painful inflammation extending from the shoulder to the wrist. It may have much of the appearance of erysipelas, and often the physician who first sees the reaction fears a severe infection. Wet dressings of ice water, the lotion of lead and opium, or 50 per cent. alcohol afford the most relief. The same rule is to be followed in such cases. Allow the local reaction to entirely subside and then begin by small doses. *It should be recognized, however, that in the majority of cases no disturbing reaction occurs; there is some local infiltration and a little heat which subside within a few hours.*

The question of a possible danger from anaphylaxis may be considered. In the beginning of the serum treatment, before the nature of and danger from anaphylaxis were appreciated, and when much larger doses of the serum were given without any relation to the time element, we had a few reactions which were undoubtedly anaphylactic in character. About ten to fifteen minutes following the injection there occurred a sensation of suffocation, the skin of the whole body itched intensely and became reddened, and particularly about the face, became edematous. The reaction was very distressing to the patient but passed in a comparatively short time. If the directions given above are followed, no danger from such a cause will arise. I have seen a few reactions of the type of local anaphylaxis described by Arthus. These never occur until a few previous injections have been given. Instead of a diffuse swelling and infiltration there is a small area of intense reaction immediately at the point of injection, and this reaction has all the characteristics of a small abscess. These rarely occur and the physician is inclined to conclude that his technic has been faulty or that the serum has been infected. In a few instances it has been advisable to open the abscess, while some of them have pointed and opened spontaneously. The contents have been sterile in every case that I have seen. There is in my opinion every reason to class these reactions with those described by Arthus, who noted that repeated injections of antigen in a partially immunized animal would occasionally produce an abscess.

It rarely happens that the needle punctures a small vein and the whole dose of the serum enters the circulation at once. If this patient has had a number of previous injections and if as much as a full tube has entered the vein there may be an immediate reaction of the following character: The patient has an intense pain in the back and experiences a sense of suffocation, the skin becomes flushed and itches intensely, and the patient is nauseated and may vomit; syncope may follow. Such a reaction, if it occurs, follows directly after the serum is injected. The patient should lie down at once, the clothing about the neck loosened, iced towels applied to head and if desired aromatic spirits of ammonia inhaled. It is quite unnecessary to do anything more, for before a hypodermic injection can be prepared the reaction has largely passed. Th whole disturbance quickly subsides and the patien aside from being somewhat frightened, is quite al right. Such a reaction is very unusual. I myself hav had only two in the last three years, and I have given thousands of injections during this time. If th physician has never seen such a reaction and does no know that it may occur, he, as well as the patient is likely to be frightened, a situation which cause much useless distress to all concerned.

The reactions which follow the injection of thi serum are no serious bar to its use, provided the conditions outlined above are carefully followed. The reactions which have been described are not the usua results. They have been described at such length in order that the physician may know all the complications and be prepared to steer a safe course. It needs no lengthy description to picture the situation where no reaction takes place. Small doses should be given at first with careful observation of the effects and a gradual increase to the full dose. If repeated injections are given without permitting a sufficient interval between times for reactions to clear up, the arms will get into a very bad condition, the patient will have a continuously high temperature and be very uncomfortable. Moreover, the desired therapeutic effect will not be obtained.

So much has been said about the severe reactions that the impression may have been made that these are the rule. Such is not the case. The majority of patients show a very mild, or no reaction. They need no particular care in this respect, but unless the physician knows what may follow the injection, he is in no position to advise the patient.

The final word may be said about the reaction. Some patients cannot at any time take more than half a tube, 8 minims, and they do not need more to get excellent results. It is not a matter of variation of the activity of the serum but is purely a question of the individual's sensitiveness. The same serum given to one patient in doses of 1 c.c. causes no reaction of any moment, while to another it may be entirely too large to be borne with comfort. Experiments are under way at the present time to find a suitable method of eliminating these local reactions and permitting a slow absorption.

It must be understood that the serum treatment is only a part of the medical treatment, and all those medical measures which have been proved of value should be instituted. It may seem trite to voice such a precaution, but my experience has shown me that many physicians regard the serum as a short cut to cure without the necessity of employing medical common sense. It is expected that a nervous, weak, sleepless, nauseated patient with a rapid, dilated, decompensated heart will make a prompt recovery after a few injections of serum and yet be allowed to conduct himself in the meanwhile as he pleases. No sane physician fails to treat a diphtheria patient as a sick person because the antitoxin has been administered. Patients with hyperthyroidism must be regarded as sick persons although they may not have such a degree of physical weakness as compels them to remain in bed. The patient, unless only mildly affected, must in the beginning of treatment have as complete rest as can be obtained. This rest means freedom from mental, emotional and physical exertion. Careful inquiry will often elicit some particular factor of work or worry which has been instrumental in causing the disease or keeping it active, and this must as far as possible be corrected. If the patient is seriously affected, complete rest in bed is necessary, and sympathetic, talkative friends rigidly excluded. The same rule often applies to members of the family from whose petty disputes and vexatious interferences the patient at times stands sorely in need of protection. Exophthalmic goiter patients are highly sensitive and often react with an explosion to trivial annoyances.

No feature of medical treatment which has proved of value need be omitted merely because serum is to be given. The time has passed in this treatment when all other means of medical alleviation may be withheld for the purpose of demonstrating the effectiveness of the serum in controlling the disease. There are a considerable number of patients who do not respond to other medical treatment, but no measure which makes for the welfare of the patient should be neglected.

ACTION OF THE SERUM

Before considering the treatment of the different types of hyperthyroid patients I wish to state briefly my ideas as to how the serum acts. It has been generally referred to as a specific cytotoxic or cytolytic serum for the reason that it is developed by the same method as the serum which had produced lytic effects in the normal organs. In my opinion the disease may be looked on as a toxemia. The tissues of the body are oversupplied with thyroid secretion, which acts as a toxic substance. Many substances are known which in small doses act as physiologic stimulants but which in larger doses are distinctly toxic. To correct hyperthyroidism we need to counteract the toxic effect of this secretion and reduce the activity of the gland to physiologic proportions without destroying it. The serum in the dose used for therapeutic purposes is not actively cytotoxic. In the experiments which served as the basis for the production of this serum, 15 c.c. of a cytolytic serum made against the kidney were administered to a dog weighing 12 kg. at one intravenous injection. Under such a dosage active cytolytic effects were observed. No comparable dose of thyroid antiserum has ever been given to a human patient. The dose of 1 c.c. to a patient weighing 50 kg. is less than one-fiftieth the amount given to the dog. Furthermore, it must be remembered that the antigen from which the serum is developed is very largely made up of the colloid of the gland, a cell product and not from the proteins of active cells. From a theoretical point of view, therefore, it is not unreasonable to suppose that the serum is largely antitoxic and not cytolytic. I believe that clinical evidence is convincing that it acts as an antitoxin and protects the general tissues of the body.

Rabbit Experiments.—Some years ago I made a series of experiments to test this point, the results of which have never been published. A number of rabbit thyroid glands were collected and the protein prepared from them as has been already described in the preparation of the human antiserum. With this antigen a small dog was immunized. Six rabbits from the same litter were then divided into two lots, one of which served as a control. Both lots of rabbits were treated by injecting them subcutaneously each day with protein from rabbit's thyroid glands. The doses were gradually increased until each rabbit received each day the protein from five pairs of normal rabbit thyroid glands. One lot of three rabbits was treated with the serum from the dog immunized with rabbit thyroid and the other lot with normal dog serum. The rabbits treated with the immune serum did not show the effects of the treatment to anything like the same degree as those given the normal serum. The latter animals lost weight and had constantly a temperature from 1 to 2 degrees higher than the protected animals.

In some of the very acute, toxic human cases the relief from the toxemia obtained by serum injection is so prompt and complete that one is strongly led to the conclusion that the action is that of an antitoxin. The conditions are such that I have not been able to obtain human glands which at one time were diseased and the cause of symptoms, and later have been restored to normal function by serum. Most persons who have been relieved of the trouble show a keen interest in keeping their glands. This twofold activity serves to explain the results which will be mentioned later. Probably if given in very large doses a distinct cytolytic effect might be shown. The purpose of the treatment, however, is to relieve the toxemia and not to cause an immediate destruction of the gland. The restoration of the gland to normal size and function is a process which often requires months to complete, and is accomplished by a mildly acting inhibition rather than by sledge-hammer blows.

APPLICATION OF THE SERUM TREATMENT TO DIFFERENT TYPES OF THE DISEASE

The primary step in treatment is the diagnosis. With the increasing interest in the subject during recent years the diagnosis is more often made, and the early development of the disease is not infrequently observed. But one of the greatest impediments to better treatment is the fact that patients so frequently wait until the condition is far advanced before seeking medical aid. And they are not entirely to be blamed for this. In the early stages the patient often appears to suffer from excessive good health. They are animated with many interests and activities; they may have no ache or pain, the appetite is excellent, often extraordinary, they sleep well, and except for breathlessness on exertion appear to themselves to be quite well. The physician does not usually have an opportunity to treat them at this stage and such a result is in part due to the fact that the diagnosis is frequently not made when it should be. As an example of this point my own experience of the last year will serve. Only a very small proportion of my patients apply for general medical treatment, and yet in one year I have found twelve whose real difficulty was hyperthyroidism, which was promptly relieved by proper treatment. All had had medical advice from a number of physicians who had not discovered the difficulty. If in a comparatively small number twelve proved to have been wrongly diagnosed, I am sure that men who have a large general practice frequently fail to appreciate the nature of the disease. So much depends on the presence of exophthalmos that it is unfortunate that it has been described as one of the cardinal symptoms of the disease. No one factor in the medical treatment of the condition will be of more help in the treatment than an early diagnosis.

For the purposes of this article the different types of the disease will be classified under six heads:

1. The early mild cases in young women from 12 to 20 years of age.
2. The early typical cases in patients over 20 and under 40.
3. The well-advanced typical cases.
4. The acute toxic inoperable cases.
5. The severe advanced cases of long standing.
6. The atypical cases.

Group 1.—Young women in school and college, shop girls and debutantes not infrequently react to overwork and undue excitement by showing an enlargement of the thyroid gland which often develops quite rapidly to a point where it attracts attention. As a rule they do not show much if any exophthalmos but they are physically weak, the heart rate is above one hundred and very sensitive to physical exertion, tremor is well marked, and the skin is flushed and sensitive. They show all the evidences of a mild hyperthyroidism. (It is not my purpose here to enter into a complete description but merely to outline the condition so that it may be recognized.)

These patients may not need serum at any time. It is my practice not to give serum to them until they have been under treatment for two or three weeks. They must be put at rest, school, college and social activities stopped, and complete relaxation obtained. Attention must be given to the general medical conditions regarding sleep, diet, stomach and bowel conditions. It has been my experience that the syrup of ferrous iodid in 15 or 20 drop doses in ½ glass of water after meals is one of the best tonics that can be given to such patients. In some cases I give also the neutral hydrobromid of quinin in 3 or 5 grain doses twice a day. They will need to be under restraint for from six to ten weeks and should not resume full activity for from four to six months. Most of them show early improvement and they may not need anything further to effect a complete recovery. If the conditions do not begin to improve promptly or if it is delayed, the progress may be hastened by the use of serum. In these cases the beginning doses should not be larger than 5 minims and the injections need not be made oftener than three days. The dose is gradually increased, allowing the reaction to subside entirely before repetition of the dose. The length of treatment required varies with the case, but the limit given above covers the majority. After the condition is well controlled the injections should not be stopped abruptly, but the interval should gradually be increased until finally they may be made every ten or twelve days.

Group 2. —In this group the same symptoms may be shown and the condition may arise from the same causes, but there are many cases found here that have had a so-called simple goiter for years without symptoms, that under the pressure outlined above, with the additional factor of pregnancy, have become troublesome. It is probable that many of these patients have shown exacerbations of a milder form before but have not sought medical help. These patients are not, as a rule, so quick to recover as those in Group 1. The same general plan of treatment is to be followed. It is advisable to begin serum treatment at once with most of these patients and it will need to be given for a longer time than in Group 1, and the additional duties and distractions incident to their age make them somewhat harder to control.

Groupe 3.—The patients included in this group have had the disease in a well-marked form for a long enough time to have permitted its characteristic effects to be well marked. No uniform length of time is required to produce these changes. They may occur in cases of only a few months' standing or it may require several years. Recovery need not be expected in this group for several months and the patients should be frankly told that they cannot expect immediate recovery and that their habits of life for at least one year will need careful regulation. It is useless to put such patients to bed for two or three weeks, give them serum and tonic treatment during this time and then expect them to resume normal life and all its activities again. I have often had remarkable improvement during such a period, but unless the condition is considered a serious one by both the physician and patient, much disappointment is bound to result. The serum injections will need to be continued at two to three day intervals for four or five months, bearing in mind what has been said heretofore about the reaction. When the patient has gained weight and strength, is sleeping well, and has a pulse rate of from 90 to 100, the interval may be increased, but this increase must be gradual with the patient under careful observation and a return to the former interval if there is a failure to control the symptoms. Serum must be continued often for a year before it is safe to stop altogether. I have at present under my care three cases that belong in this group in which the patients have made an excellent recovery after fifteen months' treatment. Another patient with a history of the disease for three years has made a recovery after five months' treatment; but such a favorable outcome is not the rule. Again I wish to emphasize the necessity of using medical common sense in dealing with these patients. If the physician confines his services to the injection of serum it is certain that failure will be a common event.

It is hardly a feasible matter to discuss serum treatment as means of treatment by itself for the reason that one rarely uses serum as the only therapeutic measure. In the patients in this group certain general statements may be made respecting the use of other medicines. After the symptoms have been well controlled, it is often a decided advantage to give the patient a tonic. Neutral quinin hydrobromid is often helpful at this time. Iron, arsenic and strychnin are at times necessary. The administration of iodin in small doses may be of great value. After the toxemia of the disease has subsided iodin may be given in small doses. Not more than ½ grain of potassium iodid three times a day should be given as a beginning, but its administration should be continued over a long period of time. If the dose is increased it should not be a sudden increase to a large dosage. Even after the symptoms are well controlled the administration of iodin in doses which would not ordinarily cause any disturbance may be followed by a sharp exacerbation of the disease. It is quite erroneous to suppose, however, that iodin can never be given to a hyperthyroid patient with any benefit. Large doses should never be given, and even with small doses the patient should be under close observation until his sensitiveness to it has been determined. The use of thyroid extract with patients in this group is a matter which requires considerable experience before proper cases can be selected. If given during the early stages of the treatment it is quite likely to cause a marked exacerbation of the symptoms. Every year I see a number of patients who have been severely injured by the free administration of thyroid extract given to reduce the size of the goiter. Not infrequently a patient appears with severe symptoms of hyperthyroidism after a period of thyroid treatment to reduce weight. The commercial sale of thyroid for this purpose should be prohibited.

Group 4.—The patients in this group are severely affected by the disease. A considerable percentage of them die from the toxemia, and it requires the most exacting care to bring such a patient through to complete recovery. The development of the disease may be rapid from the start, but in the majority it will be found that a mild condition of hyperthyroidism has been present for some time, and for various reasons has developed into an acute toxic condition of grave prognosis within a few weeks. The disease in this form presents roughly two types; the *asthenic* type resembling to some degree the profound physical prostration of Addison's disease, and the *sthenic* type in which there is not such profound prostration and evident toxemia, but tremendous stimulation of the nervous system with symptoms that resemble in some degree those of chorea major. To present the characteristics of these two groups it seems best to describe a patient in each class.

CASE 1.—*Asthenic Type.*—The patient was a woman aged 27, married for three years. She had always been a thin, wiry woman weighing from 110 to 120 pounds, very quick in her movements and unusually keen mentally. There was a history of rather rapid gains and losses in weight within the limits mentioned above. She had had measles, whooping-cough and mumps as a child, but as an adult had never been sick with the exception of an occasional sore throat. Examination of her throat revealed the right tonsil somewhat enlarged with the left one absent except for a few tabs of lymphoid tissue. Four years before the present illness she had had a peritonsillar abscess on the left side. The throat had been full since her first menstruation, which occurred at the twelfth year. Goiter had not been observed until attention was called to it during her present illness. She had passed through a normal pregnancy and had given birth to a healthy child eight months previously. For a few weeks before her present attack she had noted that she tired more quickly than usual, was out of breath climbing stairs and at times had palpitation. Her sleep had not been good for a few weeks and she had frequently had severe headaches. She had always been constipated. For two weeks before her present illness began she noted that her bowels moved from one to three times a day without a cathartic. Present attack followed a week of unusual social activity. She returned from a function at which she had danced many times feeling very tired, and had gone at once to bed and to sleep. At 6 a. m. she awoke with a very uncomfortable feeling about her heart, she had a severe headache, was nauseated and vomited twice. From this point she grew steadily worse until I saw her two weeks later at which time her condition was that described below. There was no exophthalmos but the lids remained half closed. Both lobes and isthmus of the gland were moderately enlarged, hard and somewhat nodular.

The blood-pressure varied from 100 to 120. Pulse at the wrist was small, thin and rapid. Abdominal aorta, however, had a marked pulsation; the heart did not have the heaving impulse often seen in this condition, the apex beat was diffuse and best felt about 4 inches from midsternal line. The pulse-rate varied from 150 to 180. At the slower rate a distinct systolic murmur could be heard over the apex. There was a prominent pulsation in the veins of the neck, and a marked thrill over the gland. The skin was at times dry and at others moist on soles of feet and palms of hands. The patient was restless but moved with difficulty. Physically she was extremely weak and could scarcely articulate in answer to questions.

She had no appetite, and the tongue was dry and heavily furred except at the borders of the tip which were red with the papillae raised. She could retain practically no food, complained of nausea, abdominal tenderness and was altogether a very sick patient. The temperature by rectum varied between 99.5 and 101.5.

Mentally she was extremely depressed, at times almost like a melancholia, and could not properly orient herself with respect to time or her surroundings. She often had great difficulty in choosing the proper word to express herself and would then break down in a fit of weeping. Sleep was induced with the greatest difficulty. She did not respond well to the usual hypnotics and had been almost entirely sleepless for three days and nights at the time I first saw her.

Treatment.—It is in cases of this kind that serum treatment has shown its most striking results. The patient was evidently overwhelmed by the toxemia. A preliminary injection of 8 minims of serum was made at once. Six hours later a full tube, 16 minims, was given into the other arm. That night the patient slept quietly without hypnotics for a period of ten hours. There was only a very slight reaction at the point of the second injection and none at the first. Injections of a full tube of the serum were given twice on the second day of the treatment, and thereafter a full tube every day for a period of ten days. At this time a marked reaction developed at the point of injection so that an interval of four days elapsed before more serum was given. From that time the treatment was continued in practically the same manner as has been described for the previous group. The effects of the injections were at once apparent. The toxemia was controlled from the beginning; the patient began to eat on the fifth day with fairly normal appetite and digestion although it was necessary to use a mild cathartic for two months. After nine months' treatment the patient made a complete recovery. At the time treatment was begun the patient had emaciated to a skeleton. During the period of treatment she gained 58 pounds.

The case has been described in detail for the reason that there are few clinical descriptions of this type of the disease in the literature, and because it is an example of a toxic case in which full doses of the serum were needed to control the toxemia. It cannot be concluded, however, that every such patient will need treatment in the same manner. In another patient of the same character even more of the serum was given during the first few days of treatment. It has been my observation that such patients will often take these comparatively large doses of serum without any disturbing reaction in the beginning of the treatment. But it is not safe to conclude that they will not so react, or that even if they do not react in the beginning that they may not later.

CASE 2.—*Sthenic Type.*—A married woman aged 24, the mother of two children, aged 6 and 3 years, had always been a thin woman of a nervous temperament while her two sisters were of larger frame and weighed from 60 to 70 pounds more than the patient. Aside from the infections of childhood she had never had any serious illness, and had always considered herself well, although a picture taken two years before showed a marked exophthalmos and evident goiter. During the previous summer she had lost weight, and noticed that although she had a voracious appetite and consumed large quantities of food, she did not gain weight, and became breathless on slight exertion. She had become very talkative and irritable in the last month, although her appetite continued good. During the last two weeks she had slept but little and did not respond to hypnotics. She had never had headaches, but during the last month had from eight to twelve bowel movements daily and for a week preceding treatment had been nauseated. A physician was called two days before I first saw her at which time she had first taken to bed because of a severe attack of paroxysmal tachycardia, accompanied by nausea and vomiting.

At the time of my first visit the patient was very thin but had not reached the degree of emaciation frequently seen in this disease. She was exceedingly restless, constantly rolling from side to side and moving her legs and arms almost continuously. At times her arms and hands were thrown violently about in aimless movements. The skin was flushed and sweating profusely; dermographia was shown by an intense reaction. She had a marked exophthalmos. The gland was much enlarged, smooth and elastic, the right lobe being larger than the left. She had a temperature of 101 by mouth. The pulse was rapid, varying from 160 to 200 and irregular, at times uncountable, soft and of low tension. The cardiac impulse was diffuse, feeble during the rapid systoles, heaving and forcible during the slow beats. A loud systolic murmur was heard over the apex and body of the heart. The abdominal aorta showed a violent pulsation. The blood-pressure was 110 mm. Mentally the patient was on the verge of mania, her thought directed to a great variety of subjects within a minute, at times laughing inordinately at nothing and shortly thereafter having a fit of weeping.

The tongue was dry and red, the papillae swollen and the throat dry, although the patient consumed large amounts of liquid.

The slightest excitement caused a great reaction in her pulse and mental condition. She had heard the question of operation mentioned the previous day and had not recovered from the shock it gave her.

Treatment.—A full tube of the serum was given, immediately followed by 1/8 grain of morphin and 1/200 grain of atropin by hypodermic injection. She quieted in a half hour and that night slept for six hours quietly. The temperature the following morning was 99 by mouth. The following three days she received a full tube of serum each day. The last injection caused a small local reaction so that a day's interval was allowed to elapse before the following injection. Because of the local reaction, serum from this time could be given only at forty-eight-hour intervals. The patient had only the one dose of morphin and no hypnotic during the remainder of the treatment. The temperature remained normal after the third day, the excessive restlessness gradually quieted, the nausea was relieved and three weeks after treatment began all evidence of the previous severe attack had disappeared. The patient was now a thin woman, with a pulse of from 110 to 120, an excellent appetite, sleep normal, the exophthalmos had diminished, and the mental condition was normal. The patient continued to make an uneventful recovery, the treatment being continued for a period of eight months; but in the latter part of that time injections were given at ten-day intervals.

It is in these very severe types of the disease that the antitoxic properties of the serum are best shown. The relief obtained in such patients is often quite as striking as that obtained in diphtheria from the administration of the antitoxin. After the severe toxemia is relieved it is generally necessary to continue the treatment for some time to produce final satisfactory results. In a few instances I have had patients in this group of acute development recover with the same promptness that they might from an acute infection of the same severity.

Group 5.—In this group are placed the patients who have had the disease in a chronic form for many years. They may have been damaged beyond the possibility of complete repair, and the whole organism is in a condition of disorganization. In some instances the digestive apparatus has suffered the most, in others the heart is most seriously injured. There is a tendency as the disease progresses to become less typical in its manifestations and to express itself more markedly in disturbances of some particular function. The patients must be studied individually with great care to be sure that they are still in a condition of hyperthyroidism. Patients in this group are not as favorable subjects for any form of treatment as those previously described. Treatment must be continued for a longer time and with greater watchfulness for complications. Serious mental breakdowns, diabetes and nephritis are occasionally found, intercurrent infections not infrequently prove most disastrous and the task of the physician is hard and tedious. Some patients in this class I have treated for two years with serum with an ultimately satisfactory result. Others have not been benefited so much and have likewise failed of improvement after operation. As a rule, however, serum will produce good effects if the gland is still in a condition of marked overactivity. If three months' serum treatment produces no decided benefit it is in most cases not worth while to continue. The benefit is in most cases subjective in the beginning; the patient feels better although no decided change may be seen in the pulse rate or the nervous phenomena. Gradually the nervous condition improves, the patient gains weight on the same diet, and gains strength and self control as the hyperthyroidism diminishes. It is not necessary to give additional specific directions for the use of the serum in this group.

Group 6.—*The Atypical Cases.*—The atypical cases are the most unsatisfactory to treat of all forms of thyroid disease. Patients in this group often show the most bizarrre combinations of hyperthyroidism and hypothyroidism, and have many indications that other ductless glands, pituitary and pancreas may be involved. Serum treatment has a very limited application in this group. If the hyperthyroid symptoms are decided, serum may be tried, and occasionally a brilliant result will follow. As yet we have no satisfactory laboratory method for determining the presence of an oversupply of thyroid secretion in the blood. Therefore, a careful analysis of the symptoms and all attendant features of the condition must be made. Extracts from other ductless glands such as thyroid, pituitary, adrenal and pancreas, are in suitable types indicated. This group of cases can be presented only by citing in detail a considerable number of case histories with the method of treatment followed; and such a procedure is beyond the province of this paper for the reason that serum treatment plays such a minor rôle.

SOME CONSIDERATIONS CONCERNING SERUM VERSUS SURGICAL TREATMENT

The surgeons prefer early cases and urge the physician not to wait until the disease is so far advanced that secondary changes of a serious nature have resulted before recommending the patient for operation. Undoubtedly the best results from operation are to be obtained by operation in the early stages of this disorder, but the same holds true precisely of the proper medical treatment including serum treatment. If operation is to be performed in the early stage of all hyperthyroid cases, much needless surgery will result.

The surgeon employs the means with which he is most familiar to effect a cure; he is accustomed to a quick solution of the problem, and as a rule is unwilling to guide the invalid patient through a somewhat prolonged course of treatment. My experience in the treatment of this condition has led me to the conclusion that much needless operating for its relief is now the practice. Disregarding the dangers attendant on the operation, it is my belief that from the physiologic point of view it is better practice to enable the patient to recover and keep the gland than to remove it to effect the same end. And in saying this I do not disregard the large factor of safety in the gland, or the argument that only diseased, useless tissue is removed. When the whole gland is involved in the pathologic process, as it frequently is, it must be assumed that the portion remaining after operation is restored thereby to approximately a normal condition. It is possible in a large percentage of cases to restore the whole gland to equally good conditions by serum treatment and leave the patient with the factor of safety provided by nature. A large proportion of hyperthyroid patients are under 35 years of age, and the physiologic function of the gland decreases somewhat with age; besides, there is a well-recognized progress in the overactive gland toward a condition of hypo-activity. The question may be considered, therefore, whether the patient who has been operated on may not suffer at a later period of life from too little thyroid function. The operation has not been in vogue long enough to answer this question accurately, and the statistics of any one surgeon are likely to be incomplete because of an inability to trace the patient. It may be argued, of course, that the immediate condition demands relief regardless of any hypothetic difficulty in the future. But is it not wise to give the patient relief by a means which insures as far as possible safety in the future from lack of thyroid function? And it must recognized that relief from hypoactivity is not to be completely obtained by the simple administration of thyroid extract.

It is not my purpose in making these statements to visit a sweeping condemnation on the operative treatment. No one with any experience in the disease can question its place as a valuable therapeutic procedure, and I am quite willing to grant it the first place; but it is my opinion that operation should not be undertaken as a first resort without a careful consideration of all the factors. It has too often been decided merely on the consideration as to whether it is a surgical possibility to operate without losing the patient. Unless the indications are very clear, the patient should have the benefit of medical treatment, and in my practice this generally includes serum treatment before operation is undertaken.

The surgeon argues for an early opportunity to operate and not seldom speaks of the medical deaths which might have been avoided. The physician, on the other hand, often has his patients returned after operation without benefit. The surgeon may refuse to operate when conditions are unfavorable, but the physician cannot refuse his services merely because the patient is desperately ill. So that in considering the statistical results from the two methods of treatment some consideration must be given to the fact that surgical cases are to a considerable degree selected. Not infrequently the patient refuses operation or seeks medical aid at a time when operation is not to be considered. The physician cannot take the point of view occasionally voiced by the surgeon that other treatment than surgery is useless.

SERUM TREATMENT AS A PREPARATION FOR SURGICAL OPERATION

Many physicians and most surgeons feel that the surgical removal of a portion of the gland is the only safe method of treating this disease. These men are inclined to feel that the patient is not safe from a relapse unless the overactive gland is largely removed. There is no question that operation is a necessity with some cases and advisable in those patients who are unable or unwilling to be treated medically. In some cases surgery is determined on from the beginning and it is desired to put the patient in the best possible condition for operation. The administration of serum for this purpose accomplishes such an end effectively in most cases. It must be remembered that not all cases respond equally well, and the mode of treatment is not different than would be followed if no operation was to be done. The relief of the nervousness, quieting of the heart and the gain in strength prepare the patient most excellently for the ordeal of operation. Some care will at times be necessary not to carry the period of preparation too far, or it may result in such complete relief that operation will be refused. The danger of severe hyperthyroidism following the operation is lessened, and the period of convalescence hastened if the active symptoms have been controlled by serum. These statements are not hypothetic but are based on the experience obtained from operation in many cases. Not infrequently the serum has been used to control the symptoms of acute hyperthyroidism following operation. The surgeon has not expected the explosion to occur, but it would seem better practice to prepare the patient in advance by giving a supply of thyroid antitoxin than to control the toxemia after it has once begun.

SERUM TREATMENT AFTER OPERATION

It is by no means rare to see cases that have not been much improved by the ligation and excision operations commonly employed. The portion of gland remaining may or may not have grown, but the symptoms are nearly if not quite as troublesome as before. In some instances there has been a short period of partial relief immediately following the operation with a gradual relapse later. Further operation is not feasible and the patient seeks relief in medical treatment. These patients often respond quickly and it at times appears that the removal of a portion of the gland shortens the period of treatment necessary to control the remainder. There is a limit to the amount of serum which it is feasible to give to any patient at one time, and there appears to be a relation between the amount of serum given and the toxemia which it is to control. When there is only one-fourth of the gland remaining, the antitoxic and inhibitive action of the serum is quantitatively more effective than when it is required to combat the whole gland. I have not infrequently seen serious relapses in such patients completely controlled in six weeks. On the other hand, patients who have been operated on are often in desperate conditions on account of complications of the heart, kidney and digestive tract. Such patients need to go to the hospital for a general overhauling in addition to serum administration. And it may be discovered that serum treatment is not indicated. In maintaining a brief for the medical treatment I do not wish to have it appear that surgery has no place in treatment, but I wish to emphasize most emphatically the fact that many patients who have been operated on are by no means cured and that they often require prolonged and careful medical treatment to restore them to health.

RESULTS OF SERUM TREATMENT

The serum has been used in the treatment of more than 3,000 patients having hyperthyroidism of different degrees. From the classification given earlier it will be seen that these patients cover the very severe cases as well as the mild, early cases. The precise result which will be obtained with any given patient cannot be precisely foretold. Such a situation confronts the physician, however, in every field of therapeutics. Experience with the serum and with the disease is an important factor in the treatment. Physicians are occasionally unwilling to take the time to learn the necessary precautions and nearly always come to grief. I recently saw a patient whose physician had ignored the careful directions given him and persisted in giving a full tube of the serum every day for a week in beginning the treatment in spite of the fact that each injection caused a reaction of increasing severity, and no time was allowed for these to subside before repeating the dose. Such carelessness is most culpable. The patient was in a very uncomfortable condition with a continuous temperature of from 101.5 to 102, sleepless, nauseated and with a general cutaneous erythema. Each point of injection was represented by large, red, indurated, intensely painful areas. Two of these pointed and discharged a quantity of thin, sanious fluid containing numerous mononuclear cells, but cultures gave negative results. It required two weeks of careful attention before the patient recovered from the effects of this malpractice. This instance is cited because I wish to emphasize the fact that the results of treatment depend in large part on the care and intelligence with which it is directed.

The results of the treatment may be classified as follows:

Fifty per cent. of the patients have been cured in the sense that they are strong and able to meet all the demands made on them. They are of normal weight, have a normal heart, have no tremor, are not nervous, have no gastro-intestinal disturbance and perform all their accustomed tasks without undue fatigue. In some instances the goiter, although much reduced in size is still enlarged, and in others exophthalmos persists to noticeable degree. Some years ago one of the best-known surgeons who operate for this disease stated that in his experience no patient who had the disease in a well-marked form ever made a complete recovery by any treatment. And he defined complete recovery by stating that he meant that no symptoms of the disease should be evident. This conservative statement may be contrasted with that of other men who claim from 85 to 90 per cent. complete recoveries. I am able to state, however, that a large portion of the 50 per cent. included in the list of cured as first defined show no evidences of the disease, and are normal persons. They pass rigid physical examinations and would never be suspected of having had the disease at any time. None of the cardinal or secondary symptoms can be discovered.

Thirty per cent. of the patients treated show a very marked improvement, to such a degree that they meet all the usual demands of life without undue reaction. Under unusual physical or emotional strain they react more than normal persons do. The two symptoms which are most evident with them are a gland larger than normal, and in many cases a mild exophthalmos. Some of this group ultimately improve to a point permitting them to be called well.

The remaining 20 per cent. includes those who have not been so markedly benefited, those who have been operated on, those who have not been benefited and those in whom the disease has proved fatal. The percentage of fatal cases in patients who have had serum treatment for a period of six months is very small.

ENDAMEBIC PYORRHEA AND ITS COMPLICATIONS

A PRELIMINARY NOTE *

J. S. EVANS, M.D.
AND
WILLIAM S. MIDDLETON, M.D.
MADISON, WIS.

The study of the relation of pyorrhea and oral foci of infection to systemic disorders of a probable toxic origin received a marked stimulus from the recent discovery of the causative relation of endamebae by Smith and Barrett,[1] 1914. In their study, the presence of the *Endamoeba gengivalis* Gros,[2] 1849, was constant in forty-six cases of pyorrhea. The independent works of Chiavero[3] and Bass and Johns[4] corroborate the constancy of this finding in gingival infections.

Prior to this investigation, the extensive clinical and experimental research in the subject of oral sepsis had shed considerable light on its relation as a distant focus for systemic toxemias. Hunter[5] had long advanced the theory of an oral septic origin for numerous systemic disturbances, more notably, pernicious anemia. More recently, Billings, Rosenow and others had emphasized the importance of oral sepsis as a factor in remote general conditions. The efficacy of autogenous bacterial vaccines had been tested, and the variability of results both locally and generally had opened the question of a possible complexity of causative factors.

The application of the specific drug for the treatment of amebic dysentery, ipecacuanha or its active principle, emetin (alkaloid), to the treatment of an analogous condition in the mouth, was the next rapid step in our knowledge of pyorrhea. Two modes of procedure have been followed. The first, that of Smith and Barrett, was the local injection or application to the affected gums of a weak emetin hydrochlorid solution. At first a 1 per cent. solution of the hydrochlorid proved irritant in some cases, so that a strength of 0.5 per cent. has since been administered. The customary routine has been daily injections of a small portion, often only a fraction of a drop of this solution, into each pocket. Smith and Barrett,[6] in their preliminary report, noted the marked improvement to complete cure of thirteen cases of Rigg's disease so treated. Since that time many cases of correspondingly good results have been added to their list. Several ingenious devices have been evolved to meet the demands in certain cases referred by us to dentists. The use of air pressure to separate the gum from the tooth has been of assistance in some instances (Dr. S. H. Chase). The use of blunt-pointed needles (Dr. Kent Wood) and the replacement of the hypodermic needle by a dental file (Dr. E. J. Hart), the hanging drop of emetin solution adapting itself by capillarity to the smallest pockets where no needle could be introduced, have both been valuable refinements. The application of a heavy petrolatum to the gum margin after each treatment appears of value. Barrett, in a more recent article,[7] has carefully covered the ground of the surgical dental care, which must supplement any specific treatment.

[5] Hunter: Brit. Med. Jour., Nov. 19, 1904.

The more recent announcement of Bass and Johns of their discovery of endamebae in eighty-five out of eighty-seven cases of Riggs' disease, and of its rapid subsidence after the subcutaneous administration of emetin hydrochlorid, constitutes the proof of the efficiency of a second method of treatment or of administration of the specific drug. Smith, Middleton, and Barrett,[8] in a recent study of tonsillar endamebae and their relation to systemic disturbances, noted in several cases the disappearance of endamebae from the cryptic contents on the subcutaneous administration of emetin hydrochlorid.

The present study constitutes a brief preliminary report of a series of cases under observation in the University of Wisconsin Medical Clinic. In all, seventy-two oral cases have been examined by the usual method, heated stage, warm slide and cover slip, the material scraped from the depth of the pocket being immediately mixed with warm normal saline and mounted. Seventy cases showed endamebae ranging in size from 8 to 32 microns in diameter, filled with granular material but no contractile vacuoles; the pseudopodia varied widely in size, length and activity; the ectoplasm was decidedly hyaline, and only after an interval was there an outpouring of the granular endoplasm into the newly formed hyalin pseudopod. These amebae fall under the heading of *Endamoeba gengivalis* Gros. The type *Endamoeba kartulisi* Döflein, 1901, was associated with the *Endamoeba gengivalis* in two cases. According to the literature, the differentiation of these two types is to a great degree based on the difference in the size and activity of the pseudopods, those of the *kartulisi* being much broader and more active. Of these two points there could be no doubt in the cases noted; but an added differential point was observed, namely, the refractive quality of the substance of the pseudopods of the *kartulisi* was much more marked than that of the common forms. Indeed, the difference was almost that of hyaline and waxy renal urinary casts. An unclassified ameba was noted in two cases of pernicious anemia along with the type gengivalis. This ameba possessed a definite endoplasm and ectoplasm, was from 10 to 30 microns in diameter, its pseudopodia were rapidly thrown out, frequently subdividing, but never was there noted an outflow of the very highly refractile granular endoplasm into the pseudopodia. The two negative cases showed considerable gum retraction with dentine erosion.

A point to which our observation has led us to attach considerable importance is that of the mechanical interference by metallic filling and crown or plate attachments with the normal adaptation between the crusta petrosa or cement and the gum or pericementum (ligamentum circulare dentis of Kölliker). Invariably such cases have shown pyorrhea in these localities. Whether this is a constant finding and whether the presence of an irritating foreign body determines the condition, we cannot judge at this time.

Of the seventy pyorrhea cases with amebae present, fifty-four were treated by the local injection of 0.5 per cent. emetin hydrochlorid solution. The results were practically uniform in the marked improvement of the pyorrhea. The period of treatment varied from four to twelve days, with an average of about seven. In a few instances the patients complained of "tender" gums, but the great majority remarked early in the course of their treatment on the new experience of an ability to brush their teeth without the pain or the bleeding noted prior to the treatment.

After an interval of from several days to a week following the last treatment, which corresponds to an apparent local cure, a reexamination for amebae was made. Even though the second examination was negative, as a precautionary measure, a subcutaneous course of emetin was instituted. Two plans of dosage were followed: a series of small doses, daily ⅛ grain doses of the hydrochlorid for eight days, or a shorter series of larger doses, ½ grain repeated with a day intervening followed by ¼ grain on two successive days. The reason for this supplementary treatment has been to insure the death of any endamebae penetrating the deeper tissues of the gums, and therefore possibly unscathed by the local injections. Another rational procedure would be periodic subcutaneous injections, say at monthly intervals over several months, to prevent the multiplication of encysted amebae which resist the biochemical amebicidal action of ipecac.

Only five cases have been treated with subcutaneous injections alone. The results in these have been entirely satisfactory, but with ambulatory cases we have not felt justified in using the rather large doses suggested by Bass and Johns. To us, this very fact constitutes a real drawback to the use of the remedy subcutaneously alone.

The constitutional manifestations associated with endamebic interstitial gingivitis are the disturbances attributable to a toxemia of any other origin. Fifty-two, or 74 per cent. of the seventy pyorrhea cases showing endamebae, displayed constitutional symptoms or disturbances of more or less marked degree. We have endeavored to group the constitutional derangements in these cases attributable to a toxic factor under several heads: (*a*) arthritic, (*b*) neuritic, (*c*) digestive, (*d*) hemic, and (*e*) miscellaneous.

Under these headings twenty-six individuals, 50 per cent. of the persons exhibiting constitutional symptoms, or 27 per cent. of the total endamebic pyorrhea cases, showed arthritic symptoms of varying degrees, most frequently, however, of the type denoted as arthritis deformans. Six persons, 11 per cent. of the total constitutionally affected, consulted us for neuritic involvement, and a similar percentage showed hemic changes. Two patients suffered from obscure digestive disturbances. The remaining thirteen individuals fall into a miscellaneous group, whose components cover a wide range. Certain of these will be discussed individually. In such a broad general classification we have been forced to pick out the most prominent symptom of a toxic complex, and we have therefore sacrificed the complete picture for the purpose of presenting its most evident detail.

[8] Smith, A. J.; Middleton, W. S., and Barrett, M. T.: The Tonsils as a Habitat of Oral Endamebas, The Journal A. M. A., Nov. 14, 1914, p. 1746.

The application of a specific drug for the relief of a supposedly specific infection is an acknowledged therapeutic principle. The further application of this principle to the relief of remote conditions complicating the original specific lesion is justified. However, in this instance we are not compelled to assume an amebic character for the remote disturbance arising from the primary gingival focus. The mere relief of a focus of toxic absorption frequently explains the subsequent alleviation of a toxic derangement.

Seventeen of our twenty-six arthritic patients have received local treatment with marked improvement or the absolute relief of the interstitial gingivitis in all cases. Of these patients, ten have experienced decided improvement subjectively in their joint symptoms; three have had but slight relief from their arthritic pain, and the remaining four have shown no definite change. Two arthritic patients not treated locally, together with thirteen from the foregoing group undergoing local treatment (nine of these were improved and four unimproved under the local care), have been treated by the subcutaneous administration of emetin hydrochlorid. Of the four patients unimproved by local treatment of the gingival condition, none has shown maintained improvement even under the combined treatment. Two of these to the roentgenogram show well-marked osteo-arthritis. A third is undoubtedly a case of traumatic bursitis, in which the arthritis is a secondary factor, and the fourth is a very extreme long-standing case of arthritis deformans. In all, nineteen cases of arthritis have received the various forms of treatment with no apparent improvement in four cases, with indifferent results in three, but with decided unmistakable improvement in twelve cases, 63 per cent. of those treated, two of these being treated by the subcutaneous method alone.

The group of neuritis cases has been disappointing because of our inability to follow the subsequent course of five of the six persons referred to dentists for local care. The only patient returning for the supplementary subcutaneous treatment has shown no change in the neuritic condition.

Of the two cases with digestive derangement as the prominent symptom complex, both were improved by local treatment, further improvement being noted in one following the administration of emetin hydrochlorid subcutaneously. In both cases malnutrition was the most important factor, though neuroses usually attributable to general toxic disturbances were manifest. We believe that the improvement in these cases was due partly to the removal of a toxic focus, thereby correcting a metabolic disturbance, and partly to the betterment of the local condition in the mouth, which was followed by improved mastication and increased appetite.

The six cases with hemic disturbances included two cases of pernicious anemia, and four simple secondary anemias of rather moderate grade. We have been unfortunate in our inability to follow the pernicious anemias. One of them was started on emetin subcutaneously, but a return of a previously existing gastro-intestinal disturbance made its continuance inadvisable. A gain of up to 500,000 in the total red corpuscle count was noted in several of the secondary anemias on the removal of the gingival toxic focus by the emetin treatment. Similar changes in the blood picture of several cases grouped elsewhere have been noted after the subsidence of the pyorrhea.

We freely admit a question of doubt as to the etiologic relation in the group of miscellaneous conditions associated with pyorrhea. However, the relief of certain remote symptoms and conditions, which undoubtedly had a toxic focus as a basis, under the emetin treatment has led us to include the whole number. For instance, a case of obstinate uncontrollable headaches, whose source could not be discovered, responded quickly on the relief of a pyorrhea. A still more obscure case of marked splenic enlargement or tumor without a blood picture characteristic of any pathologic lesion was observed for two months without a diagnosis and without any change in size. There was, however, a most extreme pyorrhea. The local improvement in this condition under the local use of emetin hydrochlorid was attended by a reduction of the splenic tumor of 1½ inches in both the longitudinal and transverse diameters; a total reduction of over 2 inches in both diameters has followed the combined local and subcutaneous administration of the same drug. Other associated conditions noted in this miscellaneous group include accessory nasal sinusitis, endocarditis, continued unexplained leukocytosis, and the toxic cases falling under a broad, general heading of lowered nutrition and lowered general vitality. Among this type of cases only continued treatment and observation can possibly note a change of condition. Additional cases of the nature of visceral parenchymatous degenerations, as occur in the myocardium, liver and kidneys in any toxemia, will possibly be noted in the pursuance of this study.

The question of local reaction on the subcutaneous injection of emetin hydrochlorid in our cases has been most interesting. For instance, a case of arthritis whose pyorrhea has been cleared up by local treatment will show no reaction at the points of subcutaneous injection of two successive half-grain doses of emetin. On the third or fourth dose of only ¼ grain, a most marked local reaction in the form of a wide, indurated areola of inflammation about the point of injection occurs. This local reaction may be attended by a temporary exacerbation of the general symptoms, usually followed by a marked improvement. We have been led to think of this reaction as an index of a point of saturation, when, with the death of numerous amebae the strength of emetin in the blood having reached a lethal point, a great amount of bacterial and possibly amebic toxin is liberated. Of course, this explanation is tentative, and subsequent observations may rule it out, but the alleviation of the general symptoms succeeding such an occurrence strongly supports this view.

As to the manner of the production of the toxic reaction in structures remote from the gingival focus, the several explanations advanced by Smith, Middleton and Barrett[8] might be quoted:

> Much must depend on the local circumstances governing absorption, and much, too, must depend on the number and type of associated bacteria. Whatever *other* relation may obtain between the amebas and the accompanying vegetable

micro-organisms, one may be certain that the amebas feed largely on the latter; and in this bacterial phagocytic action they doubtless set free from this and from that organism different endotoxins. Doubtless bacterial toxins thus originating play a more important part than do toxins from the amebas themselves, if there be amebic toxins.

In regard to the exact method of action of either toxin, we may assume the selective action of the specific toxins to determine the system or the structure involved. In this connection, the old theory of the metabolic origin of many of the complications mentioned above may present itself in a new light. The liver is to a great degree responsible for the disposal, breaking up or removal of toxins arising within the body. It is, therefore, barely possible that certain of the systemic disorders may arise from a disturbance of the normal metabolic function of the liver. As to the hemic complications, the degrees of secondary anemia noted might readily arise from a bacterial hemolytic toxin, but our observations on the active lysis of engulfed red corpuscles in numerous instances lead us to the belief that the endamebae either through an intracellular or extracellular hemolytic toxin, or both, may be even a more important factor.

In conclusion, we would impress the facts that constitutional disturbances are very frequent complications of endamebic pyorrhea, that arthritis, particularly of the type arthritis deformans, is the most frequent complicating disorder, and that the results from the local and general administration of emetin hydrochlorid in the relief of the pyorrhea and the marked improvement of the arthritic condition are very encouraging in a large percentage of cases. In addition, unexpected relations between pyorrhea and certain remote conditions are established through the response to the emetin treatment.

We are indebted to the clinical staff of the University of Wisconsin, to the dentists of Madison and to Dr. Allen J. Smith of the University of Pennsylvania for assistance in the treatment of this series of cases and for timely suggestions during this period of preliminary observation.

SODIUM CITRATE IN THE TRANSFUSION OF BLOOD*

RICHARD WEIL, M.D.
NEW YORK

Blood mixed in proper proportions with a solution of sodium citrate does not clot, owing to the well-known fact that the calcium salts are no longer available for coagulation. Such blood may be kept for many days in the ice-box, without losing its oxygenating function. After one week the cells show little change under the microscope, and very slight reduction in the resistance to toxic physical or biologic agencies. After a few days there is merely some tinging of the supernatant fluid. Experimentally, I have found that guinea-pigs or dogs may be practically exsanguinated, and can then be rapidly restored by venous transfusion of citrated blood, even if the blood is several days old. No unpleasant reactions occur. Human patients have been treated in the same way, receiving in various cases amounts ranging from 10 to 350 c.c. of citrated blood. The blood was used fresh in some instances; and in others, it was from three to five days old. Such injections are perfectly well borne and produce no apparent disturbance of any kind except a transient rise of temperature and polyuria.

The method is simple. Blood is aspirated from a vein and is at once well mixed with sodium citrate in 10 per cent. solution in water, in the proportion of 1 c.c. of solution to 10 c.c. of blood. Exceptionally one encounters blood which requires slightly more or less citrate proportionately. Preliminary tests, 0.1 c.c. of the solution to 0.5 c.c., 1 c.c. and 2 c.c. of blood, respectively, being used, enable one to determine rapidly the requisite proportions in any individual instance. If the mixture is made in the syringe, in cases in which not more than 50 c.c. are to be transfused, the transfer can be made directly from donor to donee. If larger amounts are to be used, the blood is expelled into a flask, from which the injecting syringes are filled. In drawing the blood, it is convenient to use a three-way stop-cock which communicates with the needle, with a 10 c.c. syringe containing the citrate, and with a large aspirating syringe.

The same method has been used for direct transfusion in dogs. The needles are introduced into the veins of donor and donee, and are both connected by a T-shaped tube with a syringe. An accessory syringe permits of the injection of the citrate solution into the tubing between the syringe and the donor's needle. The blood is alternately aspirated and expelled, the direction of the current being controlled by two stopcocks. The apparatus is very simple, and requires the help of only one assistant.

A possible objection is based on the influence of the sodium citrate on the coagulation time of the donee. This has been tested for me in a series of cases by Dr. Beck of the General Memorial Hospital. The figures indicate that the introduction of large amounts of 20 per cent. sodium citrate solution do not lower the coagulation time in the least. In fact 5 gm. of sodium citrate reduces the coagulation time by one-half. The tests have been made on blood aspirated from the vein immediately before, and ten minutes after the injection. It gradually returns to normal.

The uses of this method require little discussion. For the frequent injection of small amounts of blood, it offers obvious advantages. For the direct transfer of large amounts, it may be compared with the method introduced by Satterlee and Hooker. It has, however, the obvious advantage that sodium citrate is always easily obtainable, which is not the case with hirudin. The fact that the blood can be kept on hand for some days may be of value in cases of threatened hemorrhage, as in gastric ulcer, or typhoid. Indeed, its effect on coagulation time indicates its use in hemorrhagic conditions. Essentially, the method is similar to the old method which relied on the use of defibrinated blood. It is, however, simpler than this, and avoids the effects attributed to the presence of fibrin ferment in the defibrinated blood. The possible disadvantages connected with its use can be determined only by prolonged observation.

In selecting the blood to be transfused, it has been customary to mix the serum and the cells of donor and donee in varying proportions, in order to avoid the dangers resulting from agglutination or hemolytic effects. I have found it quite satisfactory to use the following method for the purpose: The citrated bloods of the two individuals are mixed in narrow tubes as follows, three tests being made: One c.c. of each; 0.1 c.c. of one, to 0.9 c.c. of the other, and vice versa. After incubation for one hour, agglutination may easily be determined. Hemolysis is disclosed by the color of the upper layer, if the cells have settled sufficiently; if not centrifugation is required. This method is much less elaborate than that at present in use, but has the advantage that it preserves the natural conditions.

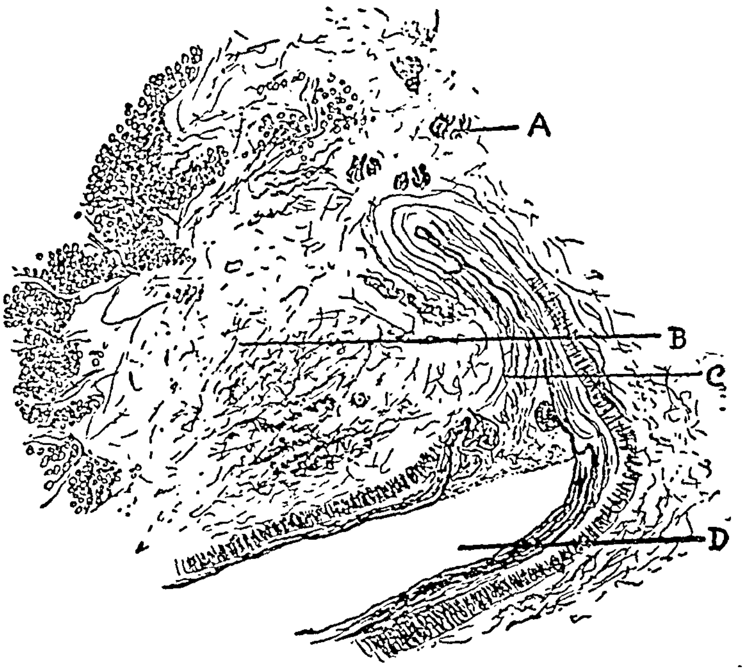
970 Park Avenue.

REPAIR OF DEFECTS IN BLOOD VESSELS BY FREE GRAFTS OF FATTY TISSUE *

L. ELOESSER, M.D.
SAN FRANCISCO

Feb. 7, 1914, while removing the glands during an operation for cancer of the penis, part of the femoral vein to which they were firmly attached had to be cut away. The patient was 78 years of age, the veins thick and sclerotic; proper material for venous suture was not at hand. Hemorrhage was temporarily stopped by pressure. A bit of fatty tissue removed from the wound in the groin was tacked over the opening in the vein by a fine silk stitch which did not pierce the vein itself, but passed through the adjacent tissue and was crossed over the graft. On releasing the pressure there was no further bleeding. The patient died twelve days afterward in a senile delirium. Necropsy showed the lumen of the vein to be free of clot and its walls smooth. The graft was firmly adherent and not necrotic in spite of the fact that the wound was suppurating and the graft surrounded by pus. Microscopic sections showed a good cell stain in the transplant, although there was much leukocytic infiltration; the lumen of the vein was free, the intima not degenerated. The site of the graft is readily seen in the drawing by the break in continuity of the elastic fibers of the vein, which have not bridged the defect.



Illustrating repair of breach in vein wall by autotransplant of fat. *A*, silk sutures; *B*, graft; *C*, defect in wall of vein filled out by graft; *D*, lumen of vein. Magnification × 10. Weigert's elastica stain.

Carrel and Guthrie[1] in their well-known experiments succeeded in patching arterial defects with various substances, using peritoneum and even rubber. Jiano[2] repeated these experiments and applied them clinically in a case of femoral hernia where the femoral vein had been accidentally wounded. A defect was caused 1 cm. wide that took in half the circumference of the vein. This was patched with a pedicled flap from the hernial sac and covered for better security with a layer of the surrounding loose connective tissue.

Hilse,[3] Binnie[4] and others have called attention to the efficacy of a free graft of fat or a pedicled omental flap in the arrest of hemorrhage from parenchymatous organs. Hilse noted that it was often unnecessary to stitch the graft to the wound surface, and that simple pressure continued for a few minutes would suffice to secure a fibrinous attachment firm enough to assure permanent hemostasis.

Kirschner[5] and later Chiasserini[6] experimented with a cuff of fascia interposed as a segment between the ends of a circularly resected artery; thrombosis, however, occurred at the suture-line. Davis[7] wrapped strips of fascia around blood-vessels to reinforce a suture and Halsted[8] suggests their use in aneurysms. Both Kirschner and Davis used pieces of fascia in suturing parenchymatous organs and call attention to the prompt hemostasis. Hohmeier[9] and König[10] used free grafts of fascia to repair defects in hollow viscera—trachea, esophagus, intestine, bladder, etc.

Conditions may occasionally arise in which closure of a rent in a vessel by suture is impracticable, whether because of sclerosis, inaccessibility, lack of a proper instrumentarium or because of the time required for this delicate work. In these cases repair by means of a small free graft of fat or fascia offers a simple substitute. For the repair of small defects in veins the graft of fat or fascia has the advantage that no suture of the vessel itself is needed, a few simple retaining stitches which hold the graft in place without piercing the vessel wall being sufficient. The procedure is consequently more simple than repair by suture, needs no specially delicate instrumentarium, and is easier, quicker and safer, there being no threads in the lumen of the vessel on which clots may form.

CONCLUSION

Free grafts of fat or fascia sewn over defects in the walls of veins offer a *simple and safe substitute* for the repair of these defects by suture.

135 Stockton Street.

THE NEED FOR DETAILED SPUTUM REPORTS

SUPPLEMENTARY REPORT

ARTHUR T. LAIRD, M.D.
NOPEMING, MINN.

The bare statement in a laboratory report that the sputum does not contain tubercle bacilli gives the physician comparatively little help in arriving at a diagnosis, and may be absolutely misleading. It is important that he should have in addition some idea of the character of the sputum submitted by the patient. A dozen negative reports from mouth and throat specimens would be of less value to him than one report on a specimen that came from the lungs. The designation of the sputum as "mucoid" or "purulent" would be a helpful addition to the ordinary report, but a somewhat more detailed description of the macroscopic and microscopic characteristics of the specimen would be of still greater value.

In a previous communication,[1] a method of making reports was suggested, by the use of which, it was declared, the physician would be informed with some degree of certainty whether the specimen was derived from the upper air passages or was really from the lungs; in other words, he could tell whether the specimen was a "mouth" specimen or a "bronchial" specimen.

Under "macroscopic appearance" the specimen is described as watery, mucoid, mucopurulent, purulomucoid, purulent or bloody. If one of the other varieties is simply blood-streaked, the fact is noted; but the specimen is not called bloody unless it consists of pure blood.

In the microscopic examination, the presence or absence of tubercle bacilli is noted. Their number is estimated according to the Gaffky schema, and their arrangement is recorded if desired.

Under the heading "cells," particular attention is given to squamous epithelial cells and to pus cells (polynuclears). If the former are present in large numbers so that they are prominent elements in the picture, they are given precedence in the statement of cells present. On the other hand, if the pus cells are numerous they are recorded first. The presence of small round cells, alveolar cells, and, in appropriately stained specimens, of eosinophils, may also be mentioned. Mononuclear cells rarely form the majority of the elements present.

In regard to secondary organisms, a note is first made stating whether they are few or many. More details as to the varieties present may then be added.

A table of 541 examinations showed that there was a natural grouping of the specimens into four main classes. Since the publication of the article referred to, the number of cases in which the method has been applied, at the Adirondack Cottage Sanatorium and at Nopeming Sanatorium, has increased to 2,509, as shown in the accompanying table. (The summaries were made by Dr. George D. Heist and Samuel Marcus.)

The examinations were made by seven or eight different men, yet the results are substantially the same as in the first report. A mucopurulent sputum, containing many pus cells and few secondary organisms, is in most cases a "bronchial" specimen, and if it does not contain tubercle bacilli, the doctor may be satisfied that the test was a fair one. If the specimen has been coughed up from the lungs, it is not usually much contaminated by mouth or throat secretions. On the other hand, a specimen may to the naked eye be almost equally purulent; but if under the microscope it contains many squamous epithelial cells and numerous secondary organisms, it is more likely to be derived from the throat or nose ("throat" specimen). In catarrhal conditions of the nose and throat such specimens, thick and yellow in appearance, are frequently obtained. Watery and mucoid specimens, like the droplets emitted in ordinary coughing, in which sputum is not raised from the lungs, do not usually contain tubercle bacilli, and the acceptance of reports on such specimens as a basis for excluding a diagnosis of tuberculosis is an injustice to the patient.

TABLE SHOWING CHARACTER OF SPECIMENS OF SPUTUM IN A SERIES OF TWENTY-FIVE HUNDRED AND NINE CASES*

Type	Macroscopic Appearance	Cells Predominating	Secondary Organisms	T.B. +	T.B. —	Total	Per Cent. +	Per Cent. —
1	Watery or mucoid	Squamous epithelial cells	Many	19	388	407	4.7	95.3
2	Purulomucoid	Squamous epithelial cells	Many	48	421	469	10.2	89.8
3	Purulomucoid	Pus cells.......	Few	215	290	505	42.6	57.4
4	Mucopurulent	Pus cells.......	Few	452	223	675	68.4	31.6
5	....	Other combinations	......	130	323	453	28.7	71.3
	Totals......	....	......	864	1,645	2,509	34.4	65.6

* The headings "T. B. +," "T. B. —," "Per cent. +," Per cent. —" indicate, respectively, the presence and absence of tubercle bacilli. Types 1 and *2* are "mouth" or "throat" types; types 3 and 4, "bronchial" types.

STRANGULATED EPIGASTRIC HERNIA

W. C. DANFORTH, B.S., M.D.
Surgeon to Evanston Hospital
EVANSTON, ILL.

A man, aged 80, for a number of years had had a mass in the median line above the umbilicus. This mass, which evidently was an epigastric hernia, had suddenly shown evidences of strangulation, and it was in consequence of this that he was seen. The strangulation presumably had followed a bronchitis which had occasioned severe coughing. Operation was performed at once. The hernia was found to escape through an opening in the linea alba about 3 inches above the umbilicus. There was a distinct peritoneal sac, which, on being opened, disclosed a mass of omentum about the size of a small orange. This was ligated off and the hernial opening closed. The patient made a good recovery so far as the wound was concerned, although the bronchitis was considerably aggravated by the anesthetic, and in consequence of this he was quite ill for a number of days.

Epigastric hernia is, in comparison with the total number of hernias, infrequent, and strangulation of an epigastric hernia is particularly so. The percentage of the occurrence of epigastric hernia has been variously given as from 1 to 5 per cent. of all hernias.

---

[1] Laird, Arthur T.: A Method for Increasing the Diagnostic Value of Sputum Reports, The Journal A. M. A., Jan. 23, 1909, p. 294.

Bull and Coley,[1] in a report of 1,500 cases of hernia, give only two cases of this type, and a later report by the same observers of 2,032 operations for hernia notes only six cases of epigastric hernia. John Phillips[2] reported only forty-two out of 7,500, a percentage of 0.56. Quain,[3] on the other hand, gives the percentage of 5 per cent.

Quain divides epigastric hernia anatomically into two classes: First, simple fat tumors or properitoneal lipomas, which protrude through a cleft in the linea alba and do not possess a proper peritoneal sac; and second, true hernias with a sac of peritoneum, in which sac hernial contents may or may not be found.

The invariable appearance of these hernias above the umbilicus and never below it is due to the anatomic relations of the recti muscles, which, below the umbilicus, come closely together, while above that point an appreciable interval exists between their sheaths, which is occupied by areolar tissue. The production of hernia of this type is therefore much easier in the upper abdomen than in the lower.

Strangulation in this type of hernia is rare. Hotchkiss,[4] writing in 1911 and reporting a case of strangulated epigastric hernia, was able to find but two previously reported cases. A search of the literature, however, shows a considerably greater number. Moschcowitz[5] of New York reports a case of strangulated epigastric hernia, and after carefully considering all the reported cases of strangulation comes to the conclusion that only ten of them can be regarded as true cases of epigastric hernia. He believes that most of the reported cases of this type of hernia are not true hernias at all, but merely cases of prolapse of the fat contained between the layers of the falciform ligament of the liver.

As the case I describe escaped through an opening in the linea alba and possessed a true peritoneal sac, and as the contents of the sac was composed of omentum and not merely properitoneal fat, I believe it should be considered as a true case of hernia.

The recognition of such a hernia is quite simple if the mass be of any size. The smaller ones might be overlooked if the examination were not a careful one. The subjective symptoms of such a lesion are dull, dragging pain in the epigastrium, increased by bending backward or kneeling, sometimes nausea or vomiting or flatulency.

Phillips[2] quotes from another writer a method of distinguishing a true hernia from a fatty mass, namely, the placing of the hand over the mass and causing the patient to cough, when, if a true hernia be present, the observer will get an impression as though water were being squirted against the hand. This writer finds that the most common site is 1½ or 2 inches above the umbilicus.

The operative treatment is as a rule very simple. The contents of the sac are returned to the abdomen, if it be bowel, and in good condition, or ligated off and removed, if it consist of omentum. The sac is closed and the split in the fascia repaired. Coley recommends the Mayo technic as used for umbilical hernia.

PROGRESSIVE LENTICULAR DEGENERATION

REPORT OF A CASE WITH NECROPSY

WILLIAMS B. CADWALADER, M.D.
Instructor of Neurology and Neuropathology at the University of Pennsylvania School of Medicine; Clinical Assistant to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases
PHILADELPHIA

Because of the great interest that is now being manifested in the functions of the lenticular nucleus and the symptoms produced by disease of this structure, I have deemed it important to record the following case of progressive lenticular degeneration. Although a few clinical cases of this condition have been described,[1] so far as I am aware the present report is the first recorded in American literature in which the diagnosis of "progressive lenticular degeneration" was confirmed by necropsy.

History.—E. B., woman, aged 19, was admitted to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases in July, 1912, in the service of Dr. Charles W. Burr. Her parents and close relatives were healthy. Her parents stated that she had always been a somewhat nervous child, but had never been really ill. They declared that she was bright and intelligent, and appeared to be robust, but that occasionally she had been subject to attacks of mild mental depression which lasted a few weeks at a time. The family, however, did not attach any importance to these attacks. In January, 1911, while seemingly in apparent health, she received a slight injury of the right hand. Immediately following this her nervousness increased, and after a few weeks she became forgetful, depressed, dull and indifferent. At this time her speech also became indistinct. This condition, it was stated, progressed slowly.

Physical Examination.—On admission, the patient appeared to be a thin young woman, inclined to listlessness and lethargy. She was uncommunicative, and would not answer questions readily. She appeared to comprehend what was said to her, but after being aroused was childish and silly in her attitude. The pupils were equal in size and reacted normally to light convergence and accommodation. There was no nystagmus, and the ophthalmoscopic examination revealed nothing abnormal. The extra-ocular muscles acted in a normal manner. The muscles innervated by the cranial nerves were not paralyzed, but there was some twitching of the facial muscles. This was more marked on the left side than on the right. The mouth was held partially open, and the tongue, the pharynx and the larynx were normal. At times there was some difficulty in swallowing liquids. Dysarthria was fairly well marked. Hearing was normal. All four extremities were spastic, but were not paralyzed. Muscular power for all movements was good. Intention tremor was well marked in the right upper extremity, but only slightly so in the left. The tremor was of the regular type—to-and-fro movements—sometimes disappearing when the limb was at rest, but becoming quite marked on the right side when any voluntary movement was attempted. There was no ataxia, but the spasticity rendered all the movements awkward and difficult. The condition of the lower extremities was similar to that of the upper extremities, but the tremor was less marked in the former and the spasticity was much greater. There was a tendency to tonic contraction of the legs on the thighs, and also of the adductor muscles, but the legs could, nevertheless, be extended. The tendon reflexes of both the upper and the lower extremities were active and almost normal. The Babinski reflex could not be elicited, and ankle clonus was also absent. The organs of the thorax and abdomen seemed to be normal.

---

[1] Auer: Nerv. and Ment. Dis., July, 1914. Cadwalader, W. B.: Progressive Lenticular Degeneration, The Journal A. M. A., Oct. 17, 1914, p. 1380.

There was no evidence of disease of the liver, and the abdominal reflexes were active and equal in intensity. Sensation everywhere was unimpaired. Both the urinary analysis and the blood examination were negative. The Wassermann reaction with blood-serum was weakly positive.

From this time on the patient appeared to be growing progressively worse. The Wassermann test was made at various intervals, but except for the slightly positive response elicited at the first examination it was always negative. The speech became more and more indistinct, and the difficulty in swallowing increased. All four extremities gradually became more and more spastic, and the tremor became less pronounced. Extension of the arms, although possible, was accomplished only with difficulty; the legs, however, could not be fully extended at the knees because of contraction. The right leg was constantly held flexed on the thigh, and the thigh flexed on the abdomen. While the patient lay on her left side the right leg was thrown over the left, which was similarly contracted; tremors still persisted in the upper extremities, and there was a lateral tremor of the head. The right elbow was flexed at right angles and the fingers were flexed on the palm of the hand, the degree of flexion varying from time to time. The muscular power, however, did not appear to be greatly diminished and the biceps and triceps reflexes were slightly exaggerated. Thirteen months after the onset, and without any essential change in the condition, the patient died.

NOTES OF THE NECROPSY

Macroscopic Examination.—The macroscopic appearance of the brain and cord was normal. On making a horizontal section through the brain at the level of the base of the ganglia no evidence of softening of the lenticular nucleus could be detected with the naked eye.

Microscopic Examination.—Sections were stained by the hemalum-fuchsin method, and with the van Gieson and Nissl stains. Sections taken at different levels of the spinal cord, when stained by the hemalum-fuchsin method, showed no characteristic lesions, but some of the cells of the anterior horns did appear to stain a darker color than normal, thus suggesting pigmentation. The cells were well formed and the nuclei had not disappeared. When stained by the Weigert method, the white columns did not show any degeneration. There was no round-cell infiltration of the meninges, the blood-vessels were not thickened, and the perivascular spaces, although large, did not contain round cells or granular débris. No evidence of syphilitic infection could be found. Sections made through the medulla oblongata, pons and peduncles revealed similar conditions. No positive evidence of disease was discovered, but the nuclei of the cranial nerves and the cells of the substantia nigra did show occasional evidences of increased pigmentation. Sections of the cortex showed nothing abnormal. The membranes were not infiltrated with round cells, and the nerve-cells and blood-vessels appeared to be normal. Serial sections were made through the basal ganglia of both sides. When examined under the low-power microscope a number of small, irregularly scattered areas of softening were readily detected in the lenticular nuclei of each side. These areas of softening varied considerably in size, the largest being about the size of the head of a pin, whereas numerous points of beginning softening appeared to be much smaller. On the whole, these areas of softening were more numerous in the putamen than in the globus pallidus. In the middle of one of the larger softened areas, as a rule a small artery stood out prominently. Its walls were not thickened, and there was no perivascular infiltration, although the perivascular space was dilated. The surrounding tissue appeared to be contracted, and there was a considerable space between it and the blood-vessel, which contained a few compound granular cells and a quantity of débris. The tissue in the region of the softened area showed marked increase in the neuroglia cells, and when stained with hemalum-fuchsin, appeared to be firmer and denser than normal. The large nerve-cells of the putamen seemed to be less numerous than in the normal condition. The internal capsules, the optic thalamus and the external capsule revealed nothing abnormal. When stained with the Weigert stain, strands of fibers here and there did not take the blue color as readily as they should normally, but positive evidence of degeneration was lacking. No essential difference in the pathologic changes on the two sides was found. The thoracic and abdominal organs were not examined microscopically. The liver did show evidences of cirrhosis, but, unfortunately, a specimen could not be secured for careful study.

During the lifetime of the patient no unqualified diagnosis had been made. Syphilis had been suspected because of the fact that the first Wassermann reaction had been slightly positive. All subsequent examinations, however, had proved to be negative. Lenticular disease had not been suspected until the case came to necropsy, when the clinical picture was immediately revealed. Unfortunately, but little information as to the earliest symptoms that developed could be obtained, but it is probable that the statement of the parents that the patient was subject to frequently recurring attacks of mental depression was of some significance. When the patient was first admitted to the hospital her mentality was distinctly impaired. She was listless, lethargic, and at times emotional. Her memory and, in fact, all the mental processes were impaired so much that at one time the development of dementia praecox had been suggested. From the very beginning there was a distinct tendency to spasticity of all the extremities and of the face, but the well-marked tremor, limited at first almost solely to the right upper limb and to the muscles of the face, very gradually affected the entire musculature, although it never became very noticeable except on voluntary movement. It is probable that the intense spasticity, which began early and seemed to develop more rapidly than the tremor, must have masked or prevented the occurrence of the latter, which might otherwise have been most pronounced. The position assumed by the patient when lying in bed was almost identical with that shown in the photograph of Homan's patient, given in Wilson's article in *Brain,* 1912, page 316. The onset was not unlike that described by Wilson as acute, in that the symptoms developed rapidly; there was nothing, however, to indicate the presence of a toxemic condition; that is, there were no fever, malaise, etc. The patient did not come under observation during this early period, so that nothing definite regarding the onset can be stated. The fact that one Wassermann examination was reported as positive seems of little significance when it is remembered that eight subsequent tests were all negative, and that there was no clinical evidence of syphilis, or any microscopic evidence of lues in the brain, findings that would seem to preclude the possibility of the existence of syphilis.

1710 Locust Street.

Community Nursing.—Dayton, Ohio, has revised its method of public nursing. Instead of having tuberculosis nurses, board of health nurses and special visiting nurses, under the new arrangement each nurse will care for all classes of cases in her district. Under this plan information concerning cases will be more easily transferred and the nurse will become better known in her district and can give more efficient service on account of a better knowledge of families as a unit. Close cooperation with the health department is provided for by each nurse being sworn in as a sanitary inspector with authority to order correction of insanitary conditions. All nurses, whether from municipal or private agencies, are under a single supervision.

SYPHILITIC ULCER OF THE STOMACH

REPORT OF A CASE EXAMINED HISTOLOGICALLY

H. L. McNEIL, M.D.
Instructor in Medicine and Clinical Pathology, University of Texas, Department of Medicine
GALVESTON, TEX.

In view of the fact that the impression prevails in some quarters that syphilitic ulcer of the stomach is a rather rare condition, and since, in spite of the assertions of others, that it is fairly common, comparatively few cases are reported in the literature, the following case would seem to be of some scientific interest:

A negro laborer, aged 50, complained of pain in the stomach after eating. The family history was negative, except that the wife had had one late miscarriage. The personal history was negative for any trouble bearing on the present illness. There had been no stomach trouble before the onset of the present illness. The patient denied lues but admitted gonorrhea.

The present illness began three months before admission with a sharp pain in the upper epigastrium, radiating to the right side, appearing from one-half to one hour after meals, being fairly constant in appearance, but varying in intensity. It was never severe enough to become a definite colic. Acids appeared to increase the pain. The patient thought that he had lost some weight, the amount of which was not known, but probably about 20 pounds.

Physical examination revealed nothing abnormal except tenderness on pressure over the epigastrium, especially just to the right of the midline. Examination of the blood showed a slight anemia (4,300,000 reds; hemoglobin 65), but nothing else of interest. The Noguchi test for syphilis was positive.

Stomach analysis after an Ewald meal showed an absence of free hydrochloric acid, a total acidity of 25, occult blood and lactic acid and Oppler-Boas bacilli. Microscopic examination of the empty stomach contents, removed by means of a Jutte duodenal tube, revealed nothing abnormal. The tube passed through the pylorus with some little difficulty (1 hour), but as soon as it had become engaged in the pylorus, an interesting change in the microscopic appearance of the contents was noted. Numerous pus cells, with a mixture of red blood cells were noted, along with a large number of cylindrical and globular gastric epithelial cells, giving a very different picture under the microscope from that obtained in the first stomach contents removed. The duodenal contents were normal cytologically and chemically.

The patient was placed in bed, and on specific treatment (mercury and potassium iodid), for two weeks. At the end of this time, there was no demonstrable improvement in his condition. The pain was as bad as before. He was afraid to eat on account of the discomfort. At this time it was noted that the administration of hydrochloric acid after meals seemed to increase the pain.

In view of the absence of any improvement in the gastric or general condition of the patient after two weeks of antiluetic treatment, it was deemed advisable to perform an exploratory laparotomy on the suspicion of the presence of a malignant condition. At operation, a marked annular thickening was made out, encircling the first part of the pyloric region. There was a general enlargement of the pyloric lymph-nodes. Also, several large mesenteric lymph-nodes were observed. Several of the pyloric nodes were as large as Lima beans. A resection of the pylorus was done. The specimen removed at operation showed an annular, apparently active ulcer, almost completely encircling the first part of the pylorus. The submucosa appeared to be most involved. The edges of the ulcer were undermined and soft. The floor was smooth. At one extreme end there appeared to be an attempt at healing. Microscopically, the picture was one of degeneration, chiefly of the submucosa, but affecting also the muscular layers to some extent, with a marked periarteritis of all the arterioles. The mononuclear elements played almost the entire part in the periarteritis. At the point where the attempt at healing was suspected, there was an evident growth of new connective tissue. The large lymph-nodes showed a simple hyperplasia.

The patient made a good recovery from the operation, received a dose of salvarsan and a thorough mercurial treatment, and was as well as ever when last heard from, about eight months after the operation. The histologic specimens were submitted to several competent pathologists and all agreed that the picture was that of a syphilitic periarteritis. No spirochetes could be demonstrated in the sections.

In a search of the literature, I was able to find only one case reported which resembled the foregoing in all respects, even to the resection of the stomach and to the histologic appearance of the lesions. This was reported by Hayem[1] in a man of 60, on whom a resection was done on the suspicion of malignancy, which condition was suggested by the stomach analyses, as it was by the stomach analyses reported above.

It will perhaps be well to state that since this case, I have been very suspicious of all ulcer cases which have fallen into my hands, and although I have seen two since then in which there were positive Wassermann reactions, I have seen no benefit to either from the administration of mercury and potassium iodid, and, in one case, of salvarsan.

I wish to thank Dr. R. W. Knox, chief surgeon of the Southern Pacific Lines, on whose service the case was observed, for permission to publish this report, and also Dr. Martha A. Wood, who prepared the histologic specimens.

BREAKAGE AND REMOVAL OF EUSTACHIAN APPLICATOR

G. W. Stimson, M.D., Pittsburgh

Recognizing the truth of the statement that it is by our mistakes as well as by our successes that we profit, I wish to submit the following short report of an unexpected and unforeseen accident that occurred to me a short time ago

A woman, aged 20 (a private patient), refined and of a highly nervous temperament, complained of fulness, tinnitus and some impairment of hearing, etc., in her left ear. The diagnosis was tubotympanic catarrh. In order to shrink the mucous membrane of the eustachian tube so that I could get a blast of air freely into the middle ear or pass a eustachian bougie, a Yankauer's eustachian applicator tipped with cotton soaked in a mixture of cocain and epinephrin was passed well into the tube. When this was removed it was discovered that the distal end had broken off, consisting of the cotton tip and an inch of the twisted wire applicator.

Thinking, or rather hoping, that it might have dropped into the pharynx, I made an attempt to pass a gentle blast of air through the tube. No sound could be heard, however, through the ausculting tube, the occlusion being apparently complete. In the hope that the end might be protruding enough from the mouth of the tube to permit its being grasped with forceps and removed, I carefully inspected the eustachian opening with the aid of the Holmes nasopharyngoscope, but there was no sign of the applicator. It then occurred to me to pass another dry cotton-tipped applicator, twirl it around with my thumb and forefinger and withdraw it. This was done and at the first trial, to my gratification, the dry cotton engaged the broken end of the wire and together with its cotton tip it was withdrawn through the catheter.

During the short interval required the patient was blissfully unconscious of what had occurred (which was particularly pleasing on account of her temperament), and only when she inadvertently caught sight of the dangling end did she unconcernedly remark, "Oh, did the cotton come off?"

While I had used Yankauer's eustachian applicators hundreds of times I had never had the slightest trouble in any way, and when I sought for a reason I found that before the sterilization of the applicator (which had been used *once* or twice before) by boiling, the cotton had been burned off, and this had taken the temper out of the wire and made it brittle, although it had withstood the pull that I always make to test whether or not the cotton is perfectly and securely applied. Of course, this should never be done; the cotton should be removed by laying the applicator flat on a glass-top table and scraping it off with a knife or some semisharp instrument.

---

[1] Hayem: Maladies de l'estomac.

In a conversation a few days ago, Dr. Yankauer told me that I was the second who had recited to him an occurrence of this sort. I hope that if this accident, which might readily prove most embarrassing, should befall another, he may find in the foregoing report some helpful suggestions and profit.

PROSTATIC ABSCESS OPENED THROUGH THE CYSTO-URETHROSCOPE WITH THE HIGH-FREQUENCY SPARK

Abe Nelken, M.D., New Orleans

Abscess of the prostate is one of the less frequent complications of gonorrheal invasion of the posterior urethra. In fully 75 per cent. of the cases, the abscess points toward the urethra, usually causing complete retention of urine and requiring regular catheterization until such time as spontaneous rupture into the urethra occurs. This is usually from seven to ten days after the onset of retention, but I have seen cases that have gone as long as three weeks before being relieved by the abscess discharging into the urethra. Operative interference is rarely justified in these cases, for incision of the abscess either through the perineum or through the urethra by perineal incision is a comparatively radical procedure when it is remembered that it is the rule for such abscesses to rupture into the urethra if given time. The simpler procedure, of draining through the rectum, save perhaps in cases about to rupture into that organ, is bad surgical practice for obvious reasons.

I have recently opened a prostatic abscess by means of high-frequency cauterization through the Buerger cysto-urethroscope, and the procedure was so simple and caused the patient so little discomfort that I believe the report may be of interest:

E. L., negro, aged 26, applied at the Touro outclinic for relief because he had been unable to urinate for the past two days. There had been gonorrhea of four weeks' duration. The bladder contained 16 ounces of slightly cloudy urine. Patient returned next day still suffering from retention. Sixteen ounces of urine were again withdrawn. Through the cysto-urethroscope, the posterior urethra was inspected. The mucosa was found to be much injected. Just behind and slightly to the right of the colliculus, distinct bulging could be seen. The flexible electrode was pushed against this bulging area and a rather mild current applied. In thirty seconds there was seen through the instrument a puff, resembling exactly a powder explosion, the field of the instrument rapidly clouded, and I knew that I had opened the abscess. The patient experienced no pain at any stage of the proceedings, which did not last more than five minutes in all. He has been emptying the bladder without difficulty since.

305 Baronne Street.

The Physician's Life.—The study of medicine is an entrancing subject; its practice require an array of virtues whose mere contemplation staggers the mind. One must meet violence with gentleness, ingratitude with equanimity, insult with fortitude, slander with silence. The physician's life is a daily exemplification of the golden rule. The very sensitiveness that inspires sympathy with pain and misery is a weapon in the hands of ignorance and malice wherewith they deal dreadful wounds, wounds which must be endured silently. Resentment can have no place in the physician's mind. Equanimity must be maintained in the face of misapprehension and abuse.—Gadsden (Ala.) *Times-News*.

PRACTICAL PHARMACOLOGY *

(Continued from page 341)

IV

A. STIMULANTS: 2. MEDULLARY—ATROPIN GROUP—(Continued)

LOBELIA

The action of lobelia is practically that of its alkaloid, lobelin, which resembles nicotin closely in its preparation and actions.

Tobacco was used formerly in a great variety of conditions, but owing to its careless use and the great toxicity of its alkaloid, many accidents resulted, and it fell into disuse in therapeutics. If the drug which has been studied more frequently should now be considered of little value, it is difficult to explain the advantages to be derived from lobelia. Lobelia itself is no longer used as an emetic as it was formerly. It would seem that physicians are loath to give up a drug which has been so long in use.

Those who wish a detailed description of lobelia, or lobelin, are referred to the larger text-books of pharmacology, for its actions are very complex. The peripheral actions of lobelin, like those of nicotin, may be summarized as consisting of stimulation of the ganglia of the sympathetic and parasympathetic systems throughout the body after small doses, followed by depression or paralysis of these ganglia with large doses. It will thus be seen that lobelin acts on the organs innervated by the sympathetic and parasympathetic systems in opposite directions, depending on the dose, and the complex nature of its effects may be appreciated when one remembers that the actions of these two sets of nerves are commonly antagonistic.

Stimulation and depression of the ganglia induce the same effect on the organ supplied as stimulation and depression of the nerve endings; hence lobelin combines in itself the peripheral actions of a number of drugs including atropin, pilocarpin, epinephrin and others. In addition to these actions it stimulates and later depresses various parts of the central nervous system.

The emetic action, for which lobelia was formerly used, points toward the medullary centers as the seat of this stimulation, and it also stimulates the vagus, vasomotor and respiratory centers.

The action on the vagus ganglia results in cardiac slowing, which is augmented by the stimulation of the vagus center, but this is soon followed by an increased heart-rate due to the depression of the ganglia. The rise of blood-pressure of peripheral origin is also augmented by the central actions.

Lobelia is not used for these effects, and it is now sought to avoid more than slight stimulation of the vomiting center, because dangerous collapse is frequent with large doses.

The treatment of poisoning is symptomatic, severe poisoning with lobelia being rare since its use as an emetic has been abandoned.

Nicotin is excreted by the kidneys in part, and the same is probably true of lobelin.

---

* This is the fourth of a series of articles on useful drugs—on practical pharmacology for the general practitioner. As soon as completed, these articles, elaborated by additional subjects, will be published in book form.

THERAPEUTIC USES

The principal therapeutic use of lobelia is in asthma, in which it is sought to utilize the paralysis of the vagus in the bronchi. It is not apparent that it has any decided advantages over the mydriatic alkaloids for this purpose, especially as the action of atropin has been found to be more lasting. Lobelia is sometimes used as an expectorant, in which case the nauseant stage should not be exceeded. So-called cardiac asthma, or the presence of severe cardiac disease complicating spasmodic asthma, is a contra-indication for lobelia.

DOSAGE

The herb is seldom employed as such, the tincture being used in doses of 0.5 to 1.5 c.c. (10 to 20 minims).

CAMPHOR

We are unable to offer a rational basis for all the therapeutic uses to which camphor is put, its exact mode of action being unknown, but it is often used as a stimulant of the vasomotor centers, partly as a result of clinical experience and partly on the basis of the results of experiments on animals.

The effects of very large doses of camphor resemble those of picrotoxin so far as the stimulant actions on the medulla are concerned, but there is an essential difference in that even moderate doses of the drugs of the picrotoxin group tend to cause depression after the stimulation has passed, whereas with camphor, depression becomes of importance only after extremely large amounts.

The convulsions which are seen after massive doses of camphor are administered to animals (cats or dogs) are usually attributed to the action on the medulla, but it is probable that other parts of the central nervous system are also concerned in this action, especially in young animals. The convulsions are epileptiform in character.

Moderate doses of camphor stimulate the respiratory center, and while doses comparable to those used in therapeutics have little influence on the respiratory and vasomotor centers, in normal animals, it is quite possible that those centers may be influenced more easily by camphor, as in other drugs, when they have been previously depressed. It will be recalled that doses of strychnin less than those causing marked hyperexcitability have little influence on the normal blood-pressure, and that even convulsive doses cause only a brief, though high, rise of pressure in the normal animal.

Clinical experience seems to show that camphor is sometimes useful in improving the respiration and circulation when collapse is impending, and that it also acts beneficially on the heart, but there are many diametrically opposed observations recorded concerning its clinical value.

Camphor is widely used in Europe for its circulatory actions, especially in threatened cardiac failure, but on the other hand, certain English observers have recently reported that they were unable to detect any constant influence on the circulation after the subcutaneous injection of much larger doses than those commonly used.

It seems probable that camphor may cause some change in the distribution of the blood by constriction of the vessels in one area and simultaneous dilatation of those in another, without increasing the pressure.

It is quite possible that much of the diversity of opinion arises from differences in the methods of employing the drug, both as to the selection of cases in which it is to be used and in the mode of administration.

Camphor resembles the drugs of the picrotoxin group further in that it is absorbed somewhat irregularly, or at least, the actions are elicited to a variable degree after the administration of a given dose, and this probably depends on differences in the ratio of absorption and excretion, as mentioned in the introduction.

It has been observed in laboratory experiments that the results were somewhat more nearly uniform after the oral administration of camphor dissolved in olive oil than when it was given subcutaneously, but the two modes of administration gave only slightly different results. It is probable that the effects may be elicited most rapidly by means of the intraperitonal injection of camphor dissolved in ether, but there are mechanical difficulties involved in the injection, because of the extreme volatility of ether. The method is not recommended.

THERAPEUTIC USES

Camphor is used like other respiratory stimulants, and in collapse for its action on the respiration and circulation, and, as stated, in impending cardiac collapse. It has long been popular in combination with other drugs to promote sweating, and enjoys a certain degree of popularity in the treatment of "colds." It is not commonly used now in this way by physicians.

Other uses of camphor will be discussed in connection with aromatic stimulants and the external applications.

DOSAGE

Camphor is frequently administered internally in doses of from 0.1 to 0.3 gm. (2 to 5 grains) preferably in the form of capsules, cachets, mixtures or solutions. Camphor water, a comparatively weak solution, is given in doses of 15 c.c. (4 fluidrams). Spirit of camphor, a 10 per cent. alcoholic solution, which is the most frequently used preparation of camphor, can be given on sugar, cracked ice or mixed with cold water in doses of from 0.5 to 1.5 c.c. (7 to 20 minims). The liniment of camphor, which as its
name indicates is primarily intended for exte
though it is double the strength of the forego
be given in approximately the same dose. It
directed in the form of an emulsion. It is fr
used for hypodermic administration. A mor
preparation for the latter purpose can be
directing the use of oil of sweet almond or
in place of the cotton-seed oil used in the
preparation.

A. STIMULANTS: 3. CEREBRAL—CAFFEI THEOBROMIN

Caffein and theobromin belong to a group
stances which are commonly known as the
from the fact that they contain a nucleus whic
Fischer synthesized and called purin. Xa
dioxypurin, and theobromin and caffein are di
xanthin and trimethylxanthin, respectively.
dimethylxanthin, theophyllin, occurs in the lea
tea; it has been prepared synthetically and
theocin.

Comment has often been made on the extrao
extent to which plants which contain caffein a
among nearly all civilized peoples and even
savages, which is all the more remarkable in

the fact that there is nothing in the taste of these plants which serves to direct attention to them. It is well known that savage tribes are constantly on the alert for new poisons, and when a caffein-bearing plant is tested the psychic effects of caffein on any one who has not used it previously could hardly fail to attract attention, and lead to the further use of the plant.

Caffein does not increase the functions of the normal brain under the best conditions for mental work, that is, after sound and refreshing sleep and sufficient rest with freedom from worry, but when small doses are used after severe physical or mental effort it causes fatigue to disappear, and the perception of sensory stimuli and the association of ideas are promoted.

A good illustration of the inability of caffein, or other drug, to improve the best of normal conditions is afforded by the experience of athletes who find that caffein tends to lessen, rather than increase, their performances.

Large doses of caffein interfere with the proper association of ideas; for example, students are unable to study so effectively after large doses as without them. With very large amounts there is actual confusion of thought with ringing in the ears, flashes of light and other signs of mental disturbance. There is also restlessness due to stimulation of the motor areas, and to heightened reflexes in the brain and cord, and with excessive doses there are convulsions similar to those seen in fatal poisoning with strychnin, and death follows from respiratory or cardiac failure.

Caffein stimulates the medullary centers, causing increased respiration and rise of blood-pressure, due to stimulation of the vasomotor centers, but this is complicated by cardiac and vascular effects, and slowing of the heart from stimulation of the vagus center, which is also complicated by the direct, and indirect, cardiac actions. Obviously, the effects on the circulation are complex and variable.

Wakefulness is one of the most frequently observed effects of caffein in those who are unaccustomed to its use, especially when it is taken shortly before bedtime, but it may promote sleep when this is prevented by fatigue.

Caffein relieves certain forms of neuralgia, the etiology of which, and the mechanism of relief are obscure. It appears to enhance the antineuralgic actions of antipyretic drugs, such as antipyrin, with which it is sometimes administered.

Theobromin induces much less psychic stimulation than caffein, but it is convenient to consider them together because of the general similarity in most of their other actions.

The effect of caffein on cardiac muscle is important, but the muscular action is observed more conveniently on skeletal muscle. Extremely small amounts of caffein, such as are utilized when solutions of 1:100,000 or weaker are employed in laboratory experiments, increase the force, efficiency and rapidity of contraction of voluntary muscle, but with greater concentrations the muscle contracts less efficiently, less forcibly and more slowly, and finally goes into rigor.

Nearly all doses of caffein that produce any perceptible effect on the heart increase the rate, without increasing the force, and this effect with the stimulation of the vasomotor center results in at least a temporary rise of pressure, unless it is prevented by the antagonistic dilator action on the vessels themselves. Occasionally the force of the heart-beat is increased without any notable influence on the rate. The continued use of tea or coffee in large amounts gives rise to intermissions, extrasystoles or other forms of cardiac irregularity, which usually disappear when the beverage is discontinued or taken in greater moderation; but it is not certain that these cardiac irregularities are due exclusively to the caffein present in the tea and coffee, for indigestion may play a part in the symptoms.

German clinicians employ caffein in cardiac disease much as they use digitalis, but while these two drugs have a certain degree of synergistic action, the total effect is quite different.

The effects of caffein on the circulation are of importance with reference to its diuretic action. The vasoconstriction which at first affects the vessels of the splanchnic region, causing a rise of blood-pressure, also constricts the renal vessels, so that the secretion of urine may actually show a temporary diminution; but this renal vasoconstriction soon gives place to dilatation while the pressure in the general circulation remains high, thus securing the best circulatory conditions for diuresis. There are many persons in whom caffein and theobromin do not induce active diuresis.

Caffein and theobromin are absorbed fairly readily from the gastro-intestinal tract. Theobromin is relatively insoluble, but there is vastly more fluid in the gastro-intestinal tract than is required to dissolve the largest therapeutic dose. When it is desired to inject these drugs subcutaneously it is necessary to use them in connection with an alkaline salt such as sodium salicylate or sodium benzoate, to produce soluble preparations.

Caffein is probably broken down in the organism to dimethylxanthin before it acts on the kidney, and it and theobromin are excreted partly as dimethylxanthin, and partly as uric acid, but they do not cause any important increase in the output of uric acid under ordinary conditions. A small amount of unchanged caffein may appear in the urine after the administration of very large doses.

It is a matter of common experience that a certain degree of habituation on the part of the central nervous system occurs toward caffein on continued use, but the heart becomes more susceptible if large amounts are taken daily.

Very few fatal cases of poisoning by caffein have been recorded, and in view of the enormous use of the beverages containing it we must suppose that it is not a dangerous drug so far as the immediate peril to life is concerned; but minor toxic symptoms, including nervousness, cardiac irregularities, sleeplessness, lassitude, ill humor and headache are common; these usually call for no other treatment than the discontinuance of the beverage which is causing the trouble.

THERAPEUTIC USES

Caffein is used therapeutically for its diuretic action, especially in dropsical conditions and in nephritis, and also in cardiac disease. Aside from its diuretic action it is not easy to suggest a logical basis for its use in cardiac disease.

Caffein is one of the best of respiratory stimulants, because the stimulation has little tendency to pass into depression even with large doses.

The antagonistic action of caffein to that of morphin and other narcotics is strikingly illustrated in a well-known laboratory experiment. If a cat or dog be given alcohol until completely anesthetized, and caffein be then injected subcutaneously, the animal will speedily regain consciousness and make coordinated voluntary movements, often rising to its feet, or at least, to a sitting position. If anesthetized with ether previous to the administration of the caffein, it may regain consciousness and not pass under the anesthetic again, as it does after alcohol, owing to the slowness with which the alcohol is eliminated.

Caffein has an equally important, though not so striking, effect in animals under the influence of morphin, and on theoretical grounds, it is difficult to explain why caffein should not be given the preference to atropin as a respiratory stimulant in the treatment of poisoning by morphin and other narcotics.

Caffein in the form of tea or coffee is often useful for the relief of headache due to overexertion and nervousness.

DOSAGE

Caffein and theobromin or the several combinations of these bases with other substances may be administered in doses of from 0.1 to 0.5 gm. (2 to 8 grains). Caffein, the citrated caffein and theobromin are preferably given enclosed in a capsule or cachet or in the form of dry powder to be washed down with a copious draught of cold water. The combinations of caffein and of theobromin with sodium benzoate and sodium salicylate are readily soluble in water and are usually administered in the form of simple solutions.

The intravenous injection of caffein is not without its dangers; under no circumstances should caffein be injected rapidly into the blood-stream. The following experiments illustrate the danger: A cat required 150 mg. (2½ grains) per kilogram of weight to cause death, when a dilute solution was injected very slowly, but in another experiment the heart was stopped at once by the *rapid* injection of as little as 5 mg. (1/12 grain) of caffein per kilogram. It should be remembered that this dose corresponds to about 0.30 gm. (5 grains) of caffein for a man, or less than is commonly taken habitually by many persons daily in the form of tea and coffee without perceptible effects. When one recalls what was said regarding the effect of even fairly dilute solutions of caffein on skeletal muscle, he will appreciate the danger of rapid intravenous injections of even small amounts of caffein. If it is desired to inject the drug directly into the circulation, for which there is no apparent good reason in therapeutics, the dose should not exceed 0.20 gm. (3 grains), which should be dissolved in a fairly large amount of salt solution, and the injection should be made slowly, so that at least one minute should be consumed in the injection. It is not recommended that caffein be injected intravenously in therapeutic practice, however.

MATERIA MEDICA *

Physicians commonly object to using the beverages tea, coffee and cocoa, when the diuretic action of caffein and theobromin is desired, on the ground that too much water is thereby administered. The argument is not always well taken; every patient must have some water, and large doses of caffein and theobromin may be given with strong beverages without increasing the minimum of water, and absorption from the gastro-intestinal tract takes place promptly.

Therapeutics

PREVENTION IS GREATER THAN CURE

XVII

Whooping-Cough

This infection, which most frequently attacks children, is generally regarded by the public as a trivial disease, and consequently proper treatment and means of prevention of infection of others are frequently not instituted. Even the medical profession for many years did not consider the disease serious, but better statistics, demonstrating the causative agent of death-dealing complications, have shown that whooping-cough is a dangerous disease.

The greatest mortality of whooping-cough is indirect. A large number of those infected die of such complications as bronchial pneumonia, capillary bronchitis, tuberculosis and a few from hemorrhages, while chronic debility, anemia, emphysema, and some lesion of the central nervous system are of not infrequent occurrence. According to the United States *Public Health Reports*, in 1910, whooping-cough had a mortality of 11.4 per hundred thousand population, while scarlet fever had a mortality of 11.6, measles 12.3, and diphtheria 21.4. In young children and infants, whooping-cough causes more deaths than measles, and some statistics show twice as many deaths as measles; 95 per cent. of deaths from whooping-cough occur during the first five years of life, and the majority of these during the first two years.[1] The conclusion is self-evident that babies and young children must not be allowed to acquire whooping-cough if it is possible to prevent it. If the deaths which occur from the diseases which follow as complications from previous whooping-cough were properly recorded as secondary to whooping-cough, the seriousness of this disease would become even more evident than present statistics show.

There is no doubt that this disease is due to a contagium, and that this contagium is contained in the sputum and secretions of the upper air tract, and is transmitted to others by more or less close contact, either by droplets from spraying in sneezing or coughing, or by contact with infected handkerchiefs, napkins or bedclothes, or by contact with freshly sprayed or infected books, pencils, desks, chairs or eating utensils. Doubtless a frequent method of acquiring the disease is by kissing.

It is pretty well proved that the Bordet-Gengou bacillus is the cause of this disease. It seems to be established that the greatest infectivity occurs during the initial stages of whooping-cough, and that even during the active paroxysmal stage there is less liability of infection of others, and in the later stages there is probably no infective agent present. Some investigators even assert that a child should be allowed to return to school long before the paroxysmal stage is over, but that other children in the family of the child affected should not be allowed in school until it is shown that they will not have the disease. The disappearance of the infective bacillus and the consequent lessened danger of giving the disease to others seems to occur because some antibodies develop that prevent the further growth of the germ. It is certainly interesting that this contagious disease ceases to produce its contagium long before the symptoms of the disease have disappeared or the evident disease has ended. Whether or not this will be found true of scarlet fever and measles is of course not yet known, but it is markedly different from typhoid fever, pneumonia and diphtheria, in which the specific germs tend to persist a long time.

---

* Owing to lack of space the materia medica of lobelia, camphor and caffein has been largely omitted. It will be included when this series is published in book form.

[1] Morse: Whooping-Cough, The Journal A. M. A., May 31, 1913, p. 1677.

It has been shown that some domestic animals may be experimentally infected with whooping-cough; how frequently such animals become accidentally infected and are able to transmit the disease to children is not known. Probably, however, such a source of infection is rare. Kittens, puppies and monkeys have been experimentally infected with this germ.

Mallory and Horner[2] confirmed the opinion that the Bordet-Gengou bacillus is the cause of the infection of whooping-cough. This is a minute bacillus, occurring in large numbers among the cilia of the epithelial cells of the mucous membrane of the trachea and bronchi. It is stated that the germ does not grow above the larynx, although of course by coughing it reaches these parts. This germ is a small coccobacillus, and resembles the bacillus of influenza.

This disease is so readily acquired from one infected that some boards of health not only prohibit children who have it from attending school, but also prohibit their attending Sunday schools or public congregations, riding in public conveyances, playing in public parks, playing with other children on public squares, and from entering stores and theaters. Not to cause these children to be isolated in their homes, when fresh air is of great benefit to them, the boards of health of certain cities order that the child shall be tagged in some manner, perhaps with a button on which "whooping-cough" is printed in plain lettering. Just how carefully such ordinances will be carried out, and just how much they will reduce the frequency of whooping-cough, will be determined after full trial.

This disease occurs largely in epidemics, and young children and babies are apparently most susceptible to the disease. This may be more apparent than real from two reasons: first, because young children, necessarily remaining more in the house, are liable more frequently to come into contact with concentrated infected matter if an infected person comes near them, and secondly, because a large number of older children and the majority of adults have probably had the infection and have become immune. However, when an adult or elderly person acquires the disease it is almost invariably severe. The muscular strength of adults makes the paroxysmal coughing of much greater danger; they are more liable to emphysema, heart strain and hemorrhage. They are not so liable to have pneumonic complications. Whooping-cough, however, even in adult life, is a not infrequent stimulator of a latent tuberculosis. Often an adult, who is in close contact with a whooping-cough patient, and who may have had the disease in childhood, develops a mild form of the disease: at least they have the catarrhal symptoms and cough spasmodically occasionally. Whether the Bordet-Gengou bacillus is present in these cases has not been determined. It is a fact, however, that ordinarily one attack of the disease renders a person immune.

From the foregoing it will be seen how very important it is to make an early diagnosis of whooping-cough. While it is stated that the Bordet-Gengou bacillus may be generally demonstrated in true cases, a method termed the "complement-deviation" test is urged by some investigators. When positive, it is almost conclusive evidence of the disease being present, and when negative conclusive evidence that the disease is not present. Friedlander and Wagner[3] make the statement that in their opinion "the complement-deviation test is of the greatest possible value in the diagnosis at all stages." A description of the technic of this test is given by them.[3]

As both the identification of the Bordet-Gengou bacillus and this complement-fixation test require considerable time and skilled technic, examination of the blood for leukocytosis is suggested as a quicker method of determining whether or not the disease is present. A small leukocytosis, from nine to ten thousand, may be present as early as the third day, while during the paroxysmal stage it may run up to sixty thousand or more. It has been considered that in a suspected patient a leukocytosis from fifteen to thirty thousand (other diseases that cause leukocytosis being excluded), combined with catarrhal symptoms and the opportunity for infection, would give presumptive evidence that the disease developing is whooping-cough. In this leukocytosis there is a relative increase of lymphocytes. It is stated that this leukocytosis may be more or less present for from two to three months, and that in the stages of improvement a mild eosinophilia is found.[4] While leukocytosis is generally present in whooping-cough, its diagnostic importance must always be modified by the possibility that some other cause of this increase in white cells is present. It should also be remembered that leukocytosis is often present in young children from various causes.

The incubation period of pertussis is not definitely known, and may vary from two to ten days; therefore before it is considered safe for a child exposed to this infection to return to school or to play with other children, at least ten days must have elapsed, and perhaps a better working rule is two weeks.

Pathologically, the disease manifests itself by a catarrh of the upper bronchial tubes, trachea, larynx and perhaps pharynx and nose. The secretion is mostly mucus, with perhaps, later, a mucopurulent discharge from secondary infections. There are conditions, moreover, caused by a severe paroxysm of coughing, or by a prolongation of these paroxysms, in other words, hemorrhages; perhaps more or less emphysema; always cardiac strain, and perhaps cardiac dilatation; and, if frequent or repeated coughing, anemia and emaciation. Hemorrhages may occur from the nose, in the eyes, or even in the brain.

The cough is laryngeal in type, is at first dry, and later becomes spasmodic and paroxysmal, thus differing from that of ordinary colds; that is, the coughs occur in series, more or less periodically, or in showers. With these paroxysms there is more or less closing of the larynx, with the attempt at inspiration through a narrowed glottis, which causes the characteristic whoop. These paroxysms increase in frequency as the disease progresses, and are precipitated by any change in the atmosphere and by suddenly breathing in cold air, as by laughing, and even by swallowing food, and they sometimes occur without any apparent cause, because of irritation from the germ and its consequences. The number of paroxysms in twenty-four hours varies, but there may be as many as fifty. Early in the disease there may be a slight fever.

TREATMENT

Unless the patient has considerable rise of temperature, it may not be necessary to put him to bed, but, especially with children, the paroxysms are generally diminished if the child is kept in bed for a time, or at least kept quiet. The more active the child, the more paroxysms. Consequently, even without fever, if a child vomits almost every meal, or if he coughs so severely as to cause hemorrhages, or shows that the right side of the heart is becoming strained (which is the side of the heart most affected), he must be put to bed and remain there.

In most communities a schoolchild with whooping-cough is immediately sent home. In only a certain proportion of communities as yet is whooping-cough a reportable disease. There is no question that it should be reported; that the child affected should be isolated as much as possible; that the infection of others should be prevented, if possible, and that other children in the same family and perhaps in the same household or tenement, who are attending school, should be sent home until the period of incubation is past, dating from the last contact with the infected patient.

The methods of contact have already been suggested, and it is needless to emphasize the necessity for the school authorities to cleanse and clean the desk, chair and immediate surroundings of the child, and the books, pencils, etc., that he used. Also the children who sat in close relationship to this infected child should be watched by the medical inspector, or, perhaps, scientifically examined, as suggested above (that is, throat secretions and blood) and those who show any signs of infection should be sent home until it is shown that they have not become infected. These preventive measures seem almost too severe or too great for a disease that has been considered so simple, but, as previously stated, the disease and its results are not simple, and the number of deaths among young children is very great. One of the greatest advances in preventive medicine will be in diminishing this disease that has been so long neglected.

Instruction should be given by the physician to the mother, or whoever cares for the child with whooping-cough, as to how the prevention of infection of others should be carried out, such as the care of handkerchiefs, napkins, etc. In communities where the disease is reportable, the board of health should send instructions to the family.

The actual treatment of this disease may be divided into four heads: (1) to prevent the infection of others; (2) to shorten the disease, if possible; (3) to diminish the severity of the paroxysms; (4) to treat complications as they occur.

The first indication has already been considered.

The second indication is met by general hygiene and by drugs. Fresh air and sunshine, without exposure, are among the greatest mitigators of this disease. If the weather is pleasant, the child should be out doors or on a veranda most of the time. A child does much better in the country or at the seashore, if the season and circumstances will allow it. If the child is too sick, or the weather is such that it is impossible to remain outdoors, he should be isolated in one, or better, in two large rooms, so that while one room is being thoroughly aired and cleansed he may go to the other one. There seems to be no question that the more infected or polluted the atmosphere of a room, the more the child will cough. Whether such an atmosphere simply irritates, or he reinfects himself instead of having his infection diminished, is unimportant. The fact remains that the ventilation must be excellent to diminish the frequency of the paroxysms.

Another important factor is nutrition. If the child vomits a meal as soon as he has eaten it, during a paroxysm, in a few minutes he should be given food again, with the probability that the next paroxysm will not so quickly occur but that the food may remain in the stomach and be digested. A child that receives insufficient nourishment from any reason should be given food more frequently. The character of the food should depend on his condition, and should be that which is found to be less frequently vomited. The best diet is cereal and vegetable, with milk and eggs. The end-products of meat metabolism are likely to raise the excitability and irritability of any one whose nervous system is irritated. For this reason meat should not be given, and no tea or coffee. A patient who is not allowed meat should receive a small dose of iron once or twice a day. Calcium in any simple form may be used as a nervous sedative and a nutrient. Hot baths before going to bed relax the nervous system and quiet the patient. Also massage is sometimes soothing. Of course, it is always essential to have the bowels move daily. Plenty of water should be given the child, as the more moist the mucous membranes, the less they are irritated, and the less frequent the paroxysms. For this object many inhalants have been advised. Perhaps the most important element of these inhalants, whether sprays or steam, is the water that they contain. Sometimes bland petroleum oils atomized and inhaled soothe the irritated mucous membranes.

Various antiseptics have been suggested. The most frequently used is perhaps phenol (carbolic acid) in some form, and very popular has been the vaporization of a phenol combination in the atmosphere of the room. There is no question that phenol tends to benumb peripheral nerves. If much phenol was absorbed it would disturb the kidneys. Exactly what are the germicidal constituents or powers of such inhalants has not been determined. Phenol sprays have been used in from 0.5 to 1 per cent. strength. Antipyrin as a spray and gargle has been much used as a germicide in from 5 to 10 per cent. strength, and has been much lauded in this disease. Quinin sprays, though more disagreeable, have been used in the throat as germicides. Various combinations with thymol and eucalyptol, and other mild aromatic antiseptics, have been used as sprays and gargles or inhalants. It is quite probable that a creosote or other antiseptic inhalant may inhibit the growth of germs in the trachea and upper large bronchi, provided the patient is old enough to cooperate and inhale the vapor into the lungs to that depth. As an application in the pharynx and mouth, hydrogen peroxid solutions, 1 : 5, would be as efficient as anything that could be offered. Many times, however, these "antiseptic" inhalants or atomizing substances cause irritation and paroxysms, and must be abolished, while mild alkaline solutions, well represented by ¼ teaspoonful of sodium chlorid and ¼ teaspoonful of sodium bicarbonate in a glass of warm water, cleanse and soothe the throat without causing paroxysms.

There are still many who believe that quinin given internally will shorten the disease. It has not yet been shown that quinin inhibits the growth of the Bordet-Gengou bacillus. If there is any tendency to secondary infection in the nasopharynx, with congestion of the ears, of course quinin should not be given.

Also, to meet this indication and shorten the disease is the vaccine treatment. The exact value of vaccine in this disease has not been demonstrated.

Sill[5] made a study of this treatment in whooping-cough, and found that the dose of the bacillus should be 50 million, and this dose given every other day in ordinary cases, and every day, or 100 million every other day, in severe cases. The injections were given into the abdomen or buttocks. He thinks that the average dose should be determined by the severity of the disease, and not by the age of the child, and he vaccinated a child even as young as 1 month old. He feels sure that the length of the paroxysmal stage of the disease is diminished, and that the paroxysms are diminished in severity.

Immunizing doses, to prevent the development of the disease in other children of the family, have been given in doses of 20 million bacilli, and the dose repeated four or more times, and the disease has been apparently prevented by such vaccination. More recently Hess[6] has made a careful study of the vaccine treatment of whooping-cough, and was disappointed in this treatment of the disease; but he did find that in a certain percentage of cases immunizing doses prevented the development of the disease, although this prophylaxis was far less efficient than is typhoid vaccine in preventing typhoid fever. Positive conclusions, therefore, as to the value of vaccine treatment in whooping-cough cannot yet be made.

The third indication, namely, to diminish the severity of the paroxysms, is of great importance. It has already been stated that the more quiet the child, the less frequent will be the paroxysms. Also, if the child lies down as soon as he begins to cough, he is less likely to vomit. An elastic abdominal belt seems to be of value in controlling the vomiting and the paroxysms of young infants especially. In some patients the paroxysms are so severe that chloroform inhalations have been given to prevent the intensity of the spasms. Also, it has been stated that inhalations of chloroform actually lengthen the time between the paroxysms and shorten the disease. Chloroform inhalations may act as a germicde. On the other hand, the frequent administration of chloroform, even in small doses, is known to injure both heart and kidneys.

The most effective of all medicinal treatments, in the opinion of several authorities, is antipyrin and digitalis. A very good rule for the dosage of antipyrin is 0.05 gm. (about 1 grain) for every year of the child's age. This should be given three or four times a day, depending on the frequency of the paroxysms. The frequency should be diminished as the frequency of the paroxysms diminishes. Coincident with the antipyrin should be given digitalis in the form of the tincture, and in the dose proper for the child's age, and determined by its effect on the child's heart and pulse. The heart needs help, both from the strain of the disease and also as antipyrin might cause some weakening of the heart. The antipyrin acts by causing less irritability of the nervous system and relaxing muscle spasm. Even although the drug has disadvantages, its disadvantages are much less than the harm caused by the whooping-cough paroxysms.

The bromids have been frequently given and in large doses. They act by inhibiting the reflex activity of the nervous system and by more or less dulling the peripheral nerves in the throat and upper air passages. Chloral has been used in order to depress the nervous irritability. Atropin or belladonna have been given in large doses, and their value must be in dulling the peripheral nerves in the irritated part of the body. Atropin is a stimulant, and cannot have any good effect in this disease, unless the dose is very large, and with such large doses atropin intoxication readily occurs, that is, the pulse becomes rapid, the throat dry, the face flushed, and there is likely to be cerebral excitation and perhaps dilated pupils.

Antipyrin is best given to a child in solution, as follows:

	Gm. or c.c.	
℞ Antipyrinae	5|	ʒ iss
Aquae menthae piperitae...	100|	fl℥ iv

M. et Sig: A teaspoonful, in water, three or four times a day.

This dosage is for a child 5 years old.

Various hydrotherapeutic measures are often of value, and the hot bath is always useful in quieting the patient and relieving internal congestions.

The fourth indication, namely, to treat complications as they occur, is almost supererogation, as each complication calls for its proper treatment. However, under this heading the prevention of such complications may be urged. Vomiting may be prevented by quiet, rest for a while after eating, by the abdominal belt and by proper food. Nutrition must be kept up at any cost, and, if necessary, the child given simple liquid nourishment every three hours. Not infrequently cod-liver oil is well borne and is an oil nutriment of great value. Anemia must be prevented by iron. If it is seen that the heart is becoming strained, and the face and throat remain congested even after the paroxysm is over, showing that the right ventricle is in trouble, digitalis should be given and such rest as would be given any damaged heart. This treatment also tends to prevent hemorrhages. Even if the child is weak and the circulation is weak, strychnin is inadvisable, as it stimulates the nervous system and causes or allows more paroxysms to occur.

If the child has a history of enlarged glands or recurrent colds, or has inherited a tendency to tuberculosis, or tuberculosis has been present in the child's family, its convalescence after whooping-cough should be prolonged, and country or seashore air should be urged where possible. Certainly, such a child should not be confined in school until his nutrition has become as good as before the infection with whooping-cough occurred.

(To be continued)

THE BACTERIOLOGY OF THE WOUNDS IN THE WAR

Precisely as the European conflict has developed hitherto unused and unexpected methods of warfare, so it has brought with it new problems in military surgery and new aspects of surgical bacteriology. In previous issues of The Journal[1] we have published foreign correspondence indicating the peculiar nature of some of the wounds encountered and referring to some of the characteristics of the suppurations and wound infections and their consequences following the injuries received on the battlefields. The detailed reports[2] of some of the bacteriologic investigations which have been conducted in the French hospitals furnish an interesting account of the microbial flora of the wounds in this campaign, and serve alike to explain some of the consequences and to indicate the surgical procedures that may be called for in the management of the wounded on the French and Belgian frontiers. Examinations made in Metchnikoff's laboratory[3] in Paris indicate that so-called aseptic wounds, such as are produced by bullets and do not suppurate, are frequently free from micro-organisms. Saprophytic forms are found in rare instances and may include members of the proteus group, of which the pathogenic power is recognized to be usually slight. The proteus infections heretofore reported in man have almost invariably occurred in combination with some other micro-organism. The *Bacillus putrificus* (Metchnikoff) has also been found in such wounds, from which the organisms disappear in the course of a few days.

The list of pathogenic bacteria includes in greatest prominence pyogenic cocci, streptococci occasionally being found in almost pure culture, notably in penetrating wounds of the skull and in simple bullet wounds of limbs. The streptococci isolated are described to be of only slight virulence, and erysipelas is reported in few instances at most. The staphylococci, so frequently encountered in the surgical lesions of animals and man, accompany the streptococci in most of the open wounds, particularly when septic foreign substances such as shrapnel balls, fragments of shells and pieces of clothing are present. The wounds infected by these two groups of organisms rarely prove offensive. After drainage and suitable packing with antiseptic gauze, they heal readily and never present a gangrenous appearance.

An added danger, however, rests in the occurrence of the *Bacillus aerogenes capsulatus,* widely known also as the *Bacillus welchii* and in France as *B. perfringens,* though they are sometimes described separately. This organism, according to Doyon and Yamanouchi, has been found associated with staphylococci and streptococci in all the purulent wounds in the cases examined by them in which there was superficial or localized gangrene, benign phlegmonous conditions, or emphysematous gangrene (the *gangrène gazeuse foudroyante* of French writers).

The observation of the presence of the same organism, *Bacillus aerogenes capsulatus,* in the comparatively healthy wounds as well as in those exhibiting subcutaneous emphysema, presents a difficult problem in surgical bacteriology. Apparently it can exist as a harmless saprophyte in the pus of open wounds in the process of healing. It has, of course, long been recognized that the pathogenicity of this organism may be slight, and that its virulence is subject to great variations. Usually, when the infection follows traumatism on the extremities, it is characterized by a rapidly necrotizing inflammation with which there occurs extensive subcutaneous emphysema, and becomes extremely grave. The differences in apparent virulence thus far noted by the French bacteriologists are apparently associated with the differences in the location of the wounds. When the latter are superficial, the severer symptoms attributable to the gas-producing bacillus do not occur; they arise in the deeper parts, in which the environment and closed spaces are more favorable for the propagation of an organism that is preferably anaerobic.

If to the preceding is added the occasional finding of the organism of tetanus, the excitatory agents of the septic and systemic conditions observed are covered for a large number of the cases. The pathogenetic flora appears to be surprisingly uniform in character and to have possessed a relatively feeble virulence up to the time of the present reports. The risks involved depend on the nature of the wounds received, their depth, their ramifications, and the degree of traumatism. So far as bacteriologic considerations and infections are concerned, the surgeons are learning to distinguish the types and to treat them in a discriminating way rather than by a fixed routine of wound management. They take into cognizance the fact that whereas in most localities wound infection is almost exclusively due to staphylococci and streptococci, on the Franco-Belgian border anaerobic gas-forming organisms are present along with them. Explanation of this has been ventured from several sources. The *Bacillus aerogenes capsulatus* and other anaerobic forms reported are frequently present in the normal intestinal contents, where their presence in abnormally high proportions is indicated by a Gram stain of a smear of the feces. In a report to the sanitary service of the British army in France, Weinberg[4] therefore argues that it is logical to assume that the anaerobic organisms found in the wounds are originally of intestinal derivation. The earth in the trenches from which those suffering with emphysematous gangrene and harboring the Welch bacillus were taken is often soiled with human dejecta and manure. Remnants of filthy clothing likewise find their way into the wounds.

THE EXTENT AND SPREAD OF ROCKY MOUNTAIN SPOTTED FEVER

Since 1902 it has been generally recognized that Rocky Mountain spotted fever is a disease that prevails in certain localities in the Western States. As a result of researches, notably those of Wilson and Chowning, Ricketts and his associates, and of representatives of the Public Health Service, we now have definite knowledge as to the means by which the disease is spread from individual to individual and from one locality to another. A recent report[5] by the Public Health Service on this disease shows it to be present in nine Rocky Mountain and Pacific Coast States. Cases have been reported during more than one tick season from certain localities within these states, and these localities are recognized as being definite areas of infection; that is, they harbor infective wood ticks capable of transmitting Rocky Mountain spotted fever to human beings by their bites.

Outside of the Snake River Valley in southern Idaho and the Great Basin region, the infected areas are rather definitely outlined and small in extent as compared with the total territory in which they are included. Thus the disease is known to be present only in restricted areas of southern and southwestern Montana, southeastern Washington and northeastern California. It is probable that further investigation and the settlement of uninhabited regions in these states may show other isolated areas of infection, but there is no reason for believing that the older communities which have been free from the disease will not remain so unless infective ticks are introduced and the infection thereby established in the community. There is no evidence to show that Rocky Mountain spotted fever has been introduced into any of the present known areas of infection within very recent years, cases having been reported from the different regions involved since the disease was first recognized.

The epidemiologic study of Rocky Mountain spotted fever, however, has been both too brief and too incomplete to enable us to determine whether the disease is at present spreading into uninfected territory or what the danger of its future spread may be. Under ordinary conditions, wood ticks remain close to the place where they are hatched, and none of the animals which have been found susceptible to Rocky Mountain spotted fever infection are great travelers. Also, since the infection in animals is an acute condition, lasting not longer than two weeks, there is slight danger of their spreading the disease in the way that rats may spread bubonic plague.

For these reasons it is believed that the usual way in which the spread of Rocky Mountain spotted fever takes place is by means of infected adult wood ticks attached to their animal hosts, either domestic or wild. These large animals, which may serve as hosts for the adult ticks, may travel many miles before dropping the engorged ticks, and the distribution of the infected areas along the water courses in the Northwest seems to point to this as the probable method by which the infection was spread by deer, elk, buffalo and range cattle.

It would seem also that a real danger exists in the shipment by rail of elk and domestic animals which may harbor infected ticks to points within a radius of at least ten days' travel. It has been found that eastern ticks are capable of transmitting Rocky Mountain spotted fever experimentally, and it is conceivable that infected ticks introduced in this way into any heavily tick-infested part of the United States might establish foci of infection. The process would probably require very favorable conditions and several years' time for its completion. In the meantime the introduction of the ticks will have been forgotten and the true nature of the first case perhaps remain unsuspected.

For these reasons it will be well if physicians, particularly those practicing in rural districts throughout the United States, keep a watch for suspicious cases occurring in the spring and early summer among their patients who have been exposed to tick bites, and that the cases when recognized be reported.

A point of great practical value in Fricks' report[5] is in regard to the value of sheep-grazing as a means of tick eradication, which was first suggested by the same author[6] in 1913 and to which we referred at the time.[7] According to Fricks, the four factors on which the success of sheep grazing as a tick eradicative measure depends are, first, the removal of undergrowth and the consequent destruction of good tick country by close grazing; second, the destruction or removal from the sheep range of other mammals, domestic and wild, which may serve as hosts for adult ticks; third, the destruction of the ticks themselves, principally by tangling themselves in the wool of the grazing sheep; fourth, the placing of the problem of tick eradication on an economic basis, so that it may be carried out on an extensive scale without cost to the government, the state or the inhabitants of the valley.

[5] Fricks, L. D.: Rocky Mountain Spotted Fever: A Report of Its Investigation and of Measures Undertaken for Its Eradication During 1914, Pub. Health Rep., Jan. 15, 1915, p. 148.

The experiments made during the past season were conducted with two bands of sheep numbering about 1,500. The experiments were begun about the middle of April and terminated about the middle of July, when the sheep were sheared, dipped and returned to their owners. During the experiments, sheep of both bands were searched for dead and live ticks, and it was estimated that over 25,000 adult ticks were destroyed by the 1,500 sheep during this period.

All the observations so far made point to sheep grazing, certain important principles being borne in mind, as a practical, rapid, efficient and economical method of tick eradication in the Bitter Root Valley.

MEDICAL SCHOOL ATTENDANCE

In an article on university registration statistics, *Science*[8] furnishes a tabulation of the attendance at thirty of the universities of the country. The editor suggests that there is a theory that universities and colleges have unusually large increases in numbers of students when national economic conditions are at a low ebb, that is, during "hard times." The registration statistics presented in the article referred to seem to bear this out. The period of depression in the early portion of 1914 was prolonged by the declaration of war. Perhaps as a consequence, at least as a coincidence, three universities, Columbia, California and Pittsburgh, gained over 1,000 students each in all departments; six, Ohio State, Wisconsin, New York University, Minnesota and Pennsylvania, gained more than 500, and five others, Illinois, Nebraska, Cornell, Cincinnati and Michigan, gained over 300.

It is usually said that the increase of registration in hard times is particularly to be noted in the professional schools, apparently because business reverses make men realize that the mental capital required for professional work is of greater permanent value than the more material resources demanded for commercial and financial success. There is a noteworthy increase of registration in dentistry; the University of Pennsylvania has 663 students enrolled in its dental department; Northwestern, 578; Michigan, 318; Iowa State, 302; Minnesota, 253; Pittsburgh, 227, and Harvard, 204. The remarkable increase in all the departments of the University of Pittsburgh has brought that institution into a prominent place in the statistics, for it gained altogether 1,069 students. This gain was exclusive of any addition in numbers from attendance at summer sessions, which swelled the figures for other institutions.

The statistics referred to show that our universities now begin to rival even the largest of the foreign universities in the numbers of students registered. During the present year, and while the war lasts, there will of course be much more educational activity in this country than in any of the countries of Europe. The following universities now have more than 5,000 students in attendance: Columbia, 11,294; California, 8,180; Chicago, 7,131; Wisconsin, 6,696; Pennsylvania, 6,505; Harvard, 6,411; Michigan, 6,319; New York University, 6,142; Cornell, 5,939; Illinois, 5,664.

In regard to the number of medical students, however, the increase shown by the statistics cannot be taken as an index of the enrolments in all medical schools. Statistics gathered by the Council on Medical Education show that practically all of the medical colleges which had adopted higher entrance requirements prior to the beginning of the present session had increased enrolments. Instead of being due to hard times, however, this increase was doubtless influenced by the extensive agitation in recent years pointing to the need of a better preliminary education for students who were to enter on the study of medicine. A more immediate factor, perhaps, is that thirty-seven other medical colleges at the beginning of the present session put into effect for the first time the requirement of one year of collegiate work, in addition to the usual high school education. These thirty-seven colleges naturally had smaller enrolments which more than offset the increased registrations in the colleges referred to above. Incidentally, even the increased registration in dental colleges may have been due less to hard times than to the higher entrance requirements of these thirty-seven medical colleges.

Altogether, instead of there being an increase in the enrolments of medical colleges during this session, it is quite evident from the figures gathered by the Council on Medical Education that there will be a decided decrease. Of about sixty-five medical colleges from which reports have been received, enrolments show that this decrease will be about 8 per cent., as compared with from 3 to 6 per cent. in each of the last few years. The raising of the standards for admission to medical colleges, therefore, has had a favorable effect in decreasing the number of those who take up medicine as a life work. The number has been reduced to nearly the normal supply for this country, and that supply will be much better qualified.

CALCIUM AND PARATHYROID TETANY

The removal of the parathyroid glands generally leads to early death preceded by very characteristic nervous and muscular disturbances described under the name of tetany. Various attempts have been made to bring this pathologic phenomenon into a causal relation to a deficiency in calcium in the circulating fluids. Removal of the glands has been alleged to be attended with a loss of calcium, on the one hand, and the injection of salts of this element has repeatedly been demonstrated to suppress the tetany symptoms in affected animals. It is quite conceivable, however, that such an effect of introduction of calcium is due to a sedative action instead of a restoration of an element which may be assumed to be available in abundance in an organism possessed of a bony skeleton.

Experimental investigations in the department of pathology at Columbia University, New York, have attacked the question of the relation of calcium salts to tetany in a somewhat new way.[1] Normal blood was dialyzed in such a manner as to remove from it a large part of its calcium. The dialyzed blood when perfused through an isolated extremity produces an extreme hyperexcitability of the nerves quite like that observed in tetany. Since perfusion with blood dialyzed in precisely the same way against a fluid of the same composition, but containing calcium in the proportion found in the normal blood, causes no hyperexcitability of the nerves, it is evident that the hyperexcitability is due to the lack of the element. This effect can be attained in only a slight degree by replacing the blood of a whole animal with the dialyzed blood, since under the conditions of the experiment the tissues cannot be sufficiently depleted of their calcium. It seems probable to the New York investigators that the parathyroid secretion is not removed by dialysis, but is returned to the body with the dialyzed blood.

To bring this result into relation with the condition in tetany following parathyroidectomy, animals in tetany were bled by MacCallum and his collaborators and the blood was replaced, in one case with normal blood, in the other with dialyzed blood poor in calcium. The normal blood is said to relieve the tetany and lower the excitability immediately, whereas the dialyzed blood does not. This is the further evidence now presented to maintain that in the tetany of parathyroidectomy also the twitching and the hyperexcitability of the nerves is due to lack of calcium in the blood and tissues. An added bit of hypothesis — it must not be taken more seriously — is that the parathyroid secretion governs the conversion of a nondiffusible and physiologically useless combination of calcium into a diffusible form which is essential in maintaining the control of the excitability of the nervous system. It is suggested that the essential product is lost in the excreta and not formed anew in the absence of parathyroid secretion.

HISTOGENESIS OF NEUROMA, AND REGENERATION OF PERIPHERAL NERVES

So long ago as 1859, Bidder and Kuyfer originated the conception that axis cylinders grow outward from the nerve cells, and that regeneration of nerve fibers is a result of proliferation of the distal end of the axis cylinders, each cylinder having at its end "an incremental cone of growth." This view, which long has held sway, is now being questioned. It has been found that undifferentiated cells from the early medullary tube or neural crest, after remaining undeveloped and dormant in the tissues, may take on activity and, it is asserted, develop into nerve fibers. As seen in neuromas, Weichselbaum interpreted such undifferentiated cells as cells of the sheath of Schwann. Kennedy,[1] on examination of specimens from both ends of a nerve previous to its suture, found irregularly arranged groups of new nerve fibers both centrally and peripherally, and on the distal side were enormous numbers of spindle-shaped nuclei among the nerve fibers which he thinks had arisen by proliferation from the nuclei of the sheath of Schwann. Head and Ham[2] have shown that the ununited distal end of a nerve may remain in a "resting stage" for as long as 540 days. If then united to the central end, it is completely restored. This return to function seems too rapid for the proximal axis cylinders to have grown out to the structures originally supplied by the nerve. Recent observations by Bruce and Dawson[3] on neuromas of the central nervous system are of interest in this connection. Their observations and review of the literature are so complete that practically all that is known of the structure and histogenesis of true neuroma is stated in their article.

In their case, numerous small nodules were scattered through the pons, medulla and the spinal cord, which varied in size from microscopic groups of cells in the midst of fiber tracts or in the wall of a vessel to larger nodules easily visible and displacing the structures about them. In the cord the nodules were formed always in relation to the pia, pial septa or the adventitia of the blood vessels, both the vessels passing into the cord from the pia and those within the cord. In the pons and medulla the nodules were present in both motor and sensory tracts, and were here also closely related to the walls of vessels. The neuromatous growth appears in the pons and medulla to arise as patches among the fiber tracts, and consisted of cells derived from the sheath of Schwann, which were fusiform and joined each other end to end to form nucleated, protoplasmic tubes pushing along the pial spaces. Small or large bundles of these tubes were found. The number of tubes in each bundle varied from three to twelve or more. These tubes developed central filaments which later became axis cylinders, and about them beginning myelin sheath formation was observed. Complete myelinization did not occur, however, unless the new-formed nerve tube became connected with a central nerve cell through its axis cylinder. These new fibers pushed along the adventitia of the vessels and followed the paths of the glia fibrils or along the pial spaces, most likely because these were paths of least resistance. When obstruction was encountered, they became twisted and tangled, and tended to whorl formation. A section through a nodule at this period in its development gave the appearance of a patch of interlacing, nucleated fibers and protoplasmic tubes twisted and coiled about each other. There were numerous blood vessels in these meshes. Still later, fibrous elements would become more prominent, and tended to displace and conceal the nerve fibers.

[2] Head and Ham: The Process of Regeneration in an Afferent Nerve, Jour. Physiol., 1904-1905, xxxii, 9.

[3] Bruce and Dawson: Multiple Neuromata of the Central Nervous System: Their Structure and Histogenesis, Review of Neurology and Psychiatry, 1913, xi, Nos. 3 to 7, pp. 117, 179, 235, 293.

In the cord the nodule formation was similar, first starting from proliferated cells of the sheath of Schwann. Protoplasmic tube and whorl formation proceeded as in the brain. Here, however, the tumors were further advanced, and the histogenesis of the neuroma determined with much greater difficulty, owing to the secondary changes in the nodules, namely, fibrosis and sclerosis, which tended to destroy the nerve elements. In a few of the older tumors, individual fibers were found coming in direct contact with nerves of the anterior horn region. About the posterior roots of the cord no tumors were found, but considerable fibrosis had occurred, resulting in degeneration of the nerve sheaths in the fibrosed areas. No passage inward of new nerve fibers into the intermedullary spaces could be found here.

Naturally Bruce and Dawson, influenced by their observations, favor the view that detached neuroblastic cells give rise to true neuromas and to regeneration of nerves. Like other "peripheralists," however, they do not dispute an important influence of the central cell body on the peripheral nerve which aids in completing the myelinization of the nerve fiber and in restoring function.

The Most Difficult Art.—Accurate observation is by far the most difficult art which mankind has ever essayed. A nation may count on furnishing abundance of military talent, plenty of politicians and statesmen, enough of competent lawyers; it may even hope to have gifted artists and authors; but it can scarcely expect to produce a single master of the art of observation in a century. In a century Germany produces one Helmholtz, France one Pasteur, England one Darwin—an American peer of these three is yet to become known.—Minot.

Current Comment

USING THE MEDICAL PROFESSION AS AN ADVERTISING AGENCY

The Journal has called attention repeatedly t the way in which the medical profession has bee used by the exploiters of proprietary medicines fo the purpose of introducing their wares to the public. In the past, one of the cheapest methods o putting a "patent medicine" on the market has bee to call the stuff an "ethical proprietary," advertise i exclusively in medical journals (whose advertising rates are much less than those of newspapers), freely sample the medical profession, put up the product in packages that are plainly intended to give the public all the information that may be necessary—and let time do the rest. And time has done it. When physicians have awakened to the fact that they have once more been used as tools, and the preparation is very plainly nothing but a nostrum, then the shrewd manufacturer turns his back on the medical profession and goes over openly to the place he belongs—the public press. The Advertising Association of Chicago, in its weekly bulletin for Jan. 4, 1915, prints a letter that has been received by an American advertising man from a German firm that wanted to place a medicinal product on the American market. One paragraph in the letter bears on the matter under discussion. Here it is:

> "We beg to mention that the preparations are to be puffed in the first rank and principally so that the physicians (doctors) get acquainted with the same, and it is not necessary to puff them *for the present* in other classes of the public."

We have italicized the three words that have a special significance. Put more crudely, the proprietors of this preparation say: Advertise it at first exclusively to physicians and after they have brought it widely to the attention of the public, then it will be time enough for us to advertise it direct to the public. How long is the medical profession going to retain its unenviable distinction of being a huge advertising agency for the nostrum exploiter?

OSWALD LOEB

There are few pharmacologists capable of doing research work of the highest order, and, at the same time, well-informed, and interested in the broader problems connected with the use of drugs. It is still more rare to find a man thus qualified who has the courage to criticize fearlessly whatever partakes of fraud, humbuggery or exaggeration connected with the exploitation of drugs. Such a man was Oswald Loeb of Göttingen, whose death, while serving at the front with the German army, we briefly noted in our issue of Nov. 21, 1914. We have frequently called attention to the propaganda for reform in proprietary medicines which Professor Heubner, corresponding member of the Council on Pharmacy and Chemistry, head of the department of pharmacology at Göttingen, and one of the editors of the *Therapeutische Monatshefte*, has for some time been carrying on in Germany against great odds, and to the German Arzneimittelkommission, the aims of which are similar to those of our Council on Pharmacy and Chemistry. In this work Professor Loeb took a prominent part, and his critical discussion of new drugs in the *Therapeutische Monatshefte* will long be remembered; he brought to this usually unpopular and thankless work the same earnest love for truth and keenly critical attitude that characterized his research work. As one of the many possible examples of the manner in which he approached new drugs, his discussion of Elarson may be cited.[1] This is a new arsenic preparation put forward by Emil Fischer and G. Klemperer, names held in such high esteem that most writers seem to have been deterred from even questioning their claims. Loeb reviewed their publication, and concluded: "All this is not remarkable; it is also not remarkable that one arsenic compound sometimes succeeds when another seems to fail. When the authors remark that new arsenic compounds do not seem to them to be superfluous, the question arises if this new preparation is not really superfluous. Cannot the same results be obtained with the well-known Fowler's solution, and also, by the administration of smaller doses, not only the patient's alimentary tract but his purse be protected? . . . The clinical reports so far made do not prove that the materia medica has been enriched by it." This questioning attitude concerning Elarson seems to have been fully justified by the recent pharmacologic studies of Joachimoglu.[2] In these days, when critical readers have been forced to view with skepticism much of what appears in German medical publications concerning new drugs, when they feel that these are too often being tried before judges and juries more or less financially interested in the verdict, it was refreshing to read the discussions of Loeb and his co-workers in the *Therapeutische Monatshefte,* and we join the editorial staff of that publication in expressing our appreciation of his work and sorrow at his untimely death.

FOOD OF THE TSETSE FLY

Inasmuch as the tsetse flies are now recognized to play a very important rôle in the transmission of infectious organisms connected with the tropical diseases of both man and animals, every feature in the life habits of the insects becomes a matter of medical interest. The sleeping-sickness areas of Africa abound in swarms of these flies. They suck the blood of individuals infected with trypanosomes and thereupon become the carriers of these biologic agents and transmitters of diseases caused by them. The question has arisen whether the tsetse flies habitually feed on blood or whether other types of food are acceptable to them. The members of the Scientific Commission of the Royal Society of London, in Nyasaland, 1912-1914, under the leadership of Surgeon-General Sir David Bruce,[3] have examined the alimentary tracts of a large number of the flies caught in one of the fly areas in Nyasaland. The insects were all caught in the bush, away from the paths. The microscopic inspection showed that the food of the species investigated, *Glossina morsitans,* consists mainly of mammalian blood. Of the 500 flies examined, 288, or 57.6 per cent., were found to contain this in a recognizable state. No measurements were made of the corpuscles, which in most cases were much altered by the digestive processes; but there seemed to be a predominance of the small type of cell, such as occurs in the hartbeest, waterbuck and other antelopes. Of the flies which contained recognizable blood, only 1 per cent. exhibited nucleated blood, which was probably avian rather than reptilian. In no case was vegetable matter noted in the intestinal contents. From such experiments as were conducted in the laboratory it was conjectured that the flies feed naturally at least once in every five or six days. There is no difference in the feeding habits of the males and females.

IMMIGRATION PROBLEMS OF THE FUTURE

Among the many far-reaching effects of the present European war, the influence exerted on immigration assumes a prominent place. The end of the last fiscal year saw a total of 1,485,957 added to our population from this source.[1] The influx of immigration proceeded at the normal rate until it was given a sudden check by the declaration of war in August, when the average daily landing of 3,000 or more at Ellis Island became barely that many a week. There seems to be a general agreement that the cessation of the war will see a renewal of the flood of immigrants which will surpass anything heretofore experienced. The country is alert to this possibility, and preparations to meet the expected increase are already in evidence. The proposed changes in our immigration laws will, if enacted, enforce more rigid physical requirements than any previous legislation on this subject. There is no doubt that the country needs these added safeguards. The truth of this statement is forcibly illustrated by that section of the report of the Committee on Inquiry into the Department of Health, Charities, and Bellevue and Allied Hospitals of New York City, which deals with aliens in institutions.[2] The committee examined, as far as practicable, every patient admitted to Bellevue for a period of thirty-one days from May 19, 1913, to June 18, 1913, inclusive. Of the 3,454 admissions during that period, 363 were aliens who had been in the United States less than five years. The physicians who examined these aliens believed that there were 185 of them suffering from diseases caused by conditions which existed prior to landing in the United States. Among these were 10 cases of pulmonary tuberculosis; 15 cases of venereal disease; 81 psychopathic cases; 2 cases of epilepsy, and 2 of imbecility. This made a total of 110 patients in one month whose admission to the United States was contrary to the federal immigration law. Taking this month as a basis, the committee estimates that in one year Bellevue Hospital would receive 1,345 alien patients whose exclusion from this country is mandatory under existing federal statutes, while the total number of aliens who would be patients from causes existing prior to landing would be 2,262 yearly. This large number of physically and mentally defective aliens have succeeded in passing the examinations at entrance primarily because there are totally inadequate facilities for examining such a large number in the time allotted for the work. Now that immigration has declined to 3,000 a week, the physicians at Ellis Island have been able to make more thorough examinations. As a result of this intensive scrutiny, the percentage of defects noted has increased from the former 2 or 3 per cent. to about 7 per cent.[3] The difference in the results obtained suggests the advisability of urging the Department of Labor to provide the increased facilities which will be absolutely necessary if the physicians continue their present thorough methods of examination when immigration resumes its normal course.

MYSTERY, THE ESSENTIAL

The entire superstructure of fraud in medicine has for its foundations secrecy and mystery. Take away these elements, and that gigantic monument to human credulity—the "patent medicine" business—crumbles. Hence the frantic efforts of those who have built fortunes through the exploitation of nostrums in opposing every movement that would permit the public to know the drugs it is taking in "patent medicines." About a hundred and fifty years ago Mrs. Stephens in England claimed to have discovered a cure for "gravel and stone in the bladder and kidneys." So skilfully did she call her wares that she deluded ignorant and educated alike into a belief in her discovery. Dr. David Hartley, physician and philosopher, collected and published reports of one hundred and fifty cases—his own among them—showing the value of Mrs. Stephens' "cure." Convinced that Mrs. Stephens had discovered a boon to suffering humanity, many urged her to make public the secret of her formula. Quack-like she refused, but—also quack-like—she offered to give up the formula for five thousand pounds ($25,000). Attempts were made to raise this amount by public subscription, but without success. In spite of the fact that many contributed to this fund, only about thirteen hundred pounds was raised. Parliament was then petitioned to make a grant, which, in due time, it did. Mrs. Stephens got her five thousand pounds and the public got her "formula." The latter was published in the London *Gazette*. The "cure" consisted of egg shells, snails (shells and all), hips and haws, ash-keys, swine cress and various other vegetables all burned to a cinder and the ash mixed with camomile flowers and fennel and other vegetables. But alas! Now that the public knew what was in Mrs. Stephens' nostrum, it would have none of it. The cure fell into disrepute, and finally went the way of all such frauds, into oblivion. Dr. Hartley died of the disease of which he believed Mrs. Stephens had cured him.

HEAT, HUMIDITY AND WORKING POWER

The question as to what constitutes a vitiate atmosphere, and wherein the depressing effects o "bad" air are to be found, was recently considered i The Journal.[1] Of late, temperature and humidit rather than abnormal quantities of the respired gases carbon dioxid and oxygen, or the presence of harmfu expired organic products of respiration, have bee held responsible for the untoward consequences o living under conditions of poor ventilation. Drs. Le and Scott,[2] of the College of Physicians and Surgeon at Columbia University, have recently reported definit objective signs of physical inefficiency in individual subjected to an atmosphere of high humidity and high temperature. Measurements were made on the working capacity, that is, the total amount of work which excised muscles of animals are capable of doing before exhaustion sets in. The subjects were kept, to cite a specific illustration, at 21 C. (69.8 F.), with an approximate humidity of 54 per cent., in one case, and a 33 C. (91.4 F.), with a humidity of 89 per cent., in the other. The contrasts here quoted represent the distinctions between comfortable atmospheric conditions and the air of a hot, humid summer day. As an outcome there was a marked diminution in both the amount of work performed and the period of working power under the influence of high temperature and humidity. Under these conditions, furthermore, the body temperature also rose somewhat. The facts thus cited confirm by the unbiased testimony of direct experiment what the sensations and psychic responses of man have long since intimated.

THE SEX OF THE INSANE

Of approximately every five hundred persons in the United States in 1910, there was one an inmate of an insane asylum. The exact figures expressed in a recent report[3] state that in a typical community of 200,000 persons, equally divided as to sex, 208 of the males and 200 of the females would be found in the insane asylums. In the course of a year, 72 males and 60 females would be admitted to the asylums. In 1880 the total number of inmates in insane asylums in the United States included 20,635 males and 20,307 females. Thirty years later the number of male inmates had increased to 98,695, and the number of female inmates to 80,096. The excess of men among admissions in 1910 indicated a still further increase in the proportion, namely, 128 males to 100 females. An analysis of these admissions as to the specific forms of insanity involved brings to light the interesting fact that if alcoholic psychosis and general paralysis are deducted, the proportion of the sexes is practically the same. The diseases mentioned would seem to be those which, generally, are the result of dissipation. Alcohol and syphilis again established their superiority as man's most dangerous allied foes.

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Fellowships in Medicine.—The Preston School of Industry, maintained by the state of California at Ione, Cal., has offered three fellowships of the annual value of $500, plus room and board at the Preston School, available for students of the University of California in medicine, social economics, applied psychology, law, political science or agriculture.

Popular Medical Lectures.—Stanford University Medical School has commenced a series of lectures in Lane Hall. The first lecture, on January 15, was by Dr. Ray Lyman Wilbur, on "Modern Medicine." On January 29, Dr. Wm. Palmer Lucas discussed "Feeble-Mindedness, Its Coincidences and Consequences." Succeeding lectures will be delivered by Dr. Leonard W. Ely, February 12, on "The Problem of the Crippled Child"; by Dr. William Fitch Cheney, February 26, on "Colds"; by Dr. Morton R. Gibbons, March 12, on "How the State Is Providing for the Injured Working Man," and by Dr. Emmett Rixford, March 26, on "Cancer."

New State Board Officers.—At the annual meeting of the State Board of Medical Examiners, held in Sacramento, January 12, the following officers were elected: Dr. Harry E. Alderson, San Francisco, president; Dr. William R. Molony, Los Angeles, vice-president; Dr. Charles B. Pinkham, San Francisco, secretary, and Dr. W. W. Vanderburg, San Francisco, treasurer. During the year 117 certificates to practice were granted, and three licenses were revoked. During the past eleven months 103 physicians passed the examination of the board, 45 failed, and through reciprocity with other states, 348 registered on presentation of credentials.

Personal.—Dr. George Herbert Evans, San Francisco, has been appointed assistant clinical professor of medicine, and Dr. Lewis Sayre Mace, instructor in medicine, in the University of California Medical School.——Dr. Arthur Beardslee has been appointed a member of the lunacy commission of San Francisco, succeeding Dr. Charles C. Wadsworth, deceased.——Dr. Albert Houston, San Mateo, has returned from abroad.——Dr. Francis S. Cook, Brentwood, fractured his right arm January 2, while cranking his automobile.——Dr. Frank L. Horne has resigned as cashier of the bank of Newcastle and will resume the practice of medicine.——Dr. Albert Maldonado, San Francisco, was struck by an automobile recently and sustained painful injuries.——Dr. Newton T. Enloe, Chico, is reported ill with pneumonia at his home.

ILLINOIS

Fenger Fellowship Assigned.—The Fenger Fellowship of $600 for 1915 has been assigned to Dr. George L. Mathers of the resident staff of the Cook County Hospital, Chicago, who will carry on work on certain bacteriologic problems in pneumonia.

Classification of Convicts by Mentality.—The warden of the State Penitentiary, Joliet, has called in consultation, Drs. George A. Zeller, Peoria; Eugene G. Cohn, Hospital, and H. Douglas Singer, director of the State Psychopathic Institute, and George Ordahl, state psychologist, to start plans for the installation of a psychopathic institute in the penitentiary. The plan as outlined deals with the segregation of prisoners according to their mentality. The four most important things to be taken up in connection with every prisoner, are heredity, eugenics, environment and opportunity in life.

The Work of the Visiting Nurses.—During the last fiscal year, the nurses of the Visiting Nurses' Association of Chicago, visited 31,000 individuals, each visit including trained service, instruction in sanitation and hygiene and in some cases financial aid. This work was accomplished with an expenditure of $95,536.77. The association has maintained an average of 71 trained nurses during the year, has sent three nurses abroad to aid in Red Cross work, has assisted other American cities in establishing visiting nurses' associations and has cooperated with many charitable and relief organizations.

INDIANA

Milk-Borne Disease in Gary.—Fifty cases of an unidentified disease believed to be due to infected milk were reported in Gary early in January.

Academy of Medicine Incorporated.—The Kokomo City Academy of Medicine has been incorported with a capital stock of $200. The directors are Drs. George D. Marshall, Lamar R. Knepple and William I. Scott.

Active Health Officer.—Dr. Simon J. Young, Valparaiso, health commissioner of Porter, has inaugurated free Wassermann tests for all who desire. These tests are made at the county laboratory, which is in charge of a full-time laboratory man. He has also planned for a child survey of the county to be conducted by the United States Public Health Service, which has agreed in the near future to detail officers for this work.

Disease Prevention Day to be Officially Recognized.—The following resolution was adopted by both houses of the Indiana Legislature and will undoubtedly be signed by the governor. It originated with the Indiana Society for the Prevention of Tuberculosis.

"WHEREAS: The state of Indiana loses upwards of 9,000 of its citizens each year besides suffering enormous losses from sickness through the prevalence of preventable diseases; and

WHEREAS: The monetary loss entailed thereby reaches into millions of dollars besides the load of human misery and suffering; therefore be it

Resolved by the senate, the house of representatives concurring, That the first Friday in October of each year shall be recognized as Disease Prevention day throughout the state of Indiana."

Personal.—Dr. Fletcher Landgon has opened a hospital in Winchester.——Dr. Walter A. Gekler, superintendent of the State Tuberculosis Sanatorium, Rockville, has resigned to accept the position of associate medical director of the Chicago Municipal Hospital.——Dr. Clarence A. Hartley, Evansville, has been elected president of the conference of secretaries of antituberculosis societies of the state.——Dr. Charles P. Cook has been elected vice-president of the Second National Bank of New Albany.——Dr. Anna I. McKamy, New Albany, has been reelected president of the Floyd County Anti-Tuberculosis Association.——Dr. and Mrs. Frederick C. Eckelman have donated to the city of Elkhart, a 20-foot plat of ground adjoining the new Municipal Building site.——Dr. Theodore Potter, Indianapolis, has been reelected vice-president of the Indiana Society for the Prevention of Tuberculosis.

Legislative Notes.—The Indiana Legislature has under consideration the following bills, some of which have been passed on favorably by one branch of the assembly:

First.—A bill providing that no tablets containing poison in such quantities as seriously to injure the consumer or endanger his life if taken in larger quantities than that prescribed as a dose, may be sold or otherwise dispensed in the state, unless they are V-shaped and coated with red.

Second.—A bill on the housing question designed to classify "disease traps" in a similar manner as "fire traps" provides that when the health authorities shall have knowledge that any dwelling or any part thereof is infected with contagious disease, they may order the place vacated.

Third.—A bill providing for sanitary drinking cups has been passed by the senate. Last year this bill was passed by both houses and vetoed by the governor.

Fourth.—A bill to provide pensions for widowed mothers with one or more children under the age of sixteen years and under this bill a board of child welfare is created for each county to consist of five members, the judge of the circuit court, the superintendent of the schools, the county health commissioner and the chairman of the board of county commissioners and one woman who shall be a mother appointed by the judge of the circuit court.

Fifth.—A eugenic bill has passed the senate that is made to apply to only male candidates for marriage, *requesting* only men to present certificates of their good health to the county clerk before the marriage license can be obtained.

MARYLAND

Hospital for Crippled Children Incorporated.—Incorporation papers of the Burman Hospital for Crippled Children, a charity planned for the relief of infants who, from accidents or other cause, are likely to become deformed for life, have been filed with the secretary of state. The hospital is non-sectarian and will be managed by a board of directors.

Personal.—Dr. Arthur P. Herring, secretary of the state lunacy commission, at the request of Governor Manning, is making an investigation regarding the care and treatment of the dependent insane throughout the state of South Carolina, and will report to the governor recommendations and suggestions for the better care and treatment of this class of dependents.——Dr. Samuel A. Nichols is said to be seriously ill at his home near Dayton.——Dr. Henry O. Reik is delivering a series of lectures on "Seeing Nearby America First," at the hall of the Medical and Chirurgical Faculty of Maryland, for the benefit of the faculty building fund.

Health Week.—From February 8 to 13 will be the annual "Health Week" in Baltimore and each evening there will be illustrated lectures by noted physicians. The public will be admitted free to all meetings. Motion pictures will be used to show the great fight in New Orleans against rats carrying the bubonic plague, the manner in which the common housefly manages to prey on human victims, and also tuberculosis films. There will also be an exhibit pertaining to public health work of blind persons and insane patients, the Public Athletic League, fraudulent medical advertisements and one of the latest and most powerful types of the pulmotor. The program mapped out for Health Week includes a number of very interesting events. On February 8 Governor Goldsborough and Dr. Harvey W. Wiley are to deliver addresses; on Tuesday addresses will be delivered by Dr. W. L. Rodman, president-elect of the American Medical Association, on "The Prevention of Cancer," and by Dr. J. C. Bloodgood on "Local Aspects of Cancer"; Wednesday, an address will be given by Dr. Arthur J. Cramp, of The Journal of the American Medical Association, on "Fakes and Frauds in Medicine," followed by a general discussion; on Thursday, Dr. W. M. Burdick, of the Public Athletic League, will speak on "Therapeutics of Play and Medical Hygiene of Childhood"; on Friday, the address will be by Dr. W. C. Rucker, on "Menaces of Bubonic Plague and the Vaccine," illustrated by slides taken in New Orleans, and on Saturday addresses will be delivered by Drs. L. L. Lumsden, N. R. Gorter and John H. Fulton. Moving pictures will be shown at each session.

MICHIGAN

Aid to Clinic.—The members of the Ingham County Medical Society have voted unanimously to give their services to the free clinic and dispensary, which has been established under the auspices of the Ingham County Nurses' Association.

Society Organized.—The Tri-County Society of Antrim, Charlevoix and Emmett counties was organized at Petoskey, January 14. Dr. Edwin R. Moorman, Pellston, is president, and Dr. George W. Nihart, Petoskey, secretary, of the society.

Free Antitoxin Provided by City of Marquette.—In response to a petition from physicians who urged that provision of free diphtheria antitoxin would be a financial saving to the city, the city council, December 3, made an appropriation for distribution of free antitoxin in certain cases.

Home of Wayne County Medical Society.—The new headquarters purchased by the Wayne County Medical Society contain in addition to the meeting place and committee rooms, club rooms, a library, with about 15,000 volumes, a reading room and nurses' central directory, and the Detroit Clinical Laboratory. The society has at present assets of about $70,000.

Volunteer Medical Service for Destitute.—Fifty physicians of Detroit, who are members of the board of commerce, have volunteered to donate their services free in destitute cases discovered by the board.——The Florence Crittenden Home has been placed at the disposal of the board for confinement cases.——The Michigan Workmen's Mutual Compensation Insurance Company has offered the services of its medical and legal staffs to the board for use in destitute cases.

Small-Pox.—According to Dr. John L. Burkart, secretary of the State Board of Health, in 1,681 out of the 1,995 cases of small-pox reported to the State Board of Health for 1913, there had been no vaccination. Of the entire number of patients, 28 had been vaccinated seven years before the attack, 64 more than seven years before, 143 had been vaccinated but the number of years before not given, and 55 had been vaccinated after exposure. Only three deaths occurred in the total number of cases and these were all among unvaccinated persons.

Personal.—Dr. U. G. Houck, United States inspector, who has been in charge of the Niles office of the Bureau of Animal Industry, since the beginning of the campaign against the foot-and-mouth disease there about the middle of October, has been ordered to go to Glendive, Mont., to organize the work there.——Dr. Athanase E. Gourdeau, Ishpeming, is under treatment in Augustana Hospital, Chicago, for malignant disease of the throat.——Dr. Dennis V. Smith, Ann Arbor, has started for Peking, China, where he will be stationed in a missionary hospital.——Dr. Orley M. Vaughan, Covert, has been elected president of the Citizens' State Bank of South Haven.——Dr. Joseph A. Crowell, Iron Mountain, has been appointed special inspector of the State Board of Health.——Dr. Charles M. Turrell has been appointed police surgeon of Detroit.——The office and residence of Dr. Lee H. Duguid, Custer, were destroyed by fire, January 1, with a loss of about $5,000.

MINNESOTA

New Health Bureau.—At the meeting for organization of the state legislative bureau, January 18, Dr. Cornelius Williams, St. Paul, was elected president, and Dr. H. W. Hill, Minneapolis, secretary.

Personal.—Dr. William G. Crumley, Rochester, has been appointed consulting intern in the American Red Cross Hospital, Paignton, Devonshire, England, and has started for his post of duty.——Dr. John C. Staley, St. Paul, has been appointed a member of the staff of the American Ambulance Hospital at Neuilly, near Paris.

Sanatorium Notes.—Representatives from the county boards of Fairmont, Watonwan, Nicolett, Brown, Martin, Waseca and Blue Earth met at Mankato, January 8, and discussed plans for the establishment of a joint county tuberculosis sanatorium. A committee consisting of one from each county was appointed to study the project and report at a later meeting.——A bill is to be presented at this session of the legislature asking adequate preparation for the care of all tuberculosis patients.——An appropriation of $750,000 is to be asked for to supply the state aid, which is necessary to enable counties to build and maintain their own sanatoriums, and to take care of patients at other municipal institutions.——Three counties are at present operating sanatoriums, and thirty-six counties have appointed county sanatorium commissions.

NEW YORK

Dinner to Staff.—Dr. J. Wilson Poucher, surgeon-in-chief of St. Francis Hospital, Poughkeepsie, gave a luncheon to the members of the staff of the hospital on January 12.

Medical Society Convention.—The one hundred and ninth annual meeting of the Medical Society of the State of New York will be held in Buffalo April 27 to 30. Dr. Albert T. Lytle, Buffalo, is chairman of the committee on arrangements.

Directors of Tuberculosis Preventorium Meet.—The annual meeting of the directors of the Tuberculosis Preventorium for Children was held recently, at which time Dr. Hemann M. Biggs was reelected president. It was announced that during the past five years 1,600 children had been cared for by the institution.

Tuberculosis Notes.—By a vote of sixteen to eleven the board of supervisors of Otsego County defeated a resolution to submit to vote at the next election a proposition to raise $20,000 for the establishment of a tuberculosis sanatorium.——Four farms have been sold and one has been rented to the Schenectady syndicate at Eminence. It is said that the property is to be used for a tuberculosis sanatorium.

Bill Abolishing Coroners Drafted.—A bill to do away with the coroner's office and to supplant it with a medical examiner's office has been prepared by Commissioner Wallenstein, and will be presented to the board of estimate after a conference with the City Club and other civic bodies. The bill provides for a chief medical examiner at a salary of $8,000 and assistants for each borough at $6,000. The only function to be performed by the medical examiners is to determine the cause of death. The performance of necropsies will be left to the judgment of the officials concerned in the detection of crime. The chief medical examiner and his assistants will be chosen from a civil service list after an examination is held, which will be open to any citizen of the United States.

Personal.—Dr. Frederick H. Flaherty of Syracuse has been appointed by the president, Dr. Grover W. Wende, to represent the Medical Society of the State of New York on medical education, and Dr. Francis E. Fronczak of Buffalo on public health at the conference on Health and Public Instruction of the American Medical Association in Chicago, February, 1915.——Dr. Isaac W. Brewer, Taughannock Falls, has been appointed district sanitary supervisor.——Lieut. Edward C. Clark, M. C., N. Y., N. G., has been transferred from the Sixty-Fifth to the Third Infantry.——Dr. Emerson B. Lambert has been elected president of the Port Jervis Telephone Company, Dr. Charles N. Skinner secretary-treasurer, and Drs. Frank E. Gessner, Emerson B. Lambert and Charles N. Knapp have been elected directors.——Dr. Frank E. Sweatt, Essex, has gone to the Plattsburg Hospital for treatment of heart disease.

New York City

Harvey Society Lecture.—The seventh lecture of the Harvey Society series at the New York Academy of Medicine January 30 is by Prof. Hans Zinsser of Columbia University on "The More Recent Developments in the Study of Anaphylactic Phenomena."

Small-Pox on Spanish Ship.—The health officer of the port of New York, on January 12, removed thirty-five steerage passengers from the steamship *Buenos Ayres* to Hoffman Island for observation and detention. A steerage passenger from Barcelona died from small-pox four days before the ship reached port.

Educational Work Among Midwives.—The Bureau of Child Hygiene of the Health Department, in cooperation with the Midwives' Association, has arranged a series of educational meetings for the midwives of the city. It is proposed to have these talks in German, Polish, Hungarian and Yiddish, by prominent physicians of the respective nationalities.

Personal.—Dr. William H. Park has offered his resignation as dean of the New York University Medical College because of the ruling of the Department of Health that its department heads shall not hold administrative positions elsewhere. Dr. Park is director of laboratories. He will retain his position as professor of bacteriology and hygiene in the college. His resignation will probably not take effect until the end of the college year.——Dr. Samuel Kutscher, who has been seriously ill with blood poisoning, is now reported to be improving.——A fire in the laboratory of Dr. Charles H. Stanley destroyed the fruit of fourteen years' research of the Roentgen ray.——Dr. A. P. H. Sage, a member of the staff of the Kings County Hospital, was operated on for appendicitis, December 24, and is reported convalescent.

Prevention of Unnecessary Blindness.—A campaign for the prevention of unnecessary blindness was recently inaugurated by a meeting at which a lecture on "Sight Saving" was delivered by Dr. Walter B. Weidler. A series of lectures has been arranged by the New York Association for the Blind, in collaboration with the American Medical Association, the Illuminating Engineering Society and the Board of Education. It is intended to extend the campaign to other cities. The undertaking is the result of the experience of the New York Association for the Blind, which has found that the ranks of the blind could be greatly decreased by convincing the public of the need of proper hygiene, proper economic conditions, good lighting, fresh air and exercise. Other lectures will be delivered at the Lighthouse for the Blind on East Fifty-Ninth Street on February 1 and 15 and on March 1 and 15. The speakers will be Dr. Lewis W. Crigler, Dr. Ellice M. Alger, L. B. Marks and Miss Winfred Holt.

PENNSYLVANIA

List of Approved Hospitals.—The Bureau of Medical Education and Licensure has prepared a tentative list of ninety-five hospitals in the state which are approved for internships. The bureau requires that each applicant for license in the state hereafter must have served an internship in an approved hospital.

Personal.—Dr. Theodore L. Hazlett, Pittsburgh, sailed for Europe, December 19, en route to Petrograd, via Archangel, to join the American Red Cross unit on duty with the Russian army.——Dr. Benjamin J. Millard, Mt. Carmel, who has been under treatment at the State Hospital, Fountain Springs, on account of a fractured hip, is reported to be convalescent.——Dr. Edwin B. Marshall, Annville, has been appointed resident physician of the Lebanon Sanatorium.——Dr. Harry Somerville, Chest Springs, cut his arm severely while cutting ice on a pond near his home.——Dr. George W. Mellon, Philadelphia, has started for Europe in charge of insane and mentally deficient immigrants being returned to Switzerland. At the completion of this mission, he will join the American Red Cross in France.——Dr. Samuel C. Jaspan, formerly assistant physician at the Mt. Alto State Sanitarium of the Pennsylvania Department of Health, has resigned and entered practice at Trenton, N. J.——Dr. Charles E. Helm, Bart, had a narrow escape from drowning while crossing a flooded creek at Hoovers Lane.——Dr. John M. Sheedy, Altoona, sustained a comminuted fracture of the left arm, by a fall on a slippery pavement, January 5.

Philadelphia

Gross Lecture.—The annual Samuel D. Gross lecture was delivered at the Jefferson Hospital by J. Chalmers Da Costa, professor of surgery at the Jefferson Medical College.

Contracts Awarded.—The contracts for the construction of a new observation building and a nurses' home at the Philadelphia Hospital for Contagious Diseases, were awarded January 15 for $68,924 and $51,890, respectively.

Gorgas Honored.—Brig.-Gen. William C. Gorgas, Surgeon-General, U. S. Army, was tendered a reception and dinner, January 15, at the University Club, by members of the Sewanee Alumni Association.

Personal.—Dr. Albert P. Brubaker has been reelected president of the Society for Ethical Culture.——Dr. Francis D. Patterson was elected president of the Philadelphia Safety Council January 19.——Dr. E. Kilbourne Tullidge, who sailed for Europe December 8, has been made a member of the medical staff of the Red Cross Hospital, Vienna.

TENNESSEE

Outbreak of Spinal Meningitis.—Cases of spinal meningitis, with three deaths, are reported from the northern part of Rutherford County.

Organization of Medical Inspectors of Schools.—A corps of medical inspectors for the public school of Knoxville was organized on January 12, and assignment of inspectors to schools and appointment of a board of consulting specialists were made.

Personal.—Fire in a bank in the Bank of Commerce & Trust Company's Building, Memphis, January 11, damaged the offices of Drs. James B. McElroy and Hugh B. Kincaid.——Dr. S. M. Covington, College Grove, was stabbed on December 24 by an escaped patient from the Central Hospital for the Insane,-Nashville, but his injuries are believed not to be serious.

Vaccination Urged on Citizens.—The occurrence in various places of small-pox has caused vaccination to be urged and very generally practiced throughout the state. According to Dr. R. Q. Lillard, secretary of the State Board of Health, the disease has assumed a very malignant form in certain sections. For several years the type of small-pox encountered has been very mild. In Shelby County more than 3,000 patients have been treated during the past nine years without a single death.

TEXAS

Personal.—Dr. Addeson L. Lincecum, El Campo, has been appointed assistant state health officer.——Dr. John W. Kuykendall, Fort Worth, who was injured in a collision between his automobile and a street car, January 16, is reported to be improving.——Dr. William M. Shytles, Venus, has been appointed a member of the staff of the State Hospital, Terrell.——Dr. Henry F. Lewis, Nugent, sustained serious injuries in a machinery accident, January 11, and is under treatment in a sanatorium in Abilene.——Dr. Roy D. Wilson, Houston, has been elected medical director of the Bankers' Health and Accident Insurance Company.——Dr. George M. Graham, Austin, has been appointed state bacteriologist.——Dr. Murff F. Bledsoe has been elected chairman of the Port Arthur Branch of the Texas Public Health Association.

Review of Health Work.—The report of the State Health Department made by Dr. Ralph Steiner, Austin, reports the following achievements during the present administration: four new gasoline launches added to the quarantine branch of the service and the quarantine station at Aransas Pass repaired and made habitable; sanitary code enacted into law; state sanatorium for the care and treatment of consumptives erected at Carlsbad at approximate cost of $100,000; diphtheria antitoxin, antimeningitis serum and vaccine distributed at nominal prices; establishment of bacteriologic laboratory; manufacture and free distribution of antityphoid vaccine; abolition of common drinking cup in railway trains and stations; inauguration of a hookworm campaign carried out in forty-four counties with over 65,000 microscopic examinations and over 17,000 treatments given.

CANADA

Small=Pox Among Indians.—Small-pox is very prevalent on the Indian Reservation near Brantford, Ontario. The Ontario Board of Health is cooperating with the Indian Department at Ottawa, and Dr. R. W. Bell of the former board has made a special investigation into the outbreak. He found that the disease had been lurking on the reservation for two or three years, and advises a general vaccination. There have been about sixty cases.

Personal.—Dr. Robert W. Shaw, London, Ontario, has been elected chairman of the Board of Education of that city for 1915.——Sir William Osler has offered his services in connection with the McGill Base Hospital, composed of members of the faculty of medicine, students and nurses from Montreal hospitals, which will leave for the front in the spring. He will join the unit as a supernumerary colonel.——Dr. Henry R. Casgrain, Windsor, Ontario, past president of the Ontario Medical Association, is going to the front, having been appointed to command one of the field hospitals of the second Canadian contingent.——Dr. Henry Howitt, Guelph, Ontario, is spending four months at the Floronton, St. Petersburg, Fla.

Hospital News.—Representatives of the several hospitals in Toronto waited recently on the Hon. W. J. Hanna, provincial secretary, asking that the government would allow them 10 cents per treatment for each outdoor patient. On the figures submitted this would mean an increased grant of $5,000. The minister pointed out that the present was no time to warrant unnecessary increase of the hospital grants. Later on, however, the matter would be considered by the government.——The Royal Victoria Hospital, Montreal, started the present year with an increase in the cost of maintenance, but with fewer patients; it also began with a slight balance to the good, due to the sum of $500,000 left by the late Lord Strathcona. The cost of each patient was $2.20 per day, 12 cents more than in the previous year. Plans for a new pavilion for private patients donated by Mr. J. K. L. Ross in memory of his father, the late Mr. James Ross, were approved.

Canada and the Wounded.—There are 160 Canadian doctors and 103 Canadian nurses serving the allied forces in various ways. There are twenty Canadian nurses and sixteen medical men in the military hospital at Boulogne. Col. Charles Hodgetts, Canadian Red Cross Commissioner in England, states that the Canadian Red Cross Society has contributed $75,000 in cash and paid for twelve motor ambulances as a gift to the British Red Cross Society, in addition to numerous donations of blankets, etc. Col. Lorne Drum of the Canadian Army Medical Corps is in charge of the military hospital under the war office at Hempstead, the Mount Vernon Hospital. The Queen's Canadian Hospital, Shorncliffe, England, is in charge of Dr. Donald Armour and Sir William Osler; the nurses are all Canadians. The Duchess of Connaught Canadian Red Cross Hospital, Cliveden, England, is in charge of Major Gorrell, Ottawa, Canada, and the staff of surgeons and nurses will be supplied by the Canadian army medical corps. There are twelve contingent hospitals on Salisbury Plain, and Major Murday MacLaren, St. John, N. B., is in charge of the chief one. Lieutenant-Colonel Shillington, Ottawa, is in charge of the Hospital Le Touquet, France. Hon. Philippe Roy, Canadian commissioner in Paris, is in charge of the Military Hospital at Dinard, France.——Lieut.-Col. Carleton Jones, chief of the Canadian Army Medical Services, reports that the outbreak of cerebrospinal meningitis in the Canadian troops on Salisbury Plain is now under control. There have been about twenty deaths from this disease.

GENERAL

Tropical Medical Specialists to Meet.—The American Society of Tropical Medicine will hold its twelfth annual meeting at San Francisco, June 14 to 16.

Bacteriologists Elect.—At the annual meeting of the Society of American Bacteriologists held in Philadelphia, December 29 to 31, the following officers were elected: president, D. H. Burgey; vice-president, John Weinzirl; secretary-treasurer, A. Parker Hitchens, Glen Olden, and delegate to the American Association for the Advancement of Science, Dr. Milton J. Rosenau, Boston. The next regular meeting of the society will be held at the University of Illinois, Urbana, but during the summer a special meeting will be held in San Francisco.

Examination of Army Dentists.—The Surgeon-General of the Army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, N. Y.; Columbus Barracks, Ohio; Jefferson Barracks, Mo.; Fort Logan, Colo., and Fort McDowell, Cal., on April 12. Appli- cation blanks and full information can be procured by addressing the "Surgeon-General, U. S. Army, Washington, D. C." Applicants must be citizens of the United States, be between 21 and 27 years of age, graduates of a dental school legally authorized to confer the degree of D.D.S., and be of good moral character and habits. There are nine vacancies to be filled.

Bequests and Donations.—The following bequests and donations have recently been announced:

Presbyterian, St. Luke's German and Roosevelt hospitals, New York City, each about $75,000 by the will of Henry Miller.

The Detroit Tuberculosis Sanitarium, $1,400, the proceeds of a charity ball, November 27.

Dr. F. Le Roy Satterlee, New York City, about $120,000 by the will of Harriet Wells Smith.

Provident Hospital, Chicago, and Oak Park Hospital, each $1,000 by the will of Adeline Freer Sharpe, Oak Park.

Aid Association of the Philadelphia County Medical Society $1,000, an anonymous donation.

Southern Medical Society of Schuylkill County, Pa., a hospital to cost $25,000, to become the property of the society at the death of the donor, by Dr. George K. Binkley, Orwigsburg.

The American Red Cross and Non-Combatants.—At the last annual meeting of the general board of the American Red Cross, at which President Wilson presided and made an address, a resolution was passed that the American Red Cross would not solicit relief for non-combatants in the European war zone, preferring to have such relief given through different national organizations or committees. It will, however, so far as practicable and proper, act as intermediary in transmitting such relief, provided the donors designate the particular country or nation for which this relief is intended. Being a neutral organization, the American Red Cross could not undertake the distribution of such relief, nor undertake its division between different countries or nations. Miss Boardman of the Red Cross expressed the hope that under some revision of the Treaty of Geneva the Red Cross of neutral countries in the future would be enabled to carry on relief work for non-combatants under war conditions.

FOREIGN

Another French Exchange Resumes Publication.—The *Archives des Maladies du Cœur, des Vaisseaux et du Sang,* which has been suspended since the August number, has resumed publication. The publishers announce that it will appear regularly henceforth. Professor Vaquez is the chief of the editorial staff and J. Heitz the general manager. This monthly, devoted exclusively to the heart, vessels and blood, is now in its eighth volume.

WAR NOTES

Aid for Belgian Physicians.—A committee has been organized in Denmark to receive contributions for the aid of the Belgian profession, and the *Ugeskrift for Læger* publishes the list of contributors each week. The second list, January 7, cites nineteen contributors, the sums ranging from 5 to 50 crowns, about $1.35 to $13.50.

Typhus Among Russian Prisoners in Germany.—The *Deutsche medizinische Wochenschrift* states, January 1, that one of the attending physicians and an orderly have contracted exanthematous typhus in tending the Russian prisoners in the prison camp at Cottbus. There are several hundred cases among the prisoners and nine have died according to this journal.

Supply of Drugs in Russia.—According to the *Apotheker-Zeitung,* Russia has always imported nearly all the drugs used There are only a few manufacturing chemists and their output is small; chloroform, for example, has not hitherto been made anywhere in Russia, nor iodin. A scientific expedition has recently been sent to the gulf between Lapland and Archangel, in the north, to investigate algae growing there, with a view to produce iodin from them, and also from the salt in the district, which is said to contain iodin. Arrangements have also been made for the production of chloroform at Moscow.

Scientific Societies Adopt Peace Resolution.—The Federation of American Societies for Experimental Biology, comprising the following societies: Physiological Society, Society of Biological Chemists, Society of Pharmacology and Experimental Therapeutics and the Society for Experimental Pathology; the presiding officers of which are, respectively, Walter B. Cannon, Graham Lusk, Torald Sollman and Richard M. Pearce, at the annual meeting held at St. Louis, December 20, unanimously adopted the following preamble and resolution:

"Whereas: Various of the European nations with which many of our members are related by birth, descent, or intellectual friendship are now at war;

"*Resolved*, That we extend to the scientific men within these nations the hope of an early and enduring peace, which will leave the nations with no permanent cause of rancor towards each other, and which will insure to each the glories of scientific and humanitarian achievement in accordance with its own conception of these ideals."

Aid for Belgian Physicians.—Dr. F. F. Simpson, treasurer of the committee of American physicians for the aid of the Belgian profession, announces that for the week ending Jan. 23, 1915, the following contributions have been received:

Dr. W. A. Coventry, Duluth Minn.		$ 10.00
Dr. A. William Reggio, Boston, Mass.		25.00
Dr. Edward B. Heckel, Pittsburgh, Pa.		25.00
Dr. T. R. Williams, Puxsutawney, Pa.		10.00
Dr. J. Knox Simpson, Jacksonville, Fla.		10.00

Total receipts		$1,791.00
Previously reported disbursements	$990.00	
Disbursements week ending Jan. 23	660.00	
Total disbursements		$1,650.00
Balance		$141.00

Diplomatic arrangements have just been completed whereby drugs and instruments for civilian physicians may be sent into Belgium. Recent advices from Dr. Herbert Spencer of London show that our Belgian colleagues are literally starving. Three hundred additional boxes of food have been purchased at a cost of $660. Checks for this fund should be sent to F. F. Simpson, treasurer, Pittsburgh.

Ambulance Construction Commission.—At the instance of Mr. Henry S. Wellcome, the founder of the Wellcome Bureau of Scientific Research, a commission has been formed to standardize the patterns and improve the type of field motor ambulances. Sir Frederick Treves, whose long experience and distinguished service specially fit him for the task, has consented to be the chairman. The admiralty is represented by the director-general of the medical department, R. N., while the quartermaster general to the forces and the Acting director-general, Army Medical Service, represent the war office. The British Red Cross Society is, of course, represented by Sir Frederick Treves, and the St. John Ambulance Association by Sir Claude Macdonald and Sir John Furley. The remaining members are all experts. This commission will first and foremost act as a judging committee for the award of prizes of the value of $10,000 provided by the Wellcome Bureau of Scientific Research. These prizes are offered for the best designs of an ambulance body which shall fit a standard pattern motor chassis for field motor ambulances. The last day for the receipt of competing designs is June 30, 1915. It is hoped that the competition will bring in a number of ingenious designs, from which the ideal field ambulance body will be evolved. It may be asked why the competition is restricted to designs for a body and not for the complete ambulance, including a chassis. The reason is that a chassis takes much longer to build than a body, and that, when war breaks out, it is impossible to get at short notice anything like a sufficient number of any one type of chassis. On the other hand, a standardized body to fit any chassis of approved dimensions can be constructed in numbers at comparatively short notice, and a perfected body is needed to insure complete comfort for the wounded. It is hoped that the information obtained by the competition, and in other ways, will be published in some permanent form, available for future reference. Probably in addition to one design of special excellence, there will be submitted various suggestions which may be incorporated in the pattern design approved by the commission. For these a portion of the prize money has been set apart. The first prize is of $5,000, the second $2,500 and the third of $1,500. All details of conditions may be obtained from the secretary, the Ambulance Construction Commission, 10 Henrietta Street, Cavendish Square, London, W. England. The competition is open to citizens of all nations.

LONDON LETTER

LONDON, Jan. 15, 1915.

The War

THE HEALTH OF THE TROOPS AT THE FRONT

So far the amount of disease among the troops at the front has been very small, and the two zymotic diseases most to be feared have given little trouble. Dysentery has been absent, and the incidence of typhoid fever has been much below an annual rate of 2 per thousand. The case mortality has been little over 8 per cent. Great vigilance is displayed by the medical officers in promptly isolating suspected cases. The value of antityphoid inoculation is shown by the following results: The men brought into the field fall into three classes: (1) "fully protected" men, those who have received two doses of Wright's antityphoid serum within the last two years; (2) "partly protected" men, those who have not been inoculated within the past two years, or who have received only one dose, and (3) "unprotected" men, those who have never been inoculated. It is among the latter class that all the deaths hitherto recorded have occurred. Furthermore, this class has supplied about sixteen times as many cases as the fully protected class, and about six times as many cases as the partly protected. Arrangements have been made for the isolation of infectious diseases at all the British base hospitals, and an institution specially for this purpose is maintained near Boulogne. It consists of a three-story stone building on the edge of a sandy beach, and about 100 bathing huts. The building is used entirely for typhoid cases, the huts for other infectious diseases. In England provision has also been made for the care of soldiers brought home with infectious diseases. It is generations since British troops fought so near home, and the small number of home camps in times of peace have not required special military fever hospitals. Hospital accommodation has been provided for 150 acute infectious cases at a country house. In order to reduce the danger from convalescent carriers, the hut system is being installed on a scale which allows a large number of convalescents to be kept under observation, if the necessity should arise.

HOSPITAL ACCOMMODATION FOR THE INDIAN WOUNDED IN ENGLAND

The peculiar difficulties attending the care of the Indian wounded from our expeditionary force, such as language, caste, and the religious customs with regard to diet, have rendered special provision necessary not only at the front but also in England. At the fashionable and salubrious watering place of Brighton, accommodation has been provided for 3,000 wounded Indians. The general hospital for Indian troops will be located in three main blocks consisting of the Corn Exchange lent by the corporation, a school lent by the educational authority, and the Brighton Union, lent by the guardians. In addition to a large staff drawn from the medical service of the Indian army, an Indian physician and a senior Indian medical student have been appointed for each fifty beds. The sanitary arrangements have been carried out to suit the necessities and habits of the Indians. Thus the baths are all shower baths. The closets are stand-up water closets. The language difficulty has been overcome. The medical officers practically all speak the dialects; many Indian medical physicians and students are engaged, and the patients can often speak a little English. Notices are posted up in Urdu and Nagari. The cooking of the food presents special difficulties. There are two sets of cooking arrangements in each hospital, one for the Hindus and the other for the Mussulmans. The Ghurkas and Sikhs join the former. The utensils, etc., are kept strictly separate. The dietary is not very elaborate. Chupatties, which are made of plain flour and water, by hand on an iron plate, are a favorite food. When they have to a certain extent set, they are tossed from side to side by the cook, in pancake fashion. Other articles of consumption are curry and rice. The strict Mohammedans do not touch alcohol.

THE AUSTRALIAN MEDICAL SERVICE

The Australian expeditionary force which was sent to England to complete its training has been detained in Egypt because of the threatened invasion of that country by the Turks. It has an excellent medical service organized so as to correspond as near as practicable with the organization laid down for the imperial services, thereby enabling the Australian units at once to take their place side by side with the medical services in any part of the British Empire. At the outbreak of the war, three field ambulances and one light horse field ambulance (the latter corresponding to a cavalry field ambulance) were mobilized on war establishment, complete in every detail as to personnel, equipment, vehicles and horses. Almost simultaneously with this, the medical service required for lines of communication was also set going, comprising one clearing hospital, two stationary hospitals and two general hospitals. An additional light horse field ambulance and field ambulance were also mobilized. All these units correspond as regards personnel, equipment, nursing staff and accommodation for patients with those laid down for the imperial services. The complete units will afford accommodation for over 2,000 patients. The personnel is drawn not only from medical officers on the active list but also from those on what is known as the Australian Army Medical Corps Reserve. Every state has sent in its quota, the general principle being that each unit will be complete in its equipment and transport.

THE EFFECTS ON CIVIL PRACTICE

In my last letter I mentioned certain suggestions which had been made to the war office and accepted by it to prevent some of the difficulties arising from the dislocation of civil practice in consequence of physicians undertaking military duties. Some further methods were mentioned at a meeting of physicians in Glasgow by Dr. Norman Walker, who delivered an address on the work of the Scottish Medical Service Emergency Committee. This committee was constituted at the outbreak of the war, and consists of the heads of the Scottish medical schools, with certain representative physicians. It has issued a memorandum of which he discussed and explained the following points: It is held that the fee offered to a locum tenens taking the work of a physician engaged in military duty should not exceed $21 a week. Retired physicians willing to enable their brethren to serve their country were asked to send their names to the committee, and a good many names were thus obtained. A difficulty arose in that it was not easy for a physician in the neighborhood of 60 to face a hard country or colliery practice. Some had heroically undertaken work which would tax their strength. On the other hand, there are districts in which the majority of the work is done in the consulting room and can easily be performed by older men. A suggestion was made to school authorities that their whole-time medical officers should be allowed to give part of their time to general work. A fourth suggestion is that the visiting staffs of large hospitals, infirmaries and asylums should consent to a reduction of the number of medical residents and clinical assistants, and undertake a portion of the work assigned to these. This has been carried out. All hospitals have cut down their resident staffs. A distinguished professor of medicine is acting as his own house surgeon, and a well-known professor of anatomy has acted as a house surgeon in the hospital attached to his school. A fifth suggestion is that in the larger towns, young physicians whose practices are yet small should in pairs make an arrangement whereby one undertook the whole town practice for a period, while the other acted in the country for a colleague absent on duty. Women in the position of locum tenens had proved useful, though at first their offers were not received with enthusiasm. However, once the novelty wore off their services were appreciated.

THE DECLINE IN THE NUMBER OF MEDICAL STUDENTS AT SCHOOLS

The shortage of medical students attending the schools in consequence of so many having gone to the front as dressers, or in the fighting line, has given rise, as pointed out in previous letters, to serious anxiety as to the supply of physicians in the future. The army authorities have taken the view that the best thing a medical student, who desires to serve his country, can do is to complete his studies and qualify as soon as possible. Accordingly, an army order has been issued giving permission to any student who has gone to the front to return home to complete his studies, if he desires to do so. Owing to the impossibility of obtaining resident medical officers in the hospitals, senior students are being employed in some cases in their places.

THE RELIEF OF BELGIAN DOCTORS AND PHARMACISTS

The fund organized by the profession for the relief of Belgian physicians and pharmacists, both those remaining in their own country and those who are refugees in England, is receiving wide and generous support from the profession. An executive committee has been formed, and a general committee is in course of formation which is of the most representative character. It includes the presidents of the colleges of physicians and surgeons and of the Royal Society of Medicine, the General Medical Council and the provincial colleges, the chairman of the Council of the British Medical Association, the professors of medicine at the universities and the editors of the *Lancet* and *British Medical Journal*. It is recognized that while the German occupation lasts, it will not be possible to do more for the doctors and pharmacists remaining in Belgium than to dispatch certain packets of medical material with which the misery may be relieved. A start has been made in this direction, and packets will be sent regularly when it is known that they can reach their destinations without interference. The government has issued an order giving the holders of the medical diplomas of Belgian universities the right to practice in this country during the war.

BRITISH PHYSICIANS EXAMINED IN MEDICINE FOR THEIR LIVES

Two civilian physicians attached to the British Red Cross for the first Belgian unit have arrived in London from Germany after an extraordinary experience. Early in August they passed through Namur in order to form a hospital for the Belgians nearer the frontier. They were captured by the advancing Germans, who accused them of being spies, and were sent to Cologne, where they were thrown into a military prison and kept in solitary confinement for fifteen days. Not only were they closely cross-examined in the ordinary manner and told they were on trial for their lives, but also they were put through a medical examination by the chief medical officer of the command. They were asked many questions which no layman could answer, such as the symptoms of pneumonia and typhoid fever and their bacteriology, anatomic questions on the leg, and what organs would be perforated if the abdomen was pierced by a bayonet. They were not told whether the German medical officer regarded their standard of knowledge as good, but they must have "passed," as they were eventually released.

THE MANUFACTURE OF THYMOL

Hitherto the antiseptic thymol has been almost entirely manufactured in Germany, although the ajowan seeds, which are almost the sole source of the oil from which thymol is produced, are grown on a large scale only in India. The cutting off of the supplies of thymol from Germany has increased the price eightfold, and it is even now $5 a pound, as against $1.25 before the war. As the manufacturing process is quite simple, preparations are now being made to produce the drug in this country. Fortunately also a British possession provides a substitute for thymol if required. This is carvacrol, obtained from oils derived from a variety of plants, but particularly from the origanum of Cyprus.

INOCULATION AGAINST TYPHOID FEVER

Notwithstanding the great value of inoculation against typhoid fever of the soldiers going to the front, the antivivisection and antivaccination fanatics are carrying on an active campaign against it. As inoculation is not compulsory, this campaign is mischievous. Sir William Osler has issued in the lay press a strong appeal to soldiers, telling them they are leaving their homes in defense of principles for which their fathers fought and died. He says it is their duty to preserve their health, and that diseases are more fatal than powder and shot. More than half the mortality in the wars of the nineteenth century was due to preventable diseases such as typhus, typhoid, cholera, malaria and dysentery. In the South African War more soldiers died from typhoid than from wounds. The disease is prevalent in parts of northwest France and Belgium. The efficiency of vaccination against typhoid has been proved, and it is followed by slight illness, rarely by anything more serious. Among 22,000 Canadian soldiers vaccinated in this country, only twenty-two had symptoms other than the usual malaise and headache.

Excessive Sickness Claims Under the National Insurance Act

Considerable dissatisfaction with the working of the national insurance act has been expressed by friendly societies in consequence of excessive claims for illness. An official inquiry has been held, and a report made, in which it is stated that many of the physicians, having had no previous experience, do not correctly apprehend the nature of their task, the value to be placed on their certificates, the relation in which they should stand to the society, or their responsibility to the working of the whole machine. Others who have acted in the past as friendly society physicians no longer consider themselves bound to look after the interests of the societies. (*To understand this, it must be borne in mind that the national insurance act removed physicians from all control by friendly societies who no longer appoint them.*

They are simply chosen individually by the members.) As their remuneration depends on the number of panel patients they have, it is alleged that the fear of giving offense induces them to grant certificates for trivial illnesses, and to continue them after the incapacity has ceased. The committee, however, adds that there has been little evidence of definite acts of deliberate false certification. The insurance of women was a comparatively new experience under the act, and the claims for sickness so exceeded the actuarial calculation that the government had to make a special grant. The committee finds that the causes for this excess are: (1) the widespread ignorance among women of what is involved in insurance, leading them to feel that they are losing something if they do not get out more than they have paid in; (2) the large proportion of ill-paid and ill-fed women; (3) the fact that the sickness benefit is often equal to or more than the woman's earnings when working; (4) the great difficulty of supervising their behavior during sickness so that it is possible for them to do ordinary housework, or even extraordinary housework, while they are supposed to be incapable of work; (5) the loss of wages by women, generally less serious than in the case of men, and (6) illness accompanying pregnancy. Beyond these contributory causes for the excessive claims by women, the committee is convinced that the main cause of the excess is that the incidence of sickness among women employed in industrial occupations is much heavier than was anticipated, or than could have been calculated when the actuarial estimate was made. In many cases the excessive predisposition to disease arose from conditions of past childbearing, but the evidence fully substantiates the view that "experience exceeds the provision made under the act." The committee suggests as a remedy the employment of women in administering women's societies. The committee thinks that immediate steps need to be taken to produce a firm attitude by the profession with regard to improper claims for sickness. They approve the appointment of medical referees, who should be whole time officials, so that there would be no danger that practice of a panel physician or a private physician would conflict with their duties. They would be of value when a panel physician was in a state of honest doubt and desired a second opinion, and also because of the hesitation of panel physicians to declare persons able to work for fear of financial loss. The report is one more example of the dangers of socialistic schemes, however beneficently designed. The ideal of Mr. Lloyd-George that every worker should be insured against the cost of illness was a fine one, but he knew little of the technical difficulties of his gigantic scheme. A national fund into which every one can put his hand is a standing temptation to abuses. The motive which individual loss provides against waste is removed. Under the friendly societies in the past, the members exercised a check against the robbery of their funds. The societies still control the funds, but with so much state interefernce and the loss of control over physicians, their power is less and their interest is weakened.

New Radium Laboratories at Manchester

Until recently there was in this country only one establishment devoted to radium therapy, the London Radium Institute. Now, in consequence of public subscription, radium laboratories have been opened at the Manchester Infirmary which contain radium to the value of $100,000. There is accommodation for the treatment of fifteen patients a day.

The Scarcity of Physicians

The scarcity of physicians created by the war is illustrated by the statement of the secretary of the Wolverhampton General Hospital, at a meeting of the committee. He could well remember the time when it was quite a common thing, when they advertised for a house surgeon or physician, to receive from ten to twenty applications for one post. Things gradually became worse, however, until, advertise as they would, they absolutely failed to get any applications for the post vacant. He was sent off to London and visited nine of the leading medical schools, and the result was that after extreme difficulty the resident post was filled. As soon as it was known that medical officers were wanted in the army and navy, all the resident medical staff volunteered. On two occasions it had been impossible for members of the honorary staff to see all the outpatients. He had gone to London again, and did the round of the medical schools. He could not find a single man who wanted employment as a doctor, and theirs was not the only hospital in such a position. They had had to fall back on medical women. But though obtainable, they too were scarce. Their resident staff now consists of one man and three women.

PARIS LETTER

PARIS, Jan. 7, 1915.

The War

INFORMATION ON THE SURGERY OF WAR

The present war is bound to furnish a rich harvest of interesting and instructive reports on the wounds of war. Such matters are beginning to be reported and discussed before the scientific societies of Paris, especially the Académie des sciences, the Académie de médecine and the Société de chirurgie. In my letters I shall endeavor to summarize the most interesting of these papers for the readers of THE JOURNAL. Moreover, in some provincial centers there is also scientific activity which deserves to be reported. Thus in one of the temporary hospitals of Bordeaux, directed by Dr. Pousson, clinical professor of diseases of the urinary tract at the Faculté de médecine of that city, the physicians on the staff of the hospital have recently organized to hold weekly scientific meetings at which the results of their work will be reported. The proceedings will be published in a bulletin. Among the subjects already treated are vascular surgery, cerebral surgery and genito-urinary surgery.

TRANSMISSION TO THEIR FAMILIES OF NEWS OF WOUNDED SOLDIERS

At the beginning of the war, there was much complaint from the public because of the lack of news concerning the wounded. At present, things have been completely changed (THE JOURNAL, Dec. 19, 1914, p. 2242). The war department's very practical arrangements for this purpose deserve to be known. Suppose for instance, that a number of wounded men have just arrived at a base hospital. The physician in charge examines the wounds and, if necessary, verifies, completes and rectifies the diagnosis made at the point where the wounded man received his first treatment. This diagnosis, made on the same tag which indicates whether or not the patient has received tetanus antitoxin, is pinned on the wounded man's cap. The same day the physician fills out a special postal-card for each patient. These cards are of different color from ordinary postal-cards; on one side they bear, along with the address of the family, the name of the wounded man and that of the hospital where he is being cared for. The other side of the card is divided into two parts one of which is reserved for the wishes expressed by the patient and may be filled out by himself personally. The other is to be filled out and signed by the physician with indication of the character of the disease or wound. Each week thereafter, a postal-card is sent to keep the family constantly informed of the patient's condition. This bulletin of health is to be sent with the consent of the patient and to the person designated by him. This postal-card service evidently represents a sometimes considerable increase of work for the physician, but this is justified by the results.

THE ACTIVITY OF THE SOCIETY FOR AIDING THE WOUNDED

The oldest of our three Red Cross societies, the Société de secours aux blessés militaires, has just published some figures summarizing its work since the beginning of hostilities. In the region of the east, the society has organized 93 first-aid stations, 83 railway-station infirmaries and 35 canteens. It has since organized 771 auxiliary hospitals containing to-day 56,579 beds. More than 9,000 nurses are employed in the hospitals of the society, and 600 others are at the disposition of the health service in the military hospitals. The society has made numerous gifts of linen and wool clothing for the hospitals or for the soldiers at the front. From Paris alone it has sent out over 100,000 such articles as blankets, shirts and socks. These various services have occasioned large expenditures amounting to 8,520,000 francs ($1,704,000) distributed as follows: hospitals, 6,840,000 francs; railway-station infirmaries, 980,000 francs; first-aid stations, 93,000 francs; canteens, 77,000 francs; automobile ambulances, 105,000 francs; gifts to hospitals and soldiers, 425,000 francs.

ASSISTANCE FOR CRIPPLES

For a long time there has been in France an Association pour l'assistance des mutilés pauvres. It was founded in 1868 to furnish needy cripples with assistance and employment. In view of the recent events which have increased the numbers of prospective beneficiaries, the society has addressed to the public and particularly to employers, merchants, manufacturers' bankers, etc., an appeal for report of employments which might be given to men incapacitated by war injuries.

BERLIN LETTER

Berlin, Dec. 29, 1914.

Personal

Von Hansemann and F. Krause have been appointed regular salaried professors.

Professor Aschoff has been chosen rector of the University of Freiburg.

The War

SEXUAL PROBLEMS OF THE WAR

At the last meeting of the medical society for the study of sexual science, Dr. Burchard discussed the influence which the war has had and will have on sexual life. In the first place, it affects the conditions governing marriage; considerations of intelligence and of deliberation are put aside, and love triumphs over good sense in the matter of marriage. On the other hand, loose forms of sexual life, concubinage and temporary relations become less during the war, so that these forms of serious sexual urgency are suspended. (On the other hand, it is to be noted that according to the statistics of the Berlin statictical bureau, the cases of fatal peritonitis after apparently criminal abortion have fallen off remarkably since the outbreak of the war.) While prostitution is not so closely connected with war as it was in the middle ages, when crowds of prostitutes followed the army, yet the dangers both in foreign countries and at home are greater than in time of peace, since prophylactic medical control is beset with the greatest difficulties. It is the duty of physicians to determine the existence of disease in the members of the army as soon as possible, and to guard against it by instruction regarding the dangers of illegitimate intercourse and the measures of prevention. Moreover, we may be sure that prostitution serves the purpose of the spies to a large extent. Of no less importance are the mental diseases in the war which are related to the sexual life. The lecturer had seen many cures of sexual neurasthenia, especially such forms as are similar to traumatic neuroses, which also are improved in the field. Other questions of sexual science which will be stimulated by the war are eugenics and racial hygiene, and the determination of sex. The study of the latter has made such progress through animal experiment that it is to be hoped it will soon be carried far enough so that the great loss of males will be compensated for. The question was also raised as to what bearing these facts might have on insanity and crime.

CONSANGUINEOUS MARRIAGE

This address was followed by one by Dr. Crzellitzer on the biologic effects of the marriage of blood relatives. The question was treated from the point of view of animal experiments, which were continued through many generations by the repeated pairing of brother and sister animals, or of parents with their young. Experiments with all our domestic animals gave uniform results: At first the progeny showed no recognizable effect, but after ten or twenty generations there appeared a gradual diminution of strength of constitution, the animals became smaller, more slender, more sensitive and more lacking in constitutional vigor; finally fertility failed, so that these incestuous races perished. The various diseases described by certain breeders are not incontrovertible evidence of the effect of inbreeding between healthy individuals, for the results were not tested as carefully as we must demand at the present day on the basis of the Mendelian laws. The consanguineous marriages of human beings do not stand on the same plane as these breeding experiments, because they comprise only a single union between related germinal cells. The collective investigations by interested physicians with reference to presumably healthy consanguineous parents, as they have been conducted in North America, England and France, have given contradictory results.

The condition is quite different with the investigation of diseases which occur in the progeny of such marriages, so far as the disease was latent in the parents but was awakened by the consanguineous marriage. Such conditions are recognizable by the fact that these diseases appear in the progeny of the consanguineous marriage to a greater proportionate extent than in the population at large in the community to which the consanguineous groups belong. In this way the importance of consanguinity for the occurrence of idiocy, congenital deaf-mutism and certain eye diseases, particularly pigmentary degeneration of the cornea, has been established. Crzellitzer has kept for many years the family records of a number of families in which occurred a number of inherited or possibly inherited eye diseases. In about 850 of these, reliable data with reference to the blood relationship or the reverse of the parents were obtained, so that they are available for the purpose of the investigation. In two cases it seems that a connection between the disease and the consanguinity must exist, namely, extreme myopia and strabismus. The latter result is new and is adapted to throw light on the general heredity of strabismus. Still the problem of consanguinity is only a special phase of the general problem of heredity, and is probably an instance of the superior opportunity for the persons with mixed heredity to find in their own families partners with similar mixed heredity over that in the rest of the homozygotic population, that is, among persons of pure heredity. In an organism of mixed heredity, a disposition which we call recessive may remain latent for decades but come to light on pairing with another organism of the same tendency. Thus the Mendelian laws give the key to some of the obscure problems of the ages.

STUDENTS IN THE WAR

The extent to which the students of the combined student corporations of the Swabian national university at Tübingen are participating in the war is an example of the patriotism of the German students in this gigantic struggle of the German people. All the students of a number of the societies who are in the field as reservists or as volunteers in other cases have gone either as soldiers or as nurses, while of another large part only a few have remained behind. The 143 members of the Evangelistic theological seminary have furnished 123, the 142 Catholics 100 to military service and the former 9 to the medical service. Altogether, of the 2,069 German students at Tübingen last semester, 1,500 are at the front and several hundred are in the medical service, among them citizens of all states of the empire. These figures show in a most favorable light the readiness of our university youth to sacrifice themselves for the country. In 1870-1871, 3,200 of the 13,765 students at that time in the German universities joined the army, and 1,200 were in the medical service.

THE DRUG SUPPLY

We have no lack of medicines. For camphor, the importation of which from Japan has entirely ceased, we have been obliged to resort to the synthetic product. The scientific deputation for medical affairs has reported in reply to a request from the minister that there is no objection to the external application of synthetic camphor, but that clinical experience must first be collected before an opinion can be given with reference to the internal use of this product. Accordingly, the minister has ordered investigations to be made in the university clinics and large hospitals for a period of three months on the curative effect of synthetic camphor.

Marriages

Louis Ashley Van Kleeck, M.D., Manhasset, N. Y., to Miss Grace Woodhull Van Nostrand of Little Neck, L. I., N. Y., January 16.

Bertrand Francis Drake, M.D., New Rochelle, N. Y., to Miss Jeannie Watson of Beechmont, N. Y., January 22.

Roman Daigse Martinez, M.D., White Castle, La., to Miss Ruth Comeaux of Bayou Goula, La., November 18.

Gilbert Van Vranken, M.D., Passaic, N. J., to Miss Rose Camwell of New York City, December 25.

David N. Walters, M.D., Campbellsport, Wis., to Miss Lida A. Esser of Milwaukee, January 12.

William H. Towne, M.D., Shiocton, Wis., to Miss Elsie Daniels of Seymour, Wis., December 29.

Sidney Kohn Simon, M.D., to Miss Emma R. Dreyfous, both of New Orleans, December 17.

John William Foley, M.D., to Mrs. Anna Postel Kradwell, both of Denver, recently.

John Ferdinand Golden, M.D., to Miss Florence F. Lydon, both of Chicago, January 19.

Hubert Rawiszer, M.D., to Miss Elizabeth Crowley, both of Omaha, Ga., January 20.

Deaths

Allison Maxwell, M.D. Miami Medical College, Cincinnati, 1876; a Fellow of the American Medical Association; for many years professor of diseases of the chest and clinical medicine at the Central College of Physicians and Surgeons, and dean of the Indiana Medical School, Indianapolis; a member of the Indianapolis State Board of Health for two terms; for three years a member and president of the Indianapolis Board of School Commissioners; prominent among insurance medical directors, and for several years medical director of the State Life Insurance Company, Indianapolis; died in the Methodist Hospital, Indianapolis, January 16, from embolism following a prostatectomy, aged 66.

Isaac Leopold, M.D. University of Pennsylvania, Philadelphia, 1886; a Fellow of the American Medical Association; ophthalmologist to the Jewish Hospital, Stetson Hospital and Kennington Hospital for Women, Philadelphia; medical director of the Jewish Maternity Hospital, Philadelphia, and Jewish Seaside Home for Invalids, Atlantic City, N. J.; ophthalmologist to and vice-president of the Philadelphia Jewish Sanatorium for Consumptives, Eagleville, Pa.; a prolific contributor to the literature of his specialty; died at his home in Philadelphia, January 18, from heart disease, aged 51.

Aaron Alonzo Noyes, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1850; a member of the Iowa State Medical Society; one of the organizers of the Delaware County Medical Society, Cedar Valley Medical Society, Cerro Gordo Medical Society and Upper Cedar Valley Medical Society; in 1876 a member of the examining board of the Medical Department of the Iowa State University; for eighteen years local surgeon for the Iowa Central Railroad; for forty-five years a practitioner of Mason City, Ia.; died at the home of his niece in Wauwatosa, Wis., aged 92.

William Joseph Sheehan, M.D. Yale University, New Haven, Conn., 1895; a Fellow of the American Medical Association and a well known and beloved practitioner of New Haven, Conn.; one of the founders of St. Raphael's Hospital, New Haven; died in that institution, January 13, from septic pneumonia following an arthritis of the ankle, aged 43. Members of the New Haven Medical Association served as active and honorary pallbearers at the funeral of Dr. Sheehan, and the association, at a special meeting, January 14, adopted resolutions of appreciation and regret.

John Farmer Winn, M.D. University of Virginia, Charlottesville, 1875; a member of the Medical Society of Virginia; professor of clinical obstetrics in the University College of Medicine, Richmond; consulting obstetrician to the Seventeenth Street Infirmary and Brook Avenue Obstetrical Clinic, and obstetrician to the Virginia Hospital, Richmond; for several years editor of the *Richmond Journal of Practice;* died at his home in Richmond, January 14, from pneumonia, aged 62.

Enoch Matthew Anderson, M.D. Rush Medical College, 1895; a Fellow of the American Medical Association and a well known specialist on diseases of the eye, ear, nose and throat of Spokane, Wash.; for several years in charge of the Sumpter (Ore.) General Hospital; first lieutenant and assistant surgeon of Oregon volunteers during the Spanish-American War, with service in the Philippines; died in the Deaconess Hospital, Spokane, January 11, from cerebral hemorrhage, aged 40.

Hunter Holmes Powell, M.D. Medical College of Virginia, Richmond, 1867; a Fellow of the American Medical Association; professor of obstetrics and pediatrics in the Western Reserve University, Cleveland; a member of the visiting staff of Lakeside Hospital, Cleveland, and of the consulting staff of the Cleveland City Hospital; director of St. Ann's Maternity and Orphan Asylum; president of the Municipal Milk Commission; died at his home in Cleveland, January 9, aged 71.

G. Henri Desjardins, M.D. University of the Victoria College, Coburg, Ont., 1871; was one of the founders of the Nazareth Institute for the Blind, Montreal; formerly a Papal Zouave and later a practitioner and ophthalmologist of Boston and Montreal; at one time a member of the faculty of his Alma Mater; died at the home of his sister in Montreal, January 9, aged 66.

George Allen Nash, M.D. St. Joseph Hospital Medical College, St. Joseph, Mo., 1879; a Fellow of the American Medical Association and one of the oldest practitioners of Maryville, Mo.; one of the founders of and chief surgeon to St. Francis' Hospital, Maryville; local surgeon at Maryville for the Wabash and Burlington System; died in St. Francis' Hospital, January 8, from carcinoma of the pancreas, for which operation had been performed, December 17, aged 66.

Henry Bezou, M.D. Tulane University, New Orleans, 1871; one of the leaders in the overthrow of the Kellogg government in 1874; for two terms a member of the Louisiana State Board of Health and coroner of Orleans Parish; one of the founders of the New Orleans Eye, Ear, Nose and Throat Hospital; died at the home of his daughter in New Orleans, January 10.

Charles Bowman, M.D. University of Pennsylvania, Philadelphia, 1849; in charge of an Army general hospital at New Albany, Ind., during the Civil War; one of the oldest practitioners of southern Indiana and for many years a member of the Floyd County Medical Society; died at his home, January 12, from influenza, aged 89.

James Albert Rowan, M.D. Tulane University, New Orleans, 1873; a member of the Mississippi State Medical Association and once president of the Copiah County Medical Society; one of the best known practitioners of South Mississippi; died at his home in Wesson, January 8, from cerebral hemorrhage, aged 62.

George Dodge Rowe, M.D. Medical School of Maine, Brunswick, 1868; a member of the Iowa State Medical Society; for many years a practitioner of Boone, Ia.; died in Hot Springs, Ark., January 13, from malignant disease of the bladder and intestine, eight days after a surgical operation, aged 69.

Walter W. Williams, M.D. Michigan College of Medicine and Surgery, Detroit, 1897; a member of the Michigan State Medical Society; from 1887 to 1890 a member of the house of representatives from Bay County; died at his home in Bay City, January 9, from nephritis, aged 67.

Charles Smith, M.D. Long Island College Hospital, Brooklyn, 1890; a Fellow of the American Medical Association; from 1900 to 1903 United States vice consul at Puerto Cortez, Honduras; died at his home in Riverside, Conn., January 8, from heart disease, aged 46.

Walter DeWitt Boggs, M.D. Long Island College Hospital, Brooklyn, 1910; instructor in physical diagnosis in his Alma Mater for a year; a specialist in pathology and pediatrics of Pasadena, Cal.; died at his home in Altadena, Cal., January 5, aged 32.

Charlotte W. Ford, M.D. Woman's Medical College of the New York Infirmary for Women and Children, New York City, 1873; for many years a practitioner of New York City; died at her home near Morristown, N. J., January 9, from heart disease.

Henry Walton Wood, M.D. University of Maryland, Baltimore, 1902; of Boston and New Bedford, Mass.; a Fellow of the American Medical Association and a specialist in mental diseases; died in Jefferson Hospital, Philadelphia, January 12, aged 35.

Lewis C. Hammond, M.D. Michigan College of Medicine, Detroit, 1883; health officer of Bay City, Mich., in 1910; a practitioner of Clarkston, Mich.; died January 12, from heart disease while making a professional call in Clarkston, aged 59.

Emery G. Jones, M.D. Jefferson Medical College, 1884; a retired practitioner of Wilkinsburg, Pa.; was found dead at his home in that city, January 6, from the result of a gunshot wound, believed to have been self-inflicted with suicidal intent, aged 55.

Silas W. Newman, M.D. Physio-Medical College of Medicine and Surgery, Chicago, 1888; school director and for several years president of the Board of Health of Scottdale, Pa.; died at his home, December 28, from carcinoma of the stomach, aged 61.

Diederick A. Schumacher, M.D. Wisconsin College of Physicians and Surgeons, Milwaukee, 1898; Rush Medical College, 1900; formerly health officer of Aberdeen, Wash.; died at his home in that city, December 28, from pulmonary abscess, aged 56.

Marshall William Harner, M.D. College of Physicians and Surgeons, Chicago, 1905; a Fellow of the American Medical Association; of Clay Center, Kan.; died December 4, from shock following an operation for intestinal obstruction, aged 39.

Thomas L. Thompson, M.D. Long Island College Hospital, Brooklyn, 1879; formerly a member of the Indiana State

Calculating from the bromid determination, each dose, one teaspoonful (1 fluidram), contains the equivalent of 16.8 grains of potassium bromid, and each daily dose (three teaspoonfuls) corresponds to 50.4 grains of potassium bromid.

The report shows, as might have been expected, that the Peebles epilepsy treatment consists, essentially, in giving bromids. The use of bromids in the treatment of epilepsy has been known for years. The bromid treatment is not in any sense of the word a cure; it is at best but palliative. The drug, acting as a sedative, tends to suppress the attack but should be used with the greatest circumspection and care. There is no justification for selling to epileptics, bromid-containing nostrums bearing no hint of the presence of such drugs and without warning of their powerful and dangerous character. The indiscriminate use of bromids is dangerous. The results that may follow their long continued use has been thus described:

> "In other cases evidences of mental aberration develops, the patient becoming irritable, morose and even homicidal. Sometimes, however, we find melancholy and hallucinations, and, rarely, exalted ideas. In still others a dangerous suffocative bronchitis develops, the patient may become profoundly cachectic, or the condition may resemble typhoid fever."

RADIO-REM

A correspondent sends to The Journal an advertisement of the Radio-Rem outfit (Schieffelin and Co.), which according to the advertisements, consists of a box containing eight glass stoppered bottles and an equal number of rods coated with radium sulphate. If the bottles are filled with water and the rod inserted and left to stand a certain time, the water is said to become charged with radium emanation. The claim is made that effects similar to those obtained at mineral springs are produced by drinking this "radio-active" water.

In view of the experimental and unsettled status of the use of radium in internal medicine, The Journal cannot express an opinion as to its value. Certainly convincing evidence of its utility has not been advanced.

The emanation in sufficient dosage is capable of producing marked effects on the animal organism. It is admitted, even by the strongest advocates of such treatment, (Bickel: Moderne Radium und Thorium Therapie, p. 31) that in no case is there an action on the cause of the disease. The largest class of diseases in which radium emanation has gained a reputation includes the various forms of arthritis, myalgia, neuralgia, etc. Improvement has been noted, but there are so many influences involved, especially in the class of diseases represented by the general term rheumatism, that a definite judgment is very difficult to form (see editorial The Journal, Jan. 17, 1914, p. 209). Newcomet says: "But as most of the diseases in which they (the radio-active elements) have been employed belong to a class for which certain forms of treatment have been periodically promulgated to be used for a short time, and finally be forgotten, more proof must be given of their efficiency before they can be universally adopted." (Radium and Radiotherapy, p. 288). The use of radium emanation must therefore be regarded as in the experimental stage.

Bearing in mind the very doubtful value of radium in internal medicine, the questions arise: (1) Does this apparatus give a solution of radium emanation? (2) Is the quantity of emanation sufficient to be of any value?

1. It is quite possible that the rod coated with radium sulphate may produce the amount of radium emanation claimed, but as the general practitioner is not equipped to measure the amount of radium on the stick, or the emanation in the water, he must accept the manufacturer's claim.

2. The value of radium emanation in any given condition is presumably dependent on the use of a proper dosage. Because arsenic in milligram doses is an effective remedy it does not follow that the thousandth part of a milligram will produce any effect. The dosage of radium emanation is measured usually in Mache units. Those who employ this form of treatment regard 3,000 to 5,000 Mache units as the beginning daily dose, to be increased at the end of a week if a reaction is not experienced. A dosage below this amount is not likely to be of any service. The dosage provided by the outfit described above is said to be only 100 Mache units, an amount which is probably inadequate. It should be remembered that radium produces different effects when small doses are given at intervals than it does when the total amount is given in one dose.

It is claimed that by the use of this outfit a substitute for natural mineral water may be supplied. One of the puzzling things about mineral waters is that when drunk at the spring they seem to have a different effect from that which they produce when bottled. Formerly this difference was explained by the assumption that rest, environment, regular habits and climate played a large part, but since the discovery of radium there is a tendency to attribute it to a loss of radio-activity in the bottled waters. Some natural springs, are, to be sure, markedly radio-active. Other springs to which empiricism has attributed equal therapeutic powers do not possess any exceptional radio-activity. There is moreover no convincing proof that radio-activity in mineral waters has any value. The proposition to make a mineral spring by placing a radium-bearing stick in a glass of water is another appeal to the belief in the mysterious.

ARTICLES REFUSED RECOGNITION

Reports of the Council on Pharmacy and Chemistry

Below appear abstracts of the Council's action on articles refused recognition which were not deemed of sufficient importance to require a lengthy report. Articles with the titles starred will be printed in full in the Reports of the Council on Pharmacy and Chemistry for 1914. A reprint of any of these unabridged reports will be sent on receipt of a two cent stamp. Previous instalments of abstracts appeared in The Journal, Nov. 14 and 21, Dec. 12, 1914, and Jan. 2, 1915.

G. G. Phenoleum Disinfectant

This material is a solution sold by the G. G. Chemical Company, Inc., of New York and claimed to be composed of the following ingredients:

> ". . . Volatile Hydrocarbons, Phenols, Resin Acids, Sodium Oxide and Heavy Hydrocarbons."

For it they claim the following properties:

> "PREVENTS DISEASES, KILLS SEWER GAS, PURIFIES THE TOILET."
>
> "*For any skin disease, 'tis as good for man as for beast.*"

As to its virtues as a disinfectant the manufacturers claim a phenol coefficient of 5 or 6. The disinfecting power is not however stated on the label as required by the Council for phenol disinfectants. Disregarding entirely the fact that disinfectants are available with a much higher phenol coefficient than the one claimed for this product, the statement is made that it is

> ". . . the most powerful disinfectant known."

As such claims are self-evidently unwarranted, G. G. Phenoleum Disinfectant was refused recognition.

Phytin—Fortossan

Phytin manufactured by the Society of Chemical Industry, Basle, Switzerland, and sold by A. Klipstein and Co., is an organic phosphorus compound said to be the "Acid Calcium-Magnesium Salt of Phytinic Acid (Inosit Phosphoric Acid or Anhydro-Oxymethylene-Diphosphoric Acid)" obtained from cereals and legumes.

The trade package of Phytin constitutes an indirect advertisement to the public.

The Council rejected Phytin because unwarranted and exaggerated therapeutic claims are made for this product based on the entirely undemonstrated assumptions: (1) that phosphorus is assimilated only from organic combinations (it is even implied that this must be in the form of Phytin, and that milk is incapable of supplying the phosphorus needs of infants); (2) that a long list of diseases, ranging from rickets to hysteria, are due to deranged phosphorus metabolism; (3) that all these diseases are cured or markedly benefited by Phytin.

In brief, the claims rehearse *every* point of the more or less discredited phosphorus propaganda, in exactly *the* same way as it was rehearsed successively by the exploiters of hypophosphites, lecithin, glycerophosphates, and amorphous phosphorus. It is conceded by the writers of the advertising pamphlets for Phytin that the preceding claims were erroneous; but no evidence is given to warrant the belief that the Phytin claims are less erroneous.

The misleading statements are most extreme. By the use of bold type particular stress is laid on the preposterous and vicious claim that Phytin

> "radically and permanently removes sexual debility."

Fortossan is a preparation of Phytin and sugar of milk, also manufactured by the Society of Chemical Industry, Basle, Switzerland, and sold by A. Klipstein and Co. Since Fortossan is a simple preparation of Phytin the Council voted that the rejection of Phytin should also apply to Fortossan.

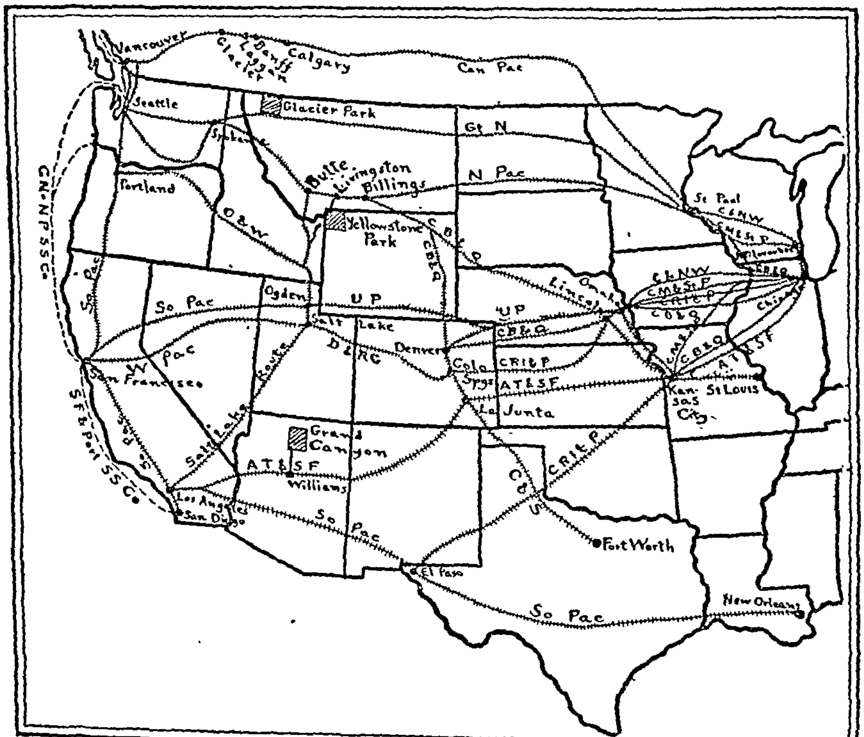
Association News

THE SAN FRANCISCO SESSION

Suggestions as to Railroad Routes Which May Be Used in Making the Trip

Preparations for the annual session of the American Medical Association, to be held in San Francisco, June 21-28, are under way. The several routes to San Francisco are here outlined briefly, in order that Fellows may have information to guide them in planning the trip. Travel from the East to the Pacific Coast passes in the main through three "gateways" — Chicago, St. Louis and New Orleans. In other words, eastern trunk lines carry passengers to Chicago, St. Louis or New Orleans and from these points, other railroad systems take them to the Pacific Coatst.

These western routes can be grouped roughly, according to the point at which they cross the Rocky Mountains, into the northern (the extreme northern one going through Canada), the central and the southern routes. Each has its attractions.



Outline map, showing some of the railroad routes to San Francisco and giving their general direction.

FROM EASTERN POINTS

From the New England States, the shorter route is through Chicago; but if the number of miles traveled and the time do not have to be too carefully considered, the trip may be southward, through New York, Philadelphia and Washington to New Orleans. From the Middle Atlantic and East Central States the more direct routings are by way of either Chicago or St. Louis, but the New Orleans gateway merits consideration, especially from the eastern section of this territory. From the South Atlantic States, New Orleans and St. Louis are the nearer gateways, but excellent trains place Chicago at the service of those from this territory.

THROUGH CHICAGO

The six railroad terminals in Chicago are here listed, beginning with the one located to the extreme southeast of the group, the several lines using the different stations being noted. (Roads coming into the city from the east and south are in roman, those going west are in italic type.)

1. Central Station, Twelfth Street and Lake Front: Illinois Central Railroad (*also operates a line west to Omaha*); and New York Central Lines, Big Four Route and Michigan Central Railroad.
2. Dearborn Station (also known as Polk Street Station), Dearborn and Polk Streets: *Atchison, Topeka and Santa Fe Railway;* Chesapeake and Ohio Railway; Chicago and Eastern Illinois Railroad; Erie Railroad; Grand Trunk Railway; Monon Route, and Wabash Railroad (*also operates lines to Omaha and to Kansas City*).
3. LaSalle Street Station, LaSalle and Van Buren Streets: The New York Central Lines, the Lake Shore and Michigan Southern Railway, and *Rock Island Lines.*
4. Grand Central Depot, Fifth Avenue and Harrison Street: Baltimore and Ohio Railroad; *Chicago Great Western; Minneapolis, St. Paul and Sault Ste. Marie Railway*, and Pere Marquette Railroad.
5. Union Passenger Station, Canal and Adams Streets: *Burlington Route; Chicago and Alton Railroad; Chicago, Milwaukee and St. Paul Railway* and Pennsylvania Lines.
6. Chicago and Northwestern Passenger Terminal, Madison and Canal Streets: *Chicago and Northwestern Railroad.*

THE NORTHERN ROUTES

From Chicago, for one of the northern transcontinental routes, the next central railroad point is St. Paul or Minneapolis. The principal lines to be considered are the Burlington; the Chicago and Northwestern; the Chicago, Milwaukee and St. Paul (this road operates a line to Seattle); the Great Western; the Rock Island, and the Minneapolis, St. Paul and Sault Ste. Marie.

From St. Paul and Minneapolis, the Canadian Pacific Route is through Minnesota, the Dakotas and the southern portion of western Canada. Its magnificent scenic attractions have made this line justly popular. The chief points of interest are at Banff, Laggan, Field and Glacier. At each of these points, the railroad company conducts a well-appointed hostelry for the convenience of sightseers. There are additional comfortable hotels provided along the route, so that it is possible to arrange an itinerary which will permit seeing the entire Canadian Rockies along this route by daylight travel.

The Great Northern route may be taken at St. Paul or directly from Chicago, as already noted. This road goes through the great wheat growing districts of Minnesota and the Dakotas, and through Montana, Idaho and Washington. The special scenic attraction of this railroad is that it provides access to Glacier National Park, a tour of which ordinarily occupies about five days.

Or, the Northern Pacific route may be selected from St. Paul and Minneapolis, with a view of visiting Yellowstone National Park. Its course is very similar to that of the

Great Northern through wheat country, "bad lands" and Rocky Mountain passes.

All these northern routes center at Seattle or Tacoma, from which points the Shasta route to San Francisco may be taken, or the final portion of the trip to San Francisco may be by boat.

THE CENTRAL ROUTES

Central lines from Chicago are over the Chicago and Northwestern to Omaha, then via the Union Pacific through Cheyenne and Ogden, and the Southern Pacific to San Francisco. This is the most direct of all routes available, and the trip can be made in about ten hours less time than over any other lines. The special trains making this fast time are extra-fare trains.

Other central routes are via the Burlington to Denver, or the Chicago, Rock Island and Pacific to Colorado Springs. These lines pass through the great corn belt—Illinois, Iowa, Nebraska and Kansas. Thirty-six hours may profitably be employed in and around Denver and Colorado Springs, visits being made to Pike's Peak, the Garden of the Gods, Manitou and other neighboring points of interest. By arranging to leave Denver in the late evening so as to pass through Colorado Springs about 4 o'clock in the morning, over the Denver and Rio Grande, one may see the wonders of the Royal Gorge early during the following day, arriving at Glenwood Springs in the late afternoon and Salt Lake City the morning following. Salt Lake City merits a stop of at least three or four hours. By leaving this point about noon over the Western Pacific, one may enjoy the superb scenery of the grand canyon of the Feather River on the last day of the journey, and San Francisco should be reached in the late afternoon or early evening.

THE SOUTHERN ROUTE

The southern route from Chicago is via the Atchison, Topeka and Santa Fe through Kansas City, La Junta, Albuquerque and Los Angeles. At Williams, a short side trip permits of a visit to the wonderful Grand Canyon of the Colorado. A well-appointed hotel, located on the edge of the Grand Canyon, permits the traveler to stay for as long or as short a time as he desires to view these wonders. Those who desire to make the trip down the canyon to the river will have to reach the Grand Canyon so that they can start down the trail by about 9 o'clock in the morning, as it takes the greater part of a day to make this trip. Parties may make arrangements to drive to different points of interest along the rim of the Canyon.

THE ST. LOUIS GATEWAY

At St. Louis all the railroads use the same station: Baltimore and Ohio Railroad; Big Four Route; *Burlington Route; Chicago and Alton Railroad;* Chicago and Eastern Illinois Railroad; *Chicago Rock Island and Pacific Lines; Frisco Lines;* Illinois Central Railroad; Louisville and Nashville Railroad; Louisville, Henderson and St. Louis Railway; *Missouri, Kansas and Texas Railway; Missouri Pacific Railway;* Mobile and Ohio Railroad; Pennsylvania Lines; *St. Louis, Iron Mountain and Southern Railway; St. Louis Southwestern Railway;* Southern Railway; Toledo, St. Louis and Western Railroad, and The Wabash Railroad (*also operates line west to Omaha and to Kansas City*). The central and southern routes noted above are the more available to those who use this gateway, connections therewith being made at Kansas City or Omaha.

NEW ORLEANS ROUTINGS

From New Orleans the direct route is over the Southern Pacific, which skirts the southern border of Texas, New Mexico and Arizona, passes through Los Angeles and goes up the west coast of California to San Francisco.

RAILROAD AND PULLMAN FARES

The following railroad fares have been announced to San Francisco and return: via direct routes from Chicago, $62.50; from St. Louis or New Orleans, $57.50; one way (not both) via Portland, Ore., Seattle, Wash., or Victoria, B. C., from Chicago, $80; from St. Louis, $75; from New Orleans, $83.75. Rates from eastern territory to these three gateways will be announced later.

The cost of Pullman service to San Francisco can be estimated from the following rates from the points mentioned. These are for space in regular line cars for a continuous trip and do not cover service in special cars or trains where stopovers are to be made at points en route to San Francisco.

Pullman rates from the following principal cities are:

PULLMAN RATES TO SAN FRANCISCO

From	Drawing Room	Compartment	Section		Tourist	
			Upper	Lower	Upper	Lower
Boston	65.00	52.00	14.80	18.50	7.80	9.75
New York	63.00	50.50	14.40	18.00	*	*
Washington, D. C.	62.00	49.00	14.00	17.50	....	9.00
Chicago	46.00	36.50	10.40	13.00	5.60	7.00
St. Louis	44.00	35.00	10.00	12.50	5.20	6.50
New Orleans......	41.00	32.50	9.20	11.50	4.60	5.75

* No Tourist.

BY WATER ROUTES

In addition to these all-rail routes, part or all of the trip may be made by water. From points on the Atlantic Coast, boats sail to New Orleans, and then through the Panama Canal or directly through the canal and up the Pacific Coast to San Francisco. This all-water route takes about two weeks, and the rates vary in accordance with the accommodations; first cabin passage, one way, between New York and San Francisco, is $125 and up. On the Pacific Coast, the trip may be made by boat between the following points: San Diego and Los Angeles, San Francisco, Portland, Seattle or Tacoma and Vancouver. Boats may also be taken at Buffalo or any of the lake points through the Great Lakes to Chicago.

The foregoing is intended rather to suggest routes which may be used in making the trip to San Francisco than to present a complete and detailed announcement of these routes. Those who contemplate the trip should consult their local passenger agents, who will be able to give them exact information regarding routes, schedules, rates and stop-over privileges.

Correspondence

Flight of Mosquitoes

To the Editor:—In the article "Prevention is Greater than Cure," in the section headed "Mosquito Pest" (The Journal, Oct. 17, 1914, p. 1392) the categorical statement is made: "Mosquitoes, unless wind-blown, travel only a few hundred yards from their source of breeding." This is incorrect. Numerous studies by many observers have conclusively shown that many species, including such proved disease carriers as *A. albimanus, C. fatigans,* and *A. argyritarsis,* travel very considerably more than "a few hundred yards," unless by "a few hundred yards" the author intends to cover 1,000 to 2,000 yards. Also, at least certain species, and among these the *A. albimanus,* travel by preference *against* a mild breeze, one not exceeding a velocity of 4 miles per hour. The supposition of mosquitoes being "blown by wind" is open to serious doubt. It is more than likely that they travel during the calm immediately following a blow. In experimental work carried on in Panama, anopheles were invariably caught in larger numbers in the traps set on the lee sides of houses.

"These salt-water mosquitoes do not carry disease."

A. albimanus and *argyritarsis* breed in salt water under certain conditions. We have found these species breeding very prolifically in lagoons with a chlorin content almost equal to sea water.

I would suggest the perusal of Le Prince's paper in the *Transactions* of the Fifteenth International Congress on

Hygiene and Demography, and the articles dealing with mosquitoes in the reports of the New Jersey Agricultural Experiment Station.

A. J. Orenstein,
Rand Mines, Ltd., Johannesburg, Africa.

A Substitute for Potassium Permanganate to Liberate Formaldehyd Gas From a Water Solution

To the Editor:—In The Journal, Sept. 19, 1914, p. 1025, I presented the formula of a mixture in which potassium permanganate was replaced by sodium dichromate.

We have found that the formaldehyd solution shipped in combination with the sulphuric acid, when subjected to the extremely low temperatures of winter, is not sufficiently stable for Northern climates. By adding 1½ fluidounces of glycerin to this formula, we have secured a stable solution that will bear moderately low temperatures without loss of efficiency and without polymerization. We are now using the following formula:

Sodium dichromate	10 ounces avoirdupois
Saturated solution of formaldehyd gas	1 pint
Sulphuric acid, commercial	1½ fluidounces
Glycerin	1½ fluidounces

We have also learned that when the acidulated solution has shown a tendency to become cloudy or milky because of the low temperatures, it may be clarified and made potent by gently warming for a long period of time.

Samuel G. Dixon, M.D., Harrisburg, Pa.
Commissioner of Health, Commonwealth of Pennsylvania.

The "Twilight Sleep"

To the Editor:—I am enclosing a little article from a lay paper—(clipping regarding the formation of a club known as the "Twilight Sleep Association"). I think the matter of the 'twilight sleep' is taking a serious character and it is high time for the American Medical Association to take steps against these quacks, whose first and only aim is the money part attached to it. They certainly have clever and excellent press agents and lead the public well.

H. Hallarman, M.D., New York City.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

THE HARRISON BILL

To the Editor:—According to my idea of the Harrison bill, it does not affect the men who write prescriptions, or prevent hypodermic medication, etc., but affects dispensers whether pharmacist or doctors of any sort. Am I correct? The $1 tax is what is troubling them. Kindly answer.

J. A. H., Pittsburgh.

To the Editor:—Relative to the recently passed federal law regulating the traffic in habit forming drugs, The Journal with its characteristic promptness presented it to the profession in a clear, compact and scientific manner.

I have no legal knowledge other than an average amount of "horse sense," but immediately on looking it over, when reading my journal, I thought that while the intentions of the framers may have been of the best, their attempts were short sighted to say the least. On the other hand, they may be the victims of some hidden power of criminal drug traffickers. This is no excuse, however, and if I am correct in the conclusions I have drawn, then the framers ought to be ashamed of themselves for making another farcical law, one impossible to enforce.

Turn to Section 6 and you will note it reads in part that "this act shall not apply to preparations or remedies for external use only." Fine isn't it? What do you think, Doctor Editor?

H. J. G.

Answer.—These are samples of inquiries received from readers of The Journal asking for details regarding the Harrison bill and its effect on physicians. This bill was before Congress for over two years, during which time it was frequently revised in committees or on the floor. On account of the numerous changes made, it is difficult, if not impossible, to know in exactly what form the bill finally passed. Three drug journals have published what purports to be the complete and exact text of the bill as enacted, yet no two of these three versions agree. It is obviously useless to comment on the bill until its exact provisions are known. A letter addressed to the United States Commissioner of Internal Revenue, asking for a certified copy of the law and of any rulings bearing on it, has elicited the reply that official copies of the bill have not yet been issued, but will shortly be published with official rulings as to its meaning, and regulations for its enforcement. As soon as this official information is available, The Journal will give a summary of the law for the benefit of its readers. In the meantime, there is no occasion for alarm or uneasiness on the part of physicians. The enforcement of a law involving so many details as the Harrison law will necessarily be undertaken slowly, and due announcement of the measure and its provisions will undoubtedly be made to all those affected by it. Several drug companies have recently sent out printed statements to their patrons regarding the provisions of this bill. In several cases, the statements made are clearly erroneous. Physicians are urged to await further information through the columns of The Journal.

METHOD OF CHAMPIONNIÈRE—EMULSION OF BALSAM OF PERU

To the Editor:—1. Where can I obtain detailed information in regard to Lucas-Championnière's method of treating fractures? Is there a book on the subject published in English?

2. Give me a formula for an emulsion of balsam of Peru containing either 5 or 10 minims of the drug to the dram of emulsion.

H. W. C.

Answer.—1. The following is a list of references to the original articles of Dr. Championnière. Practically all books on massage discuss his methods:

Lucas-Championnière, J.: Traitement des fractures par le massage et la mobilisation, Paris. Rueff & Cie., 1895, pp. 564.
Lucas-Championnière, J.: Les dangers de l'immobilisation des membres; fragilité des os; altération de la nutrition du membre, *Jour. de méd. et chir. prat.*, 1907, lxxviii, 81.
Lucas-Championnière, J.: Treatment of Fractures, *Brit. Med. Jour.*, 1906, ii, 1669.
Lucas-Championnière, J.: Treatment of Fractures by Massage and Mobilisation, *Brit. Med. Jour.*, 1912, ii, 1530.
Lucas-Championnière, J.: Traitement de la fracture du col du fémur par le mouvement immédiat et le lever, *Jour. de méd. et chir. prat.*, 1912, lxxxiv, 245.

2. Mistura olei-balsamica N. F. is an alcoholic solution of about 1 per cent. (5 grains to the ounce) of balsam of Peru and various aromatic oils.

The following emulsion gives practically 4 minims to the dram, and by increasing the amount of balsam of Peru to 4 drams, a proportion of 5 minims to the dram will be obtained. (See A. W. Gerrard, *Am. Jour. Pharm.*, November, 1880):

Balsam of Peru	3 drams
Powdered acacia	2 drams
Simple sirup	6 drams
Water ....to	6 ounces

SOUTHEY'S TUBES IN DROPSY

To the Editor:—In a communication on "Sodium Chlorid in Bright's Disease" (The Journal, Dec. 26, 1914, *p.* 2305), Dr. Paul Z. Hebert of New York refers to the use of "Southey's tubes *to reduce* dropsy." Can you give me further information *with regard* to the use of the tubes, and indicate how successful the use has *been*?

J. W. Crenshaw, M.D., Cadiz, Ky.

Answer.—The use of Southey's tubes is described as follows by G. P. Müller *in* "Practical Treatment," Musser and Kelly, Vol. I, page 689:

> The apparatus consists of a *trocar* and several cannulas, the latter having lateral openings at their distal ends. After careful cleansing of the skin with soap and water, alcohol, and tincture of iodin, the skin is punctured at right angles to the surface and the trocar and cannula pushed as far as the muscle tissue. *The trocar* is then withdrawn and the cannula fitted to a piece of rubber tubing which drains into a receptacle. *Three or four* cannulas may be introduced in this manner, and should be supported by gauze packed around them. The serum often clots in the tubes and interferes with the drainage.

This method has been generally recommended, and is of temporary service in removal of edema.

Book Notices

Operative Surgery. The Head and Neck, the Thorax and the Abdomen. By Edward H. Taylor, M.D., B.S., F.R.C.S.I., Professor of Surgery in the University of Dublin. Cloth. Price, $9 net. Pp. 524, with 300 illustrations. New York: William Wood & Co., 1914.

The author does not attempt to cover fully the operative surgery of the head, neck, thorax and abdomen, but deals only with the commoner and more important operations. There is a brief and elementary introductory chapter on the nature of infection and general surgical technic which more properly belongs in a book on principles of surgery. Ether is recommended as the general anesthetic of choice, and the statement that if chloroform were abolished, the advance of surgery would be hastened rather than retarded, shows that the British are gradually approaching the point of view so long held in this country. Hedonal as an intravenous anesthetic is recommended when patients are in a critical condition resulting from cachexia, hemorrhage, nephritis, etc. Local anesthesia receives far too scanty consideration. It is scarcely mentioned in such operations as hemorrhoidectomy, thyroidectomy, herniotomy and tracheotomy. Most of the important operations are exceedingly well illustrated. Cushing's technic is followed quite generally in the chapter on cranial surgery. For the radical removal of glands of the neck, the old curved incision is employed, which begins in the submaxillary region, extends backward and upward across the upper portion of the sternomastoid, and downward through the posterior triangle along the anterior border of the trapezius muscle. This leaves an ugly scar in the upper part of the neck. Kocher's technic is followed in thyroid operations, except that general anesthesia is still recommended. Little space is devoted to thoracic surgery, the subject being dismissed with the usual description of the operations for acute and chronic empyema, and for drainage of the pericardium. Hernia is very well given and well illustrated, as are all of the operations on the gastro-intestinal tract. A number of pathologic illustrations are employed in the chapters dealing with carcinoma of the colon and rectum. In gall-bladder work a straight incision is recommended for the simpler cases, and the Bevan method of extension when more room is required. The operations on the male genital and urinary tracts are extensively given. On the whole, the book gives a clear presentation of the subjects with which it deals, but possesses no new features that are worthy of comment.

Anesthetics: Their Uses and Administration. By Dudley Wilmot Buxton, M.D., B.S., Administrator of Anesthetics in University College Hospital, London. Fifth Edition. Cloth. Price, $3 net. Pp. 477, with 84 illustrations. Philadelphia: P. Blakiston's Son & Co., 1914.

This is essentially a manual dealing with the practical phases of surgical anesthesia. The discussions of the physiologic aspects of the question are almost entirely concerned with the more superficial phenomena associated with the action of anesthetic drugs. There is almost no mention of the really fundamental disturbances produced in the cell. Thus, there is no mention of such important generalizations as that of Meyer and Overton, concerning the relationship of the narcotic property of a drug to its partition coefficient between fat and water, or as that of Verworn in regard to the association of tissue asphyxia with narcosis. The book, therefore, again calls attention to the fact that there is no adequate presentation of what is already known about the theory of narcosis in any of the numerous works which claim to present what is termed the physiologic aspect of the subject. There are, however, many commendable features. The practical side of the administration of anesthetics is thoroughly covered. Like most Europeans, the author devotes far too much space and consideration to chloroform; but, on the other hand, it is encouraging to find as much consideration given to ether and nitrous oxid. The section on local analgesia seems a little brief, but nevertheless the subject is fairly well considered. There is an additional section on spinal analgesia and an interesting chapter on medicolegal aspects of the administration of anesthetics. One of the most interesting parts of the book is the first chapter, dealing with the historical aspect, in which due credit is given to the group of American pioneers in the application of sleep-producing drugs to surgical practice.

The Body and Its Defenses. By Frances Gulick Jewett. Cloth. Price 65 cents. Pp. 346, with illustrations. The Gulick Hygiene Series. Boston: Ginn & Co., 1914.

Good Health. By Frances Gulick Jewett. Cloth. Price 40 cents. Pp. 174, with illustrations. The Gulick Hygiene Series. Boston: Ginn & Co., 1914.

These two volumes belong to the Gulick Hygiene series, previously reviewed in The Journal. The first is intended for the elementary grades and discusses methods of personal health, what to do for the eyes, ears, teeth, finger nails, hair, etc., how to keep clean, how to get pure air and how to avoid the ills that come through violation of the laws of good health. The intention of the writer has been to write "a little book for a little child." It is simply written and freely illustrated, being divided into short chapters, each followed by a few questions intended to emphasize important points. The second book is intended for older children and deals with applied physiology as well as hygiene. The two have been adopted for use in the public schools of Kentucky, and a special edition prepared containing a supplement by the State Board of Health, which is perhaps the most unique feature of the two volumes. The apparent and close cooperation between the State Board of Health and the educational authorities is highly commendable. Figures from the State Bureau of Vital Statistics are freely quoted, showing the number of births and deaths and the number of deaths from preventable diseases in Kentucky since 1911. Special emphasis is laid on the fact that the greatest asset of the state is the health of its people, and an appeal is made to each child to assist in raising the health standard of the state to the highest possible point.

Reducing Weight Comfortably. The Dietetic Treatment of Obesity. By Prof. Gustav Gaertner, M.D. Cloth. Price, $1.50 net. Pp. 313. Philadelphia: J. B. Lippincott Company, 1914.

The author bases his practice on an experience with 2,000 cases of obesity. This experience has brought him to the employment of a diet based on the well-known principle that a reduction in the total quantity of food below the actual needs of the patient must lead to a reduction in body weight. The method depends on the careful use of the scales, with reference both to the weight of the patient and to the weighing of food. The author first subjects his patient to careful observation to determine the average difference in weight between the maximum and minimum of each day. Based on this, the diet is so regulated as to reduce the weight without encroaching on the minimum. In this way, the patients lose weight without feeling discomfort. The diet is then regulated according to a definite plan as to the amount of body weight to be lost. Details of the treatment have reference to the use of different articles of diet and of water, and also the effect of various forms of regimen. Exercise is used moderately but not to excess. The author recognizes the principle that exercise necessarily increases appetite, and hence renders it difficult to restrain the intake of food. The book is a rational and practical discussion of an important but neglected subject.

Fear and Conventionality. By Elsie Clews Parsons, Ph.D. Cloth. Price, $1.50 net. Pp. 239. New York: G. P. Putnam's Sons, 1914.

While not exactly within the field of medicine, this book can be read with profit by physicians, dealing as it does with the psychologic and evolutionary causes of fear and conventionality. The general thesis of the writer is that practically all of the conventions of modern civilization are based on or at least have their parallel in some similar, though often absurd, custom of primitive peoples. While somewhat destructive of one's own conventional ideas regarding good breeding and manners, the intellectual stimulus to be gained from reading the book is worth the risk.

Medicolegal

Power of Vice President to Contract for Medical Services

(James Sanatorium vs. Yadkin River Power Co. (N. C.), 83 S. E. R. 464)

The Supreme Court of North Carolina affirms a judgment in the plaintiff's favor for medical services rendered to one Flake, who was an employee of the defendant company. The court says that it was in evidence that Flake was taken to the hospital by the defendant's physician, who stated that he had done it by order of the defendant's vice president, and that the plaintiff would send its bill to the defendant, who would pay it. The next day the vice president called over the telephone, from the factory of the defendant, to the president of the plaintiff company, and inquired "How is my man, Flake, I sent you last night?" He further asked the details, and told Dr. James to "give him every possible attention and, if he needed any special care, to give him special nurses and he would see that there was no trouble about the money, and to send the bill to him, and the Yadkin River Power Company would pay it." Prior to that time the plaintiff had rendered medical services to a typhoid fever patient, at the request of the defendant's vice president and physician, who stated that the Yadkin River Power Company would pay the bill, and it was paid according to the evidence of both the plaintiff and the defendant.

The chief contention was that the office of vice president does not necessarily confer power to contract debts for the corporation. It is true enough that the power of a vice president depends, not on his title, for his function differs according to the by-laws or according to the use and practice of the particular company. In some railroad companies there are many vice presidents who have great authority. There are other companies in which the vice presidency is a mere ornamental position. No general rules can be laid down as to the power of a vice president to bind the company, which would arise as a presumption in the case of the president.

In this case there was evidence sufficient to go to the jury to establish the authority of the vice president to act for the company in cases of this kind. His calling up the president of the sanatorium company from the office of the defendant, stating to him that Flake had been sent there by his authority, making full inquiries about him, and directing the bill to be sent to him, saying that the defendant would pay it and asking for special attention to be given to Flake, together with the fact that Flake was also carried to the sanatorium by the salaried physician of the defendant, and the further fact that another patient had been sent there by the vice president, accompanied by the physician of the company, and that by their direction the bill had been sent to the defendant and paid by it—all these things were sufficient to submit to the jury the question as to the authority of the vice president in this case, and it would have been error to direct a non-suit on this evidence.

Opinions of Attending Physicians and Others as to Mental Capacity

(Bahl vs. Byal et al. (Ohio), 106 N. E. R. 766)

The Supreme Court of Ohio holds that it is not competent, in a proceeding to contest a will, for a witness to give an opinion as to whether the testator had capacity to make a will. But the physical and mental conditions from which it may be determined by the court and jury whether he had such capacity are facts which may be shown by manifestation of such conditions. And it is competent for the physician of a testator to express an opinion as to the actual condition of his patient's mind, founded on his study and observation of the testator while in professional attendance on him at the time and prior to the date of the will, and whether he was capable of comprehending large and complicated business propositions or the distribution of a large estate.

The court says that it is not doubted that the opinions of physicians touching questions of mental strength or weakness are competent to be given in evidence in cases in which those matters are in issue. The weight to be given the evidence in a particular case is to be determined by the jury, as the testimony of witnesses touching any other matter should be determined. Where the physician has had opportunity to observe mental conditions by reason of having acted through a sufficient period of time as medical attendant, it is proper for him to express an opinion on the actual condition of the patient's mind at the times, or during the period, in which he was so engaged. And where the grounds have been properly laid for a hypothetical question, a physician, who has properly qualified as an expert, may give his opinion as to the mental condition of the person referred to in the question under the circumstances stated therein. These principles are well recognized.

A physician, giving his opinion on the mental capacity of a testator, or other person, which is based on the actual knowledge which the physician has gained by personal contact with, and study of, such person as a patient, occupies a different relation to the matter than a physician who has no such knowledge, and who testifies in answer to hypothetical questions. The only sound theory on which the opinion of an expert is admitted at all is that he has the knowledge, training and experience with which to form a better opinion on a certain state of facts than one not so well equipped. Necessarily, the opinion of a physician, which has been formed by the slow and sure processes of time and responsibility in connection with the performance of professional duty to a patient, is more valuable than that of one who has not such advantages and gives his opinion from a hypothetical question. The line between strength and weakness in the mind is so elusive that it may well be doubted whether a stranger can be brought by descriptions of the mental manifestations of a particular individual into a position to make his testimony concerning it of great value, except in well-defined cases. There is an increasing loss of confidence in that class of expert testimony.

Malpractice Not Covered by Casualty Insurance

(May Creek Logging Co. vs. Pacific Coast Casualty Co. (Wash.), 144 Pac. R. 67)

The Supreme Court of Washington affirms a judgment rendered in favor of the defendant, which was sued by the plaintiff to recover $4,500 and costs, which the latter had had to pay because a physician and surgeon whom it had furnished to attend an injured employee had treated him so unskilfully and negligently that he was permanently crippled. The court says that the defendant had insured the plaintiff against loss and expense arising from claims or damages on account of bodily injury accidentally suffered by the prosecution of general logging operations, "and the various departments thereof, and dependent and connected operations and parts thereof." The plaintiff alleged that it was the custom of logging companies to deduct a hospital fee from the wages of each of their several employees, and use the fee in the payment of services to be rendered such employees as became sick or injured, and that the defendant knew of such custom, but the court cannot think that the facts in any way altered or modified the terms of the insurance. A demurrer to the plaintiff's complaint was properly sustained on the ground that the loss suffered by the plaintiff was not a loss covered by the conditions of the policy. The defendant's liability, of course, depended on the conditions of its policy. If it thereby undertook to answer for losses arising from claims of damages on account of the negligent failure of the plaintiff to perform a special contract wherein it undertook to furnish an employee with hospital, medical and surgical services, then it was liable to answer to the suit of the plaintiff; otherwise not. The court cannot think the policy bore this interpretation. Hospital, medical and surgical services were no part of the logging operations, and the injured employee while in the hospital was performing no service connected with the plaintiff's logging business.

Society Proceedings

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

Meeting held Dec. 14, 1914

DR. JAMES E. TALLEY in the Chair

Recent Changes in Our Concept of the Action of Digitalis

DR. H. C. WOOD, JR.: When given in physiologic dose, digitalis does not increase the blood pressure in either man or the lower animals. It is probable, however, that there is some constriction of the blood vessels, as is shown by the fact that when the slowing of the pulse is prevented, the pressure is increased, and it is probable also that the diuretic effect is due to changes in the caliber of the vessels. The slowing of the pulse, which is the most constant effect of digitalis, is, in healthy individuals, purely inhibitory. Stimulation of the vagus may produce heart block and other irregularities of rhythm. The slowing of the pulse is completely abolished by large doses of atropin. The muscular tone is not demonstrably affected after small doses, although it is possible that the largest therapeutic doses may increase it. The cardiac contractions are, however, enlarged. The effects in disease are often very different from those in health. In fever the vagus appears to be less than normally irritable, and digitalis does not slow the pulse. In chronic endocarditis the effects are different, according to whether the rhythm is normal or there is auricular fibrillation. In the latter condition, it will generally produce great slowing of the pulse. It is impossible from the present data to draw positive conclusions as to the mechanism of its action in this condition, but it is probably due to stimulation of inhibition and partly to diminished ventricular irritability, the result of better nutrition. In cases of endocarditis with normal rhythm, its effects are often much less marked. It is a mistake to give digitalis in all cases until the manifestation of toxic effect. Some conditions require larger doses to have any action, while others may be injured by full doses but benefited by small ones.

Clinical and Electrocardiographic Studies of the Action of Digitalis

DR. ALFRED E. COHN, New York: Investigations were made in patients having an early rather than an advanced stage of heart disease. The mechanism of their hearts was normal, they had no edema, and their blood pressure was within normal limits. The reduction in the rate of the heart is an effect of digitalis on which we rely, but one which we have not found constant in this type of case. Digitalis slows the sinus rhythm only in the group of hypodynamic hearts; to produce slowing is not a function of digitalis in therapeutic doses. An effect on conduction may be set down as a usual effect of giving the drug, apart from specific preexisting injury. We have noticed delayed conduction within forty-eight hours after the administration of the drug had been started. In many instances the auriculoventricular interval gradually lengthened during the succeeding three to five days, until partial heart block occurred. In some cases, however, block occurs with extreme abruptness. One arhythmia, practically unknown, the result of giving digitalis, is one in which none of the auricular beats are blocked. The auricles and ventricles continue to beat almost at the same time, but there is incomplete coordination between them. Another new sign in the electrocardiogram is an alteration in the size, shape and direction in the T-wave. The first change noted after the administration of digitalis is usually a diminution of the height of this wave, usually in the third lead first, and later in the second. The change may be noticed as early as twenty-four hours, and at the end of forty-eight hours the wave may have become iso-electric, or it may become diphasic. In some electrocardiograms, the T-wave for pathologic reasons is pointed downward. If digitalis is given, the direction of the T-wave during the action of the drug is pointed upward. While the causative factors in the change of the T-wave cannot be precisely explained, the inference is that there is an alteration in the contractile substance of the heart muscle. Two criteria appear, then, in electrocardiograms to indicate surely the fact that digitalis is acting on the heart: the first in the slight but definite lengthening in conduction; the second, the very curious alteration in the T-wave. Electrocardiographic evidence can be supplied to show that digitalis has an action during fever of a nature precisely similar to that already described in non-febrile patients. Possibly as an aid to contraction, much can be gained from the use of digitalis; but the expectation of obtaining an action on heart rate must be abandoned. There is, however, a group of febrile cases in which digitalis acts efficiently on rate. These in our experience have been patients showing auricular fibrillation or auricular flutter. Another topic long a subject of conflict is the relation of digitalis action to blood pressure. In the cases which we have studied, no alteration in pressure was found. Vascular effects, however, aside from changes in pressure, may be produced, and the untoward or beneficial nature of these require consideration. In the group of patients under consideration, no increase in diuresis takes place. In patients having edema, other factors are involved. That a specific effect on urinary output does not occur as the result of giving digitalis in the patients under discussion has an important bearing on the drug's action in edema. In connection with the mechanism of the action of digitalis, two possibilities have been much discussed; an action on the inhibitory mechanism and one on the heart muscle itself. Our studies lead us to believe that both views are partially right. So far as atropin may be taken to be a drug acting especially on the ends of the vagi, a release of the heart from a phase of digitalis action by its use indicates a nerve action of digitalis. So far as digitalis has other effects which atropin does not release, its effect on the T-wave, it may be inferred that it has an action directed more especially to muscle. Both effects can be observed at the same time.

NEW YORK NEUROLOGICAL SOCIETY

Meeting held Dec. 1, 1914

DR. E. G. ZABRISKIE in the Chair

Brain With Double Frontal Abscesses

DR. L. CASAMAJOR: The patient was a mechanic and inventor, aged 50, whose family history was negative. Between 20 and 30 he had several severe attacks of articular rheumatism, with heart complications. The patient had always been very active as a young man, and at one time was a long distance bicycle rider. Until about twenty years ago he used alcohol habitually and to excess, but for fifteen years preceding his death he had been a total abstainer. He smoked constantly and used chewing tobacco daily. During the past ten years he had worked very hard at his trade and had accomplished a great deal in a mechanical line. He took no recreation excepting a few days each summer, when he did some yacht racing.

The exact date of the onset of his present illness could not be fixed. He was in the habit of receiving osteopathic treatment for minor ailments, and was under the care of an osteopath when he came under observation, March 10, 1914. At that time he complained only of a slight frontal headache and of being unusually tired. He was slightly jaundiced. The pupils were contracted, reacting slowly. The tongue was heavily coated and the breath offensive. The temperature was normal; pulse, 60 and full. On his first day in the hospital he refused to stay in bed; he wished to go to business and insisted on smoking his pipe. On the following day he kept his bed and abstained from tobacco. He remained in his usual jovial mood, and his symptoms were such as one would expect in a case of catarrhal jaundice. His condition remained practically unchanged for four days, without improvement in appetite, appearance of tongue, etc., in spite of active purgation.

On the fifth day he was quite indifferent to his surroundings and very talkative. His headache had disappeared almost entirely, and he still complained of nothing. When left alone he talked and whistled, and was not at all disturbed when he soiled the bed by an involuntary defecation. His pulse remained slow, and the rectal temperature on the fifth day was 101 F. The urine was stained deeply with bile; it contained a trace of albumin; no sugar; there was a marked indican reaction and a few hyaline casts. No complete blood count was made, but a differential count showed 79 per cent. polynuclears. The stools were offensive and lighter in color than normal. The pupils remained contracted and sluggish, acting equally. The ears showed nothing abnormal, and there was no nasal discharge.

The patient remained in practically the same condition for another twenty-four hours, appearing indifferent when he was alone, but acting quite rational on being questioned. There was no paralysis and the reflexes were normal, excepting pupillary. His temperature, on the evening of the sixth day, was 101 F. in the rectum; pulse, 54; respirations, 18. At 8 a. m. on the seventh day after his admission, he suddenly developed a chill, the rectal temperature rose to 106 F., he became comatose, developed Cheyne-Stokes respiration and died in three hours.

The brain was removed; about half an ounce of fouling pus escaped through the right frontal lobe. Further ration showed a double frontal abscess, undoubtedly imary on the right side and extending through the corpus callosum into the left frontal lobe. No other abnormality was found. The pus contained the *Bacillus pyocyaneus.*

Some Psychologic Studies on the Nature and Pathogenesis of Epilepsy

Dr. L. Pierce Clark: The potential epileptic, as a rule, possesses a supernormal output of energy which is constant and fairly productive of good developmental results as far as the organic makeup is concerned. There is a poorly repressed or thinly inhibited outcropping of the egotistic tendencies. These characteristics of a pathologic self-love are far beyond the bounds of a pure physiologic variation. As a rule, the potential epileptic is not well adapted to his environment and cannot easily change it. He cooperates badly in social and economic settings. For the most part he is frank; the subtleties of mind are not his; on the contrary, he has a simple, childlike pattern of emotional life. He never has the scruples or doubts of the obsessive neurotic; not being hindered with the inhibitions and prohibitions of the latter class, he is often permitted to become engrossed with the lower animal instincts and passions. With the inhibitions reduced and with an overemphasized estimate of his own importance and ability, the potential epileptic finds himself in constant conflict with the outside world. While the normal individual has his infantile struggle with reality and has made the life compromise, the potential epileptic youth keeps up the baffling struggle; hence his deep-rooted dislike and even hate of the outside world. Individuals who possess the epileptic constitution lack real general interests. The libido is rigid, self-centered and crude. There are small religious promptings; the meaning and ends of life rarely engross the potential epileptic. His friendships are perfunctory: the egotistic traits prevent a free range of emotional expression. A parental attachment of the potential epileptic to his own sex is the rule, and this is especially marked in girls. The love fixation to the mother in the majority is prominent more or less throughout life. The potential epileptic's attitude toward the opposite sex is very significant: it rarely possesses the higher love attributes and more frequently evolves little beyond the simplest or grossest sexual demands. That fact alone, independent of the superadded convulsive disorder, makes marriage among epileptics almost invariably a failure.

The fit serves as an unconscious gratification to the libido. By dream analysis, the analysis of man [illegible] inor attac [illegible] nd a few major fits, this unconscious s [illegible] 's ofte [illegible] k sexual outlet; in others it is dis [illegible] f ac [illegible] pleasure affects that have been lo [illegible] ulati [illegible] essential motive in all genuine epileptic fits would seem to be at bottom unconscious striving on the part of the epileptic to return to the intra-uterine life in the mother in a state of perfect peace and *Allmacht,* with its insistent urge in the fits, and is conditioned on the stage of libido fixation in infancy, which occasionally may be so advanced as to reach into homosexuality but rarely into heterosexual life.

The seizure movements are point for point identical with the impulsive movements of the fetus and the period of earliest infancy. In the normally developing child, these muscular movements are slowly but definitely repressed as the will and the conscious life unfold: in the epileptic the impulsive movements of earliest infancy are released from conscious and voluntary control, and they reenact the fetal and infantile purposes of satisfaction of that period.

DISCUSSION

Dr. Smith Ely Jelliffe: The *Mutterleibs Phantasie* is encountered in various phenomena in addition to the epilepsies, such as in various conversions and compulsive phenomena. It would be of practical interest in the analyses of the epileptic phenomena to see just how the individual has evolved the universally present Oedipus situation through the individual muscle erotic gratification.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION

Seventy-Seventh Annual Meeting, held at Asheville, N. C., Dec. 15-17, 1914

(Concluded from page 367)

Diaphragmatic Hernia

Dr. John D. S. Davis, Birmingham: I have seen five cases of traumatic diaphragmatic hernia. When an operation is decided on, the question arises, which is the best route to follow. The thoracic route presents great advantages. It has one decided merit in injuries of the chest, in that the external wound itself serves as a guide. The chest is to be opened at the site of the wound and the course of the wound followed. Further, this is the most direct route. It affords space to reduce the hernia if one is found to exist and for enlarging the diaphragmatic wound and treating the hernia. There are two objections to thoracotomy. The first is the danger of pneumothorax; second, the route does not permit exploration of the peritoneum and its contents. In the cases in which it is important to ascertain what viscera, if any, have been wounded, an abdominal section is necessary. Each case should be approached according to its individual features, but the superiority of the transpleural route in the treatment of thoracico-abdominal wounds seems to be indisputably established. I recommend as a rule Cranwell's trapdoor opening with the base above. The resection of one rib is often sufficient, and it is seldom that the incision needs to extend above the eighth rib in front or the seventh behind.

Treatment of Angiomata by Injection of Boiling Water (Wyeth Method)

Dr. Francis Reder, St. Louis: In a series of 26 cases subjected to this treatment I have had no failures. In every instance the results have been gratifying. Most of the cases presented the lesion on the face and scalp. Four patients presented angiomata on the tongue, ranging from the size of a filbert to that of an English walnut. One patient presented the lesion on the left gluteal region as large as a cocoanut; another patient presented a fusiform angiomatous growth on the right middle finger between the second phalangeal articulation and the knuckle. This tumor caused great pain. The course of an angioma successfully injected is one of gradual diminution, the greatest progress ing made from the second to the third week. A tumor ize [illegible] 's egg usually requires six or eight weeks [illegible] ance. If the injection has been free from any accident, such as cicatrization following sloughing, the site that once harbored the angioma will appear healthy and quite normal.

The Bulgaria Bacillus in Cystitis with Alkaline Urine

DR. FRANCIS R. HAGNER, Washington, D. C.: A patient gave a history of chills, fever, recurrent attacks of urinary frequency and tenesmus extending over a period of three weeks, with cloudy, alkaline urine. Cystoscopic examination showed a bright velvety area just behind the right ureteral orifice; roentgenogram negative for calculus; the possibility of tuberculosis of the right kidney was considered, and several urinary examinations failed to show the bacilli. Guinea-pigs inoculated continued to gain weight. The right kidney urine was strongly alkaline and contained much pus and some blood, while the urine from the left was faintly alkaline, containing but a small amount of pus. Instillations into the bladder improved the patient's condition, but the urine from the right kidney continued alkaline and the pus continued to be present in the urine. I then injected the kidney with the *bulgaricus Bacillus*. Two tablets were dissolved in 10 c.c. of sterile water and injected into the kidney pelvis through the ureter catheter. The patient had no trouble for thirty-six hours, when he had quite a sharp chill, temperature rising to 103.5 F. but becoming normal in twelve hours. The day following the injection the patient's urine was acid, and although I made two more injections into the bladder, no more treatment was directed to the kidney. The patient has now been away from the hospital two weeks, his urine remaining clear, acid, and free from pus.

Massive Umbilical and Ventral Hernias

DR. ALEXIUS MCGLANNAN, Baltimore: In a series of 1900 non-strangulated inguinal hernias there were four deaths, a mortality of a little over .2 per cent., while in a series of 197 umbilical and ventral hernias operated on by the same group of surgeons during the same periods of time, there were six deaths, about 3 per cent. mortality. In this latter series there were forty-six massive hernias with three deaths, about 6 per cent. In a second series of twenty-six cases there were four strangulated hernias. Two of these patients died. Of the twenty-two non-strangulated cases, one patient died on the second day from dilatation of the heart. Sixteen patients were handicapped by lesions other than the hernia. There were six heart lesions, six renal, two of arteriosclerosis, and two of obesity.

Surgical Treatment of Perforating Duodenal Ulcer

DR. JOHN YOUNG BROWN, St. Louis: A woman aged 48, entered the hospital, March 9, 1914. A diagnosis of benign pyloric obstruction was made. Early in the morning following her admission she became decidedly worse and an immediate operation was done. The abdomen was opened through the right rectus muscle. In the region of the gall-bladder and duodenum there was marked localized peritonitis. Separating the adhesions of the gall-bladder to the duodenum a perforation the size of a lead pencil was located. It was closed immediately and reinforced with an omental graft. Posterior gastroenterostomy was out of the question and instead we did a jejunostomy with the hope of building her up by liquid feeding. She recovered nicely from this operation, and under liquid feeding she gained 12 pounds in three weeks.

The second operation consisted in opening the abdomen, closing the jejunal fistula and doing a posterior gastroenterostomy. From this operation she recovered nicely, left the hospital in two weeks, and is now in perfect health, having gained at least 20 pounds.

Use of Skin Grafts in the Ambulatory Treatment of Ulcers

DR. JOHN S. DAVIS, Baltimore: From the results obtained in the first fifty cases in which grafts have been used in the ambulatory treatment of ulcers, I feel that we have added to our armamentarium a method of treatment which has hitherto been used only on patients resident in the hospital. In other words, the successful use of grafts in the outpatient department will make for hospital economy and will also hasten the return of many patients to full wage-earning capacity.

Passive Congestion of Liver Simulating Abdominal Tumor

DR. CHARLES R. ROBINS, Richmond, Va: A woman, 42 years of age, suffered with right upper abdominal distress for ten years, during which time she had been getting steadily worse. She had not been able to lie on this side for five months without its beginning to thump. There was marked local pain and tenderness. Six weeks previous to admission to the hospital, she had been taken with a fever, during which she had two decided chills, and became jaundiced. The fever and jaundice gradually cleared up. She had a similar attack six months previously. Since her last attack her appetite had not been good. She suffered from nausea and could not take solid food or cold drinks. Her abdomen had been swollen a great deal but had subsided. In the upper abdomen to the right of the median line and coming apparently from the under surface of the liver was a globular tumor about the size of a grape fruit, which could easily be felt and which moved with respiration. It was quite tender and tense and gave the sensation of fluid in a tight sac. Owing to the large abdomen, physical signs were not distinctly elicited. The Wassermann test, examinations of blood and urine were negative. On opening the abdomen the tumor was found to be the dark swollen and congested right lobe of the liver which was prolapsed and rotated so that it projected into the abdomen, the edge of the liver being rounded off by the swelling. The liver had a slight nutmeg appearance. A section of the liver was examined microscopically and showed marked fatty degeneration with some cirrhosis and round cell infiltration. A markedly inflamed appendix was found and removed at operation.

Hemangio-Endothelio-Blastoma of Stomach

DR. J. GARLAND SHERRILL and DR. F. S. GRAVES, Louisville: We had a case of this very rare affection in a woman of 31. In 1907 she fell striking her epigastrium against the corner of a table. Later she began to complain of loss of appetite, nausea, symptoms of indigestion and epigastric discomfort. Attacks occurred especially at night with regurgitation of food and eructations of salty material. She vomited blood once or twice. There was more or less constant pain in the abdomen, which was relieved by eating. Marked anemia developed with loss of flesh and a peculiar cachexia. When examined at this time she was tender over the region of the stomach and a palpable thickening could be felt in the epigastrium. This mass moved up and down with respiration. At times it could not be felt. Blood examination at this time was negative to malaria; 3,500,000 red cells; 7,000 leukocytes; hemoglobin 30 per cent. A diagnosis of gastric ulcer was made. Rest in bed, carefully selected diet and treatment of the ulcer brought prompt improvement. Subsequently this improvement seemed to be hastened by antisyphilitic treatment. She came under observation once or twice during the next five years, but was at no time under constant supervision. Her condition remained fair, but the mass persisted, sometimes palpable, sometimes not, always following the respiratory movements and also quite freely movable. About two years ago she had an attack at night, when she felt weak, yawning, with impaired vision and a slow feeble pulse. Within thirty-six hours the stools were black and blood was detected in them. Her anemia improved at times and then recurred. The lump in the abdomen seemed to enlarge and was more tender at her menstrual periods. Wassermann test was negative. A diagnosis of gastric ulcer with a growth, probably a tumor, was made, although the possibility of a floating kidney was considered. Abdominal section was done Oct. 5, 1914. A reniform mass growing from the greater curvature of the stomach near the pylorus and covered by the greater omentum presented to view. This mass was mottled, purplish in color, and had a rather broad attachment to the stomach. It moved freely with that organ, having no other attachments. A portion of the stomach about

4 inches in length along the convex border and 2½ inches along the concave border was removed, together with the mass and a portion of the upper part of the duodenum including the pylorus, and the gastroduodenostomy was completed in the usual manner. The pathologic report on the tumor was hemangio-endothelio-blastoma.

Cure of Cancer of Uterus by Curetting for Diagnosis

Dr. Herman J. Boldt, New York City: A woman, 47 years of age, had been advised to have a hysterectomy done for cancer. The diagnosis was taken from scrapings. Not being able to find, either subjectively or objectively, the slightest evidence at that time for suspecting cancer of the corpus uteri, I proposed another curetting for diagnosis. All scrapings were found to be normal endometrium. Some time after this, two slides with the scrapings from which the diagnosis of this case had been based were given to me for inspection. They showed advanced adenocarcinoma. A number of authoritative pathologists examined these and the sections from the scrapings taken by me. All who examined the scrapings for me expressed as their opinion that it was more likely that an accidental mix-up in the scrapings had occurred than that they came from the same patient. Opposed to this is the statement of the pathologist that this could not have taken place. This would then be the first and only case in which an advanced adenocarcinoma has been cured by a curetting for diagnosis. A second case was that of a woman of 36 in whom the examination of scrapings removed by curetting, done during the course of other operations, on November 7, without suspicion of carcinoma being present, showed distinct early adenocarcinoma. When the uterus was extirpated two weeks later, the most painstaking examination of serial sections of all parts of the uterine mucosa failed to show cancer.

12 *Report of all Abdominal Cesarean Operations (571) Performed in Service of Lying-In Hospital, New York. A. B. Davis, New York.

3. **Urinary Catalase in Health and Disease.**—The urines of normal individuals and patients suffering from various diseases was examined for catalase by Kahn and Brim in order to observe whether there was any constancy in the presence or absence of catalase as regards any specific disease. Traces of catalase were found in normal urine that had been freshly voided. In the urines of a number of patients suffering with various ailments, the catalase content varied. It was found especially high in urines that reacted positively for blood, bile or acetone. Quite a number of urines of patients suffering from cancer were tested for catalase, and no variations from the normal were observed, except when bile, blood or acetone was present. Cases of lymphosarcoma and Hodgkin's disease gave very high catalase content in the urine. In severe diabetes, patients with acidosis eliminated very largely increased amounts of catalase in the urine; on the other hand, diabetics who had no acetonuria showed no variation from the normal in the amount of urinary catalase. Typhoid patients and others with general septic infections excreted increased amounts of catalase; more if bile, acetone or blood was present.

9. Abstracted in The Journal, Oct. 10, 1914, p. 1320.

12. **Abdominal Cesarean Operations.**—In 571 cesarean deliveries analyzed by Davis, 577 children were born and sixty-one mothers died. Sixty-nine children were either stillborn or died before leaving the hospital, a fetal mortality of 12 per cent. Twenty-three, or 4 per cent., were stillborn. From the 61 mothers who died following cesarean section, 62 children were delivered. Forty-four children lived, 11 died, and 7 were stillborn. Eclampsia and toxemia of pregnancy were the indications for cesarean section in 35 cases; 22, or 63 per cent., of the mothers recovered; 13, or 37 per cent., died. From these 35 women, 37 children were born, 26, or 70 per cent., of these children lived. Eleven children, or 30 per cent., were either stillborn or died. Four were stillborn. Seven died. Period of gestation in these 35 cases: 14 at the tenth month, 3 at the nine and one-half month, 12 at the ninth month, 2 at the eight and one-half month, 1 at the eighth month, 1 at the seven and one-half month, 2 at the seventh month.

Placenta praevia was the main indication in 21 cases; 2 these mothers died from sepsis; 21 children were born, children lived, 4 children died, and 3 children were stillbo The fetal mortality was due to prematurity. There wer cases of accidental hemorrhage, the mothers and 1 ch lived. One child was stillborn; 1 child was premature a died in a few hours. Seventy-eight women have b delivered more than once by cesarean section; 60 the seco time, 15 the third time, 1 the fourth time, 1 the fifth time, c the sixth time. Rupture of the uterus in labor subsequ to cesarean section occurred in 6 cases. Three mothers di Three mothers recovered. Two children lived. In these cases the children were in the uterus and alive and w delivered by cesarean section.

The main indication for cesarean section was some fo of contracted pelvis or deformity of the spinal column in 4 or 79 per cent., of the cases. There were 9 cases of so neoplasm occluding the pelvis as the main indication f cesarean section; and 9 cases following some form of su pension of the uterus required a cesarean operation. In cases an unduly large child was the indication. There we also 7 cases of post mortem cesarean section. Two childr were delivered alive. One lived six days. The others liv

23. **Ovarian Transplantation.**—In 1901 both tubes and the left ovary were removed from Storer's patient for an acute gonorrheal salpingitis of a month's duration. April 12, 1904, the remaining right ovary was freed and proved to be riddled with cysts, especially in its right half. The tubal stumps were about half an inch long. The right tubal stump was divided downward until the uterine cavity was laid well open. The ovary was then bisected from above downward, carrying the incision well down into the broad ligament, so that each half of the ovary retained at least some of its original blood supply. The cut surface of the distal half was then closed with catgut, leaving that half to function in case the other half died. The proximal segment of the ovary was then introduced into the cut in the uterine wall and lightly anchored in place with fine catgut, in such a way that most of its cortex projected into the uterine cavity. The uterine wall was then brought together over it and its pedicle, in which there was a fairly good sized artery, with deep and superficial layers of catgut. The pedicle was sufficiently long not to pull the fundus over to the right at all. A chronically diseased appendix was removed.

A month after the operation the patient menstruated in perfect comfort, more so than for three years. Storer saw her again in January, 1905. She had been menstruating regularly but for the last few months with increasing pain, and finding a mass to the right of the uterus, he opened her again and removed a shell representing the degenerated remnants of the piece of ovary left *in situ* and a peritoneal cyst the size of a child's fist. Storer examined the seat of the transplanted ovary with much care but could find nothing abnormal nor any trace of its pedicle, which may have been lost in the many adhesions present. She made a good recovery but did not menstruate for four months. She was then put on various emmenagogues and on May 25 flowed one day. In June, July and August she flowed normally. November 4 her physician wrote that she was pregnant. This putative pregnancy was sixteen months after the transplantation. Everything went as should a normal pregnancy till December 12, three and a half months after the last menstruation, when she passed with some hemorrhage a mass of detritus and the uterus rapidly decreased in size. Menstruation stopped entirely February, 1909; in May she was the picture of health but a nervous wreck and her life a torment, with hot flashes, eye ache and other symptoms of the premature menopause. Hysterectomy was done in February, 1911, in a western city and she died thirty-six hours later of a streptococcus infection.

26. **New Technic for Hare-Lip Operation.**—Ladd uses two pairs of clamps made on a suitable angle with fine teeth to prevent the skin or mucous membrane from slipping, and a slit for the introduction of a small knife to make the incision. The knife used is made double-edged like a Catlin, only very small and thin. These instruments are used in conjunction with an ordinary small pair of sharp-pointed metal dividers. The procedure of the operation is as follows: After the alveolar process has been restored in the usual manner, the desired height of the lip, minus the width of the vermillion border is determined with the dividers. This distance is then marked off on either side of the lip by pricking the lip with the sharp ends of the dividers at the points which are to form the lines of the incision. The lip and cheek are then freed from the alveolar process and superior maxilla on both sides until the fissure can be drawn together without tension. The clamps are then applied with the angles of the slits at the points A and C and the slits directed toward the points B and D. The knife is now introduced into the slit in the clamp and carried upward to the nose and downward through the border of the lip, making the incisions B A E and D C F. The clamps may now be removed and reapplied out toward the angle of the mouth to control hemorrhage. The edges of the incisions, which of necessity must be clean incisions of equal length, and consequently fitting each other, can now be easily approximated, bringing the points B to D, D to C and E to F. This is done with one row of interrupted silk stitches, including all layers, but the skin tied inside, and another row of superficial approximation stitches of the same material, including the skin only, and tied outside.

44. **Catalytic Reactions of Blood.**—An investigation was made by Lyle, Curtman and Marshall of the chief factors involved in the benzidin test for occult blood. Their results with reagents covering a wide range of concentrations of benzidin acetic acid, and hydrogen dioxid, show that the sensitivity of the test was greatly influenced by the relative concentrations of these substances. Dilute solutions of benzidin are exceedingly sensitive to pure aqueous solutions of blood, and with these reagents, under the most favorable conditions, the authors were able to obtain decided tests with 1 c.c. of blood solution of a concentration 1 to 5 million. These reagents, however, are easily affected by inhibiting substances. By increasing the concentration of benzidin, the reagent becomes more resistant to inhibitors, but fails to

respond to the more dilute aqueous solutions of blood. The acetic acid serves merely to hold the benzidin in solution; an excess diminishes the delicacy of the reagent by increasing the speed of fading.

The hydrogen dioxid functions chiefly in two ways: First, it supplies the oxygen necessary for the reaction; second, it bleaches the blue color. Although a moderate excess of dioxid accelerates the reaction, it interferes with the delicacy of the test by increasing the speed of fading. The concentration of the hydrogen dioxid should be reduced to the minimum compatible with the production of a blue color which will reach its maximum intensity within five or six minutes. To obtain consistent results, water redistilled from glass should be used exclusively, and controls should invariably be made. It is imperative that the hydrogen dioxid be added last.

46. **Studies in Endogenous Uric Acid Metabolism.**—The uric acid elimination of ten individuals was studied by Raiziss, Dubin and Ringer. It was found that on a vegetable (meat-free) diet the uric acid output was considerably lower than was previously reported in the literature. It was also found that different individuals, under the same conditions of diet and rest, eliminate practically the same amount of uric acid per day. Work and high protein intake cause an increase in uric acid elimination. In changing the diet from a mixed to a vegetable and meat-free diet, at least a week must be allowed before the uric acid output will reach a constant level. The output during the first few days is higher, in all probability, because of an elimination of accumulated purin in the tissues of the body.

On placing two individuals on a practically nitrogen-free diet, which was at the same time strictly nuclein-free, after a vegetable diet period, the uric acid elimination dropped to about half of what it was on the vegetable diet (0.040 gm. per day). On giving milk, eggs and zwieback to the extent of 12 gm. of nitrogen per day to one of these, immediately following the nitrogen-free diet, the uric acid output rose but very slightly (maximum of 0.058 gm. per day). But when the vegetable diet was resumed, the uric acid nitrogen elimination rose again to its former level of 0.104 gm. per day. These findings suggest the possibility that the true endogenous uric acid output is really much smaller than has been found heretofore, and that in order to obtain it, the subject must be kept for a long time on a strictly purin-free diet and in a condition of absolute rest.

53. **Estimation of Fat in Feces.**—The steps of the method proposed by Gephart and Csonka may be summarized as follows: Weigh out finely powdered or well mixed moist sample. Saponify with KOH in alcohol (4 gm. of stick KOH and 20 c.c. of 95 per cent. alcohol). Dilute with 50 c.c. of water and acidify with HCl (20 c.c. of 20 per cent. in 5 c.c. portions). Shake out with ether and wash ether extract. Distill off ether and dry fatty acids. Take up with petroleum ether, filter and titrate with N/10 alcoholic KOH.

Calculation: $\frac{\text{c.c. N/10} \times 0.0297}{\text{Weight of substance taken}} \times 100$-per cent. tristearin.

60. **Are We Getting Proper Value from Our Plant and Expenditure for Tuberculous?**—McSweeny's answer to the question is "No." He calls attention to the present state of affairs: An enormous number of tuberculous patients of all kinds and stages of disease and an annual expenditure on them of millions of dollars. Tuberculosis institutions bear all sorts of names and allege all sorts of objects, practically all house a medical and social hodge podge that bears small, if any, relation to the professions of their conductors. Anyone who can be proved to have a tuberculous or possibly tuberculous lesion, in he goes with the rest, without reference to the probable results. The highest type of case sets the standard, and the expenditure is the same for all. This McSweeny condemns.

The following classification and program he holds is the only one by which plant and expenditure can be made to yield its full value: 1. Cases of criminality, insanity, epilepsy, feeble mind, old age, permanent disability of other origin, alcoholism and vagrancy, complicated by tuberculosis, should not only not be treated in view of it alone, but the primary condition should be considered first and the tuberculosis regarded as a complication. This implies tuberculosis departments in institutions for these classes. 2. Cases of chronic disability, due to pulmonary impairment of tuberculous origin, should be kept in tuberculosis homes with infirmary service, to be retained there until death. 3. Cases of chronic tuberculosis without disablement should not be treated at all. Whatever the stage anatomically is immaterial. 4. There is among the many cases of tuberculosis a large fraction, early and late, who require treatment for their disease for varying, often long, periods, and are entitled to the best treatment that medical science knows, at the public expense, just as much as does the patient suffering from any other disease or injury; their interests shall not be compromised by the means apportioned being frittered away in a wholly illogical fashion; there are many kinds of tuberculosis, and we should not rob the patient who requires and will get results from treatment for the sake of those who will not, any more than we would hesitate to spend money on, or would take any less care of, or use any less effort to relieve, a case of sciatica, because there happened to be plenty of paralyzed persons to look after according to other standards. For those persons, that is, those definitely ill from tuberculosis, in an acute condition, including exacerbations and terminal stages in chronics, not comprehended in the previous exclusions, and for tuberculous persons suffering from other acute conditions, the tuberculosis sanatorium-hospitals and hospital-sanatoriums should be reserved. McSweeny believes that the cause of the present state of affairs is, first, the unfortunate tendency of physicians to regard the whole question of the classification of tuberculosis cases as settled when they tag the patient first, second or third stage, forgetting that other classifications are often more important, and second, of the artificial element in the antituberculosis propaganda now so wide-spread.

63. **Use of Emetin in Control of Hemorrhage Following Nasopharyngeal Operations.**—Twelve cases in which emetin was successfully employed to control or prevent hemorrhage during and after operations on the nose and throat are cited by Weinstein. In each instance ½ grain emetin hydrochlorid was given hypodermatically.

117. **Boiling Water Injections for Hyperthyroidism.**—Further experimental and clinical observations have convinced Porter that injections of boiling water into the gland should be substituted for the so-called medical treatment in patients with small thyroids and moderate symptoms of hyperthyroidism. This method is also peculiarly well adapted to the treatment of patients with moderate or severe symptoms and relatively small glands and especially to cases wherein the hyperplasia is circumscribed. It is therefore well adapted to the treatment of patients who have had a lobectomy done and are still suffering from symptoms of hyperthyroidism with hypertrophy of the remaining lobe. Patients with large goiters and extreme symptoms of hyperthyroidism should be treated with the injections until they become safe surgical risks and then have the gland removed. Boiling water injections are not recommended in non-toxic goiter. In such cases, as in patients with large goiters and toxic symptoms, but who are good surgical risks, thyroidectomy should be the chosen method of treatment. In substernal hyperactive goiters the removal of which would be hazardous, boiling water injections under guidance of the eye should be tried.

118. **Diagnosis and Treatment of Osteomyelitis.**—Clopton emphasizes the fact that the earliest symptom of osteomyelitis is pain in the shaft of the long bone (usually near the end), accompanying septic symptoms. In a few cases of profound sepsis, pain sense is lost. Soon there is swelling of the shaft near the joint, frequently at the epiphyseal line. At this stage the joint is not involved. Septic arthritis usually is an intense infection, with less pain and several joints involved. Tuberculosis is a chronic disease that involves the epiphysis, and syphilis may give a similar picture. The Roentgen ray is of great value, except at onset of the infection. The treatment in the acute stage is to drain to the center of the medulla by removing a narrow channel of bone along one side of the shaft. Gutta-percha tissue is used to drain this channel. The medulla should never be "cleaned out," as it is needed for the endosteal regeneration.

In the subacute or chronic stage of osteomyelitis of the femur or humerus, treatment is planned to allow the shaft to heal after efficient and sufficient drainage. If sequestra have formed, these are removed, and the cavity wiped out with gauze. It is best not to curet these cavities or to attempt to sterilize with antiseptics. The iodoform beeswax of Mosetig-Moorhof is introduced into the cavity to act as a drain, which is partially absorbed and partially extruded. Gauze should never be used as a drain in either the acute or chronic stage. When one bone of the forearm or leg is involved (and at times the humerus), the shaft is removed subperiosteally about five or six weeks after draining the acute infection. The periosteum at this time should show a sufficient thickening to cast a shadow on the photographic plate. After removing the shaft the periosteum is sutured into a ribbon joining the ends of the remaining bone, and from this periosteum new bone is formed to replace the diseased shaft. In the meantime the other bone supports the limb in its proper position. In about four months the new bone can support weight. The forearm can be useful in less time. In a small proportion of badly infected cases, bone does not regenerate completely after removal of the shaft, and bone transplantation has to be resorted to after healing is obtained. Chronic localized osteomyelitis cavities in the cancellous bone may be treated by healing under blood-clot, or drainage with Mosetig-Moorhof wax, after the bone detritus has been removed with rongeur and gauze.

119. **Pylorectomy and Partial Gastrectomy in Treatment of Gastric Ulcer.**—If the ulcer, or ulcers, are situated at or near the pylorus, as they are in about 80 per cent. of all cases, and the pyloric end of the stomach and proximal portion of the duodenum can be easily mobilized, Rodman claims that pylorectomy which gets rid of the existing ulcers, and prevents future ones to a large extent, removing, as it does, four-fifths of the ulcer-bearing area, is certainly the operation of choice. The frequency with which hemorrhage, perforation and cancer, especially the latter, follow gastro-enterostomy, show it to be wholly inadequate. Moreover the radical operations of excision and pylorectomy are only slightly more dangerous while far more beneficent in every way than gastro-enterostomy.

If, however, the converse obtains, the stomach and duodenum being bound down by adhesions to adjacent viscera, such as the pancreas, liver, gall-bladder, transverse colon, etc., simple gastro-enterostomy, the anastomosis being made about the middle of the stomach, should be practiced. If the symptoms are not relieved within a reasonable time, then pylorectomy may be performed more safely. Before such a step is taken the operator should be assured that the gastro-enterostomy is patent and functionating. The operation can also be done in two stages in those patients not in good condition, whether it be from hemorrhage, anesthetic, or other cause. It is often best to perform pylorectomy for cancer in two stages, and practically the same is true in ulcer operations, but it will be much less frequently the case.

Gastric ulcers, duodenal as well, are more frequently multiple than is appreciated. With the number and chronicity of ulcers potential dangers are increased, and radical measures are more urgently called for. Ulcers away from the pyloric end, that is, occupying the expanded four-fifths of the stomach, should preferably be treated by partial gastrectomy or removal of the ulcerated area. Although such ulcers rarely undergo cancerization, they frequently bleed and perforate, both of which dangers are increased by the freer movements of this portion of the stomach during respiration. Moreover, on this account protective adhesions are less apt to form about them, if we except the lesser curvature, which is relatively immobile. If simple excision is practicable, it should be done, as it produces a smaller mortality (1.7 per cent.) than gastro-enterostomy. In some cases it may be wise, though it is not usually so, to supplement excision by gastrojejunostomy. It all depends on the location and size of the ulcer and whether or not the stomach can presumably carry on its functions without irritating, stretching, or otherwise interfering with the line of suture.

120. **Transplantation of Ovaries.**—During the last eight years, from Nov. 15, 1906, to July 15, 1914, Tuffier has performed 204 operations. He performed homografting twenty-four times under the most favorable circumstances, but it did not prove successful. He performed seven heterograftings immediately after the removal of an ovary or after the gland had been preserved in cold storage from one hour to forty-four days, and the operation has never given a single good functional result. He transplanted an ovary from one young woman to another who presented, after the removal of ovaries and tubes very severe symptoms simulating change of life. There was every chance of success, for the patients were of the same age, of the same complexion, and had the same color hair. The disturbances were the same after as before the transplantation, the patients had all the symptoms of menopause, and after some months the ovary gradually decreased in size.

Tuffier performed 145 autografting operations. Two circumstances under which the operations were performed are cited: First, total hysterectomy and transplantation of one or both ovaries, in whole or in part. Eighty-four operations were performed in this. Second, in salpingitis, Tuffier leaves the uterus in place, removes the two adnexa, and then grafts either one or both ovaries. Sixty-five operations have been performed following this technic. After the transplantation, in which the uterus is left in place, the ovary remains unaltered for three or four months and seems to lie dormant. Sometimes it is a little tender, and the patient has all the symptoms of change of life. But after a while the ovary becomes active, enlarges, and is sometimes painful for five or six days, whereon all symptoms subside and menstruation reappears. Generally the congestion of the ovary precedes menstruation by five or ten days. On the same day when menstruation has commenced all the symptoms of menopause disappear entirely. After a month or so ovulation again takes place.

Of the sixty-five patients on whom Tuffier performed autografting operations without hysterectomy he has interviewed thirty-seven from one to six years after operation and thirty-two had their periods regularly. In the five cases which did not have regular periods, two important points were noticed; first, the patients were either more than 40 years old, or second, they were septic cases in which it was necessary to dip the graft into tincture of iodin. Certain patients have the change of life sometimes from one to three years after the operation. Sometimes the monthly flow is irregular. The results are the same whether one or two ovaries are grafted. Tuffier did twenty-eight autografts of both ovaries and has interviewed later twenty of these patients, nineteen of whom had regular menstruation. He has done thirty-seven autografts of one ovary and from this series seventeen patients were seen later and thirteen had regular periods. Of those having amenorrhea, one was over 40 years old. Tuffier concludes that ovulation and the internal secretion are not so important as is generally believed. From all these facts he believes that every month the female creates by internal secretion, a chemical substance; when this substance exists in the blood in sufficient quantity it acts on the ovary, which modifies it, and menstruation is consequently produced by this modified internal secretion and the secretion is eliminated with the flow. He has been able to localize this chemical substance in the blood. It exists in the serum, because he can produce menstruation by injecting defibrinated blood. If menstruation does not occur, then the chemical substance is retained in the circulation and causes an auto-intoxication.

124. **Transplantation of Gastric Mucous Membrane.**—Doolin's experiments showed that the autoplastic transplantation of gastric mucosa in dogs is feasible and leads to definite cyst formation. These cysts are lined with a single layer of cubical epithelium arising from epithelial islets which have survived the general necrosis of the graft. The graft depends for its nutrition on the blood-supply conveyed to it by adhering omentum. The size of the cyst so formed varies directly with the length of time since the operation. Tubular grafts of hollow abdominal mucosal tissue depend for their success on their muscularis—the canal being later lined with epithelium growing in from the surroundings.

125. **Dislocation of Os Semilunaris.**—Runyan claims that closed reduction can be accomplished in about one-half of the recent cases of dislocation of the semilunar bone by the method of hyperextension followed by flexion while counterpressure is maintained over the dislocated semilunar. Prompt diagnosis and treatment are essential in obtaining

good results. The more speedily the dislocation is recognized and reduced, the better the result. Closed reduction should always be tried, irrespective of the length of time the dislocation has existed. Closed reduction being impossible, an anterior incision should be made and the dislocation reduced. Failing in this, it is necessary to excise the semilunar, but excision should be done only as a last resort.

127. **Cancer of Breast.**—A study of the secondary deposits which are easily accessible to observation, namely, those in the skin and bones, showed Handley that these secondary deposits, commencing near the primary growth, spread in a centrifugal manner from it. While in extreme cases this centrifugal spread may involve the greater part of the area of the body, the arms below the elbows and the legs below the knees are never the seats of such deposits. Handley began to make microscopic sections of long centrifugal strips of the skin and subcutaneous tissue, radiating from the primary growth. In them, at points near the growth, isolated nodules of secondary growth could be seen. Farther out at a varying distance up to 10 inches from the primary growth, he found a narrow and elusive zone a few millimeters wide in which the lymphatic vessels were choked by cancer-cells. Beyond it the tissues were normal. This zone was met with in each of the radiating strips, and it constitutes the true growing edge of breast cancer. It may be found at any distance up to 2 feet from the primary growth. The detection of this microscopic growing edge Handley claims is the foundation stone of the permeation theory of dissemination.

These facts he explains as follows: The immense proliferative pressure of the epithelium at the primary focus forces cancer-cells into the small lymphatics, along which they grow in continuous lines. This process which Handley has called permeation is the master-process of dissemination. Reaching the lymphatic plexus into which the breast in the first instance drains, permeation involves a larger and larger circular area of this plexus, filling up its channels with lines of cancer-cells and sending offshoots into the adjoining muscular and cutaneous layers. Sooner or later cancer-cells are thus brought into the serous cavities and rapid visceral dissemination occurs.

The main operative principles deduced from the permeation theory by Handley are: First, the area which demands widest removal is that in which the growing edge is situated, namely, the deep fascia, in which is found the lymphatic plexus which forms the highway for the spread of the disease. Second, the area of deep fascia removed must be roughly circular in outline, since permeation spreads with approximate equality in all directions from the primary growth. Third, the primary growth must always be the center of the area of fascia removed. Failure to observe this rule accounts for many recurrences. Fourth, the skin and muscles being secondarily involved over a smaller area, and less widely than the fascia, the removal of a smaller area of these tissues will suffice. The removal of the embolically invaded regional lymphatic glands is, of course, essential.

130. **Modified Incision for Approaching Gall-Bladder.**—In those cases, then, in which a perfectly obvious gall-bladder drainage, stone removal, or ectomy is indicated, McArthur urges to incise the posterior sheath parallel with the tendinous fibers of the transversalis, namely, nearly transversely. To select the level for its incision about an inch above the free end of the gall-bladder, making a small opening first for confirmation of the diagnosis, by digital exploration. The incision can then be enlarged to the middle line and as far laterally as seems essential. The transversalis (posterior sheath) can, with the gloved fingers, be separated from the internal oblique with ease. When the necessary interference with the gall-bladder has been made and the latter dropped back, the cut margins of the transversalis are seen to lie in contact and its respiratory action noted as continuing normally. Then the cut edges can be whipped together with catgut sutures under absolutely no tension. The support thus given by the uncut transversalis renders tension stitches wholly unnecessary and makes easy the closure of the anterior sheath and skin.

4 and 6. **Acute Hemorrhagic Pancreatitis.**—An excellent review of this subject is given by Eve. He states that clinical experience bears out the conclusions that stasis and infection are the main elements in the causation of acute pancreatitis, and these are most commonly brought about by cholelithiasis. Egdahl, in an analysis of 105 cases, found that in 44 (42 per cent.) the disease followed gall-stones or suspected gall-stones. But in only three of these cases was the stone in or near the ampulla. In 44 cases of Körte cholelithiasis existed in 21 (47 per cent.) and in 16 consecutive cases analyzed by Dietrich cholelithiasis was found at the operation or necropsy in 8. Calculi occupied the common bile duct only twice, and in both of these they were small and not impacted. Dietrich states that in his cases gall-stones were certainly excluded only three times (18.75 per cent.).

At the London hospital during the five years 1907 to 1912 there were eleven necropsies on cases of acute hemorrhagic pancreatitis. Gall-stones were present seven times (63.6 per cent.), and a round worm occluded both pancreatic ducts in an eighth. In only one of these cases did the stone occupy the ampulla. In the remaining six cases the calculi were in the gall-bladder and were invariably multiple and small. In two cases there was a duodenal ulcer, and in one of these a constriction of the common bile duct with dilatation of the pancreatic duct was noticed; therefore gall-stones or obstruction at the papilla existed in nearly 82 per cent. of the cases. The duct of Wirsung showed evidence of stasis of secretion, or of infection in seven cases out of the eleven. It may be observed that a true estimate of the causes at work is more likely to be obtained from necropsies than from operations performed under conditions of grave illness, when the condition of the patient may preclude a careful examination of the bile passages. The exact mechanism by which the pancreas is infected evidently varies. The figures quoted indicate that the direct regurgitation of infected bile into the duct of Wirsung, owing to the impaction of a small calculus in the ampulla, occurs only in a small proportion of cases—about 20 per cent.

Eve analyzed forty cases of acute pancreatitis with reference to the symptomatology. Over one-half had premonitory symptoms of varying intensity. These consisted of attacks of pain in the upper abdomen, or occasionally over the abdomen generally (16 per cent.). The premonitory attacks of pain were in a like proportion of cases (16 per cent.) referred to the right side of the upper abdomen. In many instances the pain resembled and might be referred to cholelithiasis, and in a few to duodenal ulcer. But a fair proportion of patients shown subsequently to have gall-stone disease complained of no previous symptoms. A few cases gave a history of indigestion and flatulence. The symptoms accord with the symptoms of the group of acute abdominal crises, and closely resemble those of perforation of gastric and duodenal ulcer, of the gall-bladder, or the appendix. Many cases have been mistaken for acute intestinal obstruction. The onset is sudden, with very severe pain in the epigastrium, persistent vomiting, usually constipation, tenderness, fullness and resistance in the upper abdomen, and gradually increasing distention; the pulse is rapid and weak, the temperature lower than the pulse-rate, and not infrequently subnormal with collapse. The one symptom which gives the most probable insight into the condition is tenderness across the epigastrium and resistance over the pancreas. The most distinctive sign is epigastric peritonitis, with subsequent swelling in the left lumbar region. There being no pathognomonic sign the diagnosis is admittedly difficult and uncertain.

In the forty cases analyzed, vomiting was present in 80 per cent.; was often severe and incessant; constipation existed in 25 per cent., and was only marked in five cases. Diarrhea was present in three cases, but in one of these symptoms had existed fourteen days. Pain was almost constant, and in 50 per cent. was situated in the epigastrium or upper abdomen. In the other cases it was localized in the right hypochondrium, the right side of abdomen, or right iliac fossa; in others on the left side or left iliac fossa. Tenderness had much the same distribution as the pain. Distention existed in half of the cases. A swelling was observed in only seven (17.5 per cent.), twice in the right hypochondrium (in one of these being a distended gall-bladder), thrice on the right side of the abdomen or to the right of the umbilicus, once on the left side of the abdomen and once below the umbilicus. Cyanosis, sometimes spoken of as a characteristic sign, was only present twice; one was an acute case of twenty-four hours' duration, while in the other the symptoms had lasted fourteen days. Glycosuria was once noted, a trace of sugar being found in one of Dietrich's sixteen cases. It existed in eight of Körte's forty-four cases. One patient of Körte developed diabetes one and a half years after extensive necrosis of the pancreas, and died eight years subsequent to the operations. The general condition of patients with acute pancreatitis is indicative of an acute toxemia. Cammidge's reaction is of no definite value in the diagnosis of acute pancreatitis.

10. **Amputations in War Surgery.**—The method Fitzmaurice-Kelly advocates consists in a simple circular division of all the tissues, including the bones, at the same level, and that level the lowest possible. The skin is divided by a circular sweep, the muscles are divided at the level to which the skin retracts, and the bone is then sawn at the same level. The bleeding points are secured and tied, the nerves pulled down and cut short, and a dressing is then applied to the raw surface of the stump. The advantages claimed for the method are: 1. Economy of tissue. The amputation is performed at the lowest level at which a flap could be cut, or even lower, and all recoverable tissue is thus preserved. 2. It is applicable to otherwise hopeless cases, such as wounds, or gangrene at the root of the limbs, and in these cases carries a much better prognosis than disarticulation at the hip- or shoulder-joint. 3. It is very rapidly done, and there is very little shock. 4. The surface from which septic absorption can occur is the least possible, and the drainage is free. 5. The nutrition of the stump is unimpaired; in this respect its advantage over a flap amputation is obvious. 6. It is so simple that it is within the range of everyone, and does not need an experienced surgeon for its performance.

Beiträge zur Klinik der Tuberkulose, Würzburg

November, XXXIII, No. 1, pp. 1-110. Last indexed January 9, p. 184.

13 Theory, History and Present Status of Artificial Pneumothorax. K. Dluski.
14 *Tuberculosis of Male Genital System. M. Simmonds.
15 Early Diagnosis of Pulmonary Tuberculosis. (Inspektion, Palpation, Perkussion und Auskultation bei der Frühdiagnose der Lungentuberkulose.) F. M. Pottenger (Los Angeles).
16 *Fatal Air Embolism in Deformed Lung in Replenishing Artificial Pneumothorax. A. Mayer.
17 *Exophthalmic Goiter Symptoms with Tuberculosis. (Basedow und Tuberkulose.) Schinzinger.

14. **Tuberculosis of Male Genital Organs.**—Simmonds published an article on this subject thirty years ago, and experience since has confirmed what was scarcely believed then, that the primary infection might be in the kidney and the genital organs be only secondarily affected. In 105 cadavers he found the genital system alone involved, but in 95 there were also tuberculous processes in the kidney or bladder. The prostate seemed to have been first attacked in 50 per cent.; the seminal vesicles or epididymis in about 25 per cent. each. The usual age is from 30 to 60; tuberculosis of the female genital organs develops generally in the first to the fourth decades. Evidences of healed tuberculous processes in the prostate and seminal vesicles are extremely rare while traces of healed tubercles are found comparatively frequently in the testicles. The prognosis of genital tuberculosis in men is grave, especially when the seminal vesicles are involved. The greatest danger is from secondary tuberculous meningitis and miliary tuberculosis; a third of the men with genital tuberculosis succumbed to this complication. He found evidences of progressive tuberculous processes in the intra-abdominal parts of the genital system in 20 men who had been previously castrated for tuberculous epididymitis. Mere castration alone therefore cannot be regarded as adequate treatment for tuberculosis of the male genital system.

16. **Fatal Air Embolism in Inducing Artificial Pneumothorax.**—The trouble in the case described by Mayer, with illustrations, was due to a deformity of the lung, an abnormal peak projecting at one point and adherent to the pleura. By an unfortunate chance the needle perforated this protruding process and thus permitted air to get into a vein. The patient was a robust man and this was the fourth time the gas had been replenished. There had been no by-effects before. The injection of gas was proceeding regularly the last time and about 250 c.c. of nitrogen had been injected, when the patient drew an unusually deep breath. This pulled the needle a little to one side and the man collapsed as if struck by lightning. Under artificial respiration, oxygen and tracheotomy the cyanosis subsided but consciousness did not return and the heart beat gradually died out by the end of the third hour. Necropsy revealed the surprising fact that the greater part of the supposed tuberculous changes in the lung were of syphilitic origin. The tuberculous process was of comparatively minor importance although the sputum had contained tubercle bacilli and the Wassermann test had elicited a negative response.

17. **Exophthalmic Goiter and Tuberculosis.**—Schinzinger found a tendency to goiter in 355 of 521 tuberculous inmates of the Luisenheim sanatorium in his charge. Only 191 o the 355 in this group showed any symptoms suggesting exophthalmic goiter, while symptoms of this kind were evident in 89 of the 166 cases with an apparently normal thyroid. There were only 5 in the 521 with pronounced exophthalmic goiter but among the patients with tuberculosis in its first stage some of the symptoms characteristic of Basedow's disease were comparatively common, especially the unstable pulse and slight or moderate protrusion of the eyeballs, tremor and angioneuroses. His conclusion is, however, that these symptoms must be credited to the tuberculosis.

22 *Tardy Suppuration in the Thyroid after Typhoid. (Zur Kenntni der posttyphösen Strumitis.) E. Melchior.

19. **Suture of Vessels in War Wounds.**—This article describes experiences in the fortress of Przemysl at the time besieged by the Russians. The article was sent out from the beleaguered fortress by aeroplane, *Fliegerpost*, and was duly

received by the publishers. Jeger reports the details of his eight cases: in six any attempt to ligate the injured vessel would unquestionably have been followed by gangrene. The suture saved the limb in four in this group. The operation came too late in three of the other cases, and in another the vein had to be stretched so much to suture it that it gave way later. In this case the vein should have been patched out with a segment cut from another vein.

He gives an illustration of one case in which the arm had been shot at the junction of the upper and middle thirds, fracturing the bone and severing the soft parts until the arm hung only by a narrow bridge of the skin and muscle on the outer side. This arm was cold, anemic, no pulsation, when the patient was first seen two hours after the injury. During the interval a tourniquet had been applied above. The brachial arteries and veins and the median and ulnar nerves had been severed and each vessel was united by an end-to-end suture, as also the vena basilica. Stimulants were required as the pulse was imperceptible on both sides after the operation and the general condition was discouraging. By the second day the young man began to improve, but there was slight fever every night for two weeks and the pulse on the operated side was still weak and intermittent. By the end of the month sensation in the arm returned and under electricity and exercise he regained the functional use of his arm to such an extent that clinically normal conditions may be anticipated before long. Jeger knows of only one similar case on record, Jianu of Bucharest having reported saving an almost entirely severed arm in this way. In Jeger's case the injury was from a gun discharged accidentally close to the arm.

20. **Experiences with Cholera at the Front.**—Rauch relates how he was sent to a village of seventeen houses in which 480 men with cholera had been collected for five days. He found them lying on wet straw in rain-soaked tents, with from ten to twelve deaths a day. He at once took possession of the five largest houses, sending the inmates to their neighbors, and had the villagers bring dry straw and hay, and the cholera patients were brought into these houses. They lay with heads to the wall and the rooms were kept hot day and night. There was very little bolus alba and prepared serum on hand, so the main reliance had to be on keeping the men warm, applying moist heat systematically to the abdomen, giving the drugs at hand in turn, first tannin, then opium, and the third day a little bolus alba. Tea and a little brandy were all that was allowed the first day, then gruels of various kinds were given, especially oatmeal gruel with a little brandy. Later a little white bread was added. There were sometimes as many as 1,000 a day of cholera sick or suspects, but the mortality averaged only two a day. When the place was abandoned all the vessels were boiled, all the firearms, cartridge belts, etc., soaked in a solution of phenol, the rooms sterilized with formaldehyd and whitewashed before they left, the villagers gladly aiding to expedite their departure.

22. **Tardy Post-Typhoid Suppuration in the Thyroid.**—Melchior reports the case of a man of 52 whose mother and grandmother had goiter and the man himself had always had a very large neck. At 43 he had typhoid and during the nine years since actual goiter had developed, but without tenderness or pain. During the last six months the neck measured 47 cm., about 18½ inches, and the breathing was interfered with, so the thyroid was resected. It was found calcified in part and in the center an old abscess containing typhoid bacilli in pure culture. Gali has recently reported a somewhat similar post-typhoid case in which the interval was twenty-one years. It is characteristic of these torpid abscesses following typhoid that they do not develop until the febrile stage is past, as he shows by various examples. The organism by that time has been relatively immunized which explains the benign character of this type of abscess and also the lack of operative infection although the abscess in the thyroid, spleen or elsewhere was accidentally opened in the course of the operation in several instances. Neither the pleura nor the peritoneum displayed any irritation afterward.

Jahrbuch für Kinderheilkunde, Berlin

December, LXXX, No. 6, pp. 561-650

23 A Form of Congenital General Dropsy. (Zur Kenntnis der sogen. foetalen Erythroblastose.) H. Chiari.
24 *Filling Cavities after Bone Operations. (Zur Abkürzung der Heilungsdauer nach ausgedehnten Nekrotomien.) C. Bayer.

27 Symmetrical Gangrene in Children. (Beitrag zur Raynaudschen Krankheit im Kindesalter.) V. Lederer.
28 Pathology and Treatment of Transitory Fever in the New-Born. I. Peteri.

24. **Filling Cavities after Bone Operations.**—Bayer discusses the various methods that have been adopted for filling bone cavities after operation, and concludes that the simplest and best one is to trim the sides and edges of the bone forming the cavity, so that a smooth and uniform trough will result, and then fold in the skin and periosteum to line it throughout except where the turned-in flaps of soft parts do not quite meet in the center. A roll of iodoform gauze is sutured to fit into the long groove over the turned-in soft parts. This exerts pressure on the skin and periosteum flaps and forces them down to fit closer against the bone beneath and thus adapt themselves more accurately to the cavity. It also aids in hemostasis. A compression bandage is placed over this and left in place for two weeks. The periosteum rapidly forms new bone to fill in the cavity. How completely this is done is shown by five Roentgen pictures from typical cases. The time required for healing is reduced to about half of what it is with ordinary tamponing or other modes of treatment.

25. **Bronchopneumonia Simulating Croup.**—Suñer describes six cases with pronounced symptoms of diphtheric laryngeal stenosis but which proved by the later course or at necropsy to be merely bronchopneumonia. He finds that symptoms of laryngeal stenosis, very similar to those caused by diphtheria, may be induced by inflammation of the bronchi alone. Such inflammations may be caused by various bacteria, the diphtheria bacillus and staphylococci, such cases also may follow measles. The larynx is involved mainly in a mechanical way. In the cases that came to necropsy there was extensive bronchopneumonia of both lungs, with atelectasis and emphysematous areas between. In one case there was hemorrhagic nephritis from the general infection. The differential diagnosis from true croup may be made from the initial catarrh, which seldom occurs in true croup, from the absence of a pseudomembrane in the mouth and pharynx, and from the early appearance of symptoms of bronchopneumonia; but these are sometimes lacking. Moreover, we may have a true diphtheric membranous croup complicated by bronchopneumonia. The prognosis is serious. The treatment is that of bronchopneumonia. Diphtheria antitoxin may be given if there is any doubt about the diagnosis. The author has found intubation of great value.

In his first case the pronounced croup and râles heard over both lungs had all developed within a few hours, and the croupy stridor kept up unmodified till the child died the next day. Antitoxin had been given but without intubation or bacteriologic examination. Suñer was confident that the trouble was not primary laryngeal diphtheria, as the consultants assumed, but rather an extremely acute capillary bronchiolitis, and his further experience with other cases confirmed the fact that bronchopneumonia can develop occasionally like membranous croup. Inflammatory processes in the lower air passages are thus able to induce the signs of laryngeal diphtheria. Such cases run an unusually protracted course and are not modified by antitoxin, as in laryngeal diphtheria. In one case the croup developed after measles but subsided after two days under local moist heat to the larynx. One child of 2 had total obstruction of the larynx following a week of catarrhal trouble of the air passages. Antitoxin and intubation failed to relieve and no false membranes were discovered even at necropsy. In one of his cases necropsy showed diphtheria bacilli in a small clot in one bronchus, but no membranes, and the benefit from intubation testified to the involvement of the larynx in the inflammation. The child of 3 was convalescing from measles when attacked by the bronchopneumonia. The bronchopneumonic false croup occurs exclusively in children, and without any morbid manifestations in the larynx. There is always a preliminary catarrhal affection of the upper or lower air passages or both, then a period of gradually increasing laryngeal stenosis, and then the period of suffocation unless relieved by intubation. There is generally fever through all the stages and signs of bronchopneumonia. The disease runs its course in from two to twenty days, averaging from ten to fourteen. Only two recovered in the six cases reported.

34 *Dry Benzidin Test for Invisible Blood. (Die Blutprobe nach Artur Wagner.) M. A. Zengerle.

29. **Fracture of Lower Jaw.**—Schröder gives illustrations of the aluminum splints for the lower jaw of which he keeps a supply on hand at the front; also stout wire splints held in place by being tied to the teeth, but the greatest reliance is placed on hard rubber shells corresponding to the soft parts over the entire jaw. The fractured jaw is exposed and all devitalized tissue cut away. Then a corresponding piece of one of the rubber shells is cut out to fit the gap in the jaw and wired to the bone on the inside. He has frequently had the wounds heal by primary intention after treatment of this kind, even when half the jaw had been shot away. The patients can open and shut the mouth almost at once. A permanent prothesis can be substituted for the temporary device as soon as healing is complete, namely, in four or six weeks.

30. **Importance of Salt and Water for Normal Digestion.**—Cohnheim comments on the fact that the customs of eating in all lands, however diversified they may appear, yet have the one trait in common that the stomach is not left empty long. Another meal follows when the last has been finally all expelled from the stomach. This takes longer with certain articles of food than with others, but it depends mainly on the proportional amount of gastric juice secreted. The secretion of gastric juice also draws on the reserves of acid in the blood, he continues, and by this means the lactic acid accumulating in the blood, as it is generated in fatigued muscles, is drawn out of the blood to serve as a component of the gastric juice. This explains the promptly refreshing action of food taken when one is much fatigued. For this purpose it makes little difference what the food is; anything that "relishes" starts the secretion of gastric juice, and thus serves to relieve fatigue in this way. When fluid and salt are lost in profuse sweating, the gastric juice cannot be produced in normal amounts unless provision is made for ample intake of both fluid and salt. When the secretion of gastric juice is deficient, the stomach empties itself before digestion is complete, and the chyme is hurried along through the upper bowel, with diarrhea as the result. He emphasizes the above points with special reference to the troops in the field, reiterating the necessity for food that will stay long in the stomach, the necessity for ample intake of salt and water, and the danger of mistaking for dysentery a diarrhea which is merely the result of a deficit in gastric-juice production from lack of ingredients from which to make it.

34. **Dry Test for Occult Blood.**—Zengerle confirms the convenience and reliability of Wagner's modified benzidin test for invisible blood in the stools. (Wagner's description was summarized in The Journal, 1914, lxiii, pp. 519 and 1987.) A knife-tip of benzidin is mixed with 2 c.c. of glacial acetic acid and 20 drops of a 3 per cent. solution of hydrogen dioxid. A scrap of the stool is smeared on a dry slide lying on white paper. A drop of the above reagent is then poured on it, and if there is admixture of blood the tint changes at once to a pronounced blue.

Zengerle's experience confirms the reliability of the test not only for invisible blood in stools but in medicolegal investigation of traces of blood anywhere. His attention was attracted to the possibilities of the test in this line by finding two small blue spots on one of his fingers as he was compounding the above reagent. As if by magic he thus learned of the existence of two minute holes in the rubber gloves he had been wearing. Gauze and wool dipped in blood and then thoroughly washed with soap and hot water yet showed the characteristic blue reaction when a drop of the reagent fell on them. After a match dipped in blood had been charred to a coal, a scrap of the charcoal treated with the reagent changed its tint to bright blue, as also ash from another blood-stained match. Milk and rust do not change the tint; ferric chlorid causes a black discoloration. Pus yielded the blue tint in his tests, but there may have been traces of blood in the pus.

Monatsschrift für Geburtshülfe und Gynäkologie, Berlin

December, XL, No. 6, pp. 633-708

35 Rupture of the Intestine from Contusion during Pregnancy. (Darmruptur durch stumpfe Gewalt bei Gravidität.) J. A. Amann.
36* Diagnosis and Prognosis of Kidney Changes in Pregnancy. (Nierenveränderungen in der Schwangerschaft.) P. Wolff and M. Zade.
37 *The Stem-Pessary. (Der intrauterine Stift.) A. Martin.
38 Importance of Colostrum in the Nutrition of the New-Born. (Ernährungsverhältnisse Neugeborener.) G. Benestad.

36. **Kidney Changes in Pregnancy.**—Wolff and Zade say that among their 3,477 deliveries, 1909 to 1913, there were 106 cases of severe disturbance of kidney function, that is, in about 3 per cent. In 52 of the cases there was eclampsia; in 21 kidney disease arising during the pregnancy and caused by it; in 31 chronic nephritis, and there were 2 cases that could not be definitely classified. Most of the cases of eclampsia were in primiparae, as also a slight majority of the cases of *nephropathia e graviditate,* but the majority of the cases of chronic nephritis were in multiparae. Wolff and Zade conclude that with our present methods of examination the different forms of kidney disease during pregnancy cannot always be distinguished with certainty. During the puerperium, and later, chronic nephritis may develop from the kidney trouble started by the pregnancy or left by eclampsia. There is a predisposition to recurrence of *nephropathia e graviditate* in later pregnancies. Albuminuric retinitis may be observed in pure kidney affections and in eclampsia. In chronic nephritis during pregnancy, albuminuric retinitis has not the bad prognosis that it has if occurring outside of pregnancy. The retinitis may be caused by a kidney disturbance superposed on the chronic nephritis, and may disappear with the former at the end of the pregnancy.

37. **The Stem-Pessary.**—The stem-pessary has fallen into disrepute but Martin believes that it has a legitimate use in certain cases of amenorrhea and oligomenorrhea, especially those caused by infantile development of the uterus. He has had excellent results in such cases and has never seen any harm from its use if strict asepsis was observed.

53 Technic for Plaster Casts and Dressings. Trumpff, F. Noll and A. Most.
54 The Food Supply and Expense during the War. II. (Die Ernährung der deutschen Zivilbevölkerung im Krieg.) v. Müller, Hecht and Others.

43. **Crippled Veterans After the War.**—Grassmann comments on the fact that the wounded either die at once or recover, as a .rule, so that there will be an exceptionally large proportion of cripples left after this war in comparison with others in which infection decimated the wounded. He urges physicians everywhere to bear in mind the ultimate restoration of the earning capacity, and to bring everything to bear that will ward off crippling deformity. A few thousand dollars spent now to equip institutions in which passive and active exercise can be taken under medical supervision may save thousands from becoming dependent cripples, restoring them to active life.

49. **Simple Differential Diagnosis of Typhoid.**—Rhein regards the diazo reaction as an important aid in differentiating typhoid. The ordinary diazo test is rather complicated, but the urochromogen reaction is practically as instructive, while this requires only from three to ten drops of a 1 per thousand potassium permanganate solution added to urine diluted one-half. (It was described in The Journal, 1914, lxii, 886.) Rhein has found that the outcome is equally reliable if merely one crystal of the permanganate is dissolved in the diluted urine in a test-tube. The yellow tint appears at once as the crystal dissolves in the test-tube as it is shaken.

52. **Treatment of Pyocyaneus Infection.**—Bollag has found nothing better than a 2 per cent. solution of liquor of aluminum acetate, with which the dressings are impregnated, in treatment of wounds infected with the *Bacillus pyocyaneus.* This arrests its growth and clears the wound, and gives it a chance for healthy granulations.

Wiener klinische Wochenschrift, Vienna

December 10, XXVII, No. 50, pp. 1583-1608

55 *Cholera. O. Buiwid, L. Arzt and E. Wiener.

57 Wounds of the Skull in War. (Beitrag zu den Schadelverletzungen im Kriege.) H. v. Haberer. Commenced in No. 49.

55. **Cholera in Cracow District.**—Buiwid and Arzt maintain that cholera is easier to keep under control than any other epidemic disease. The first case was found in the Cracow district October 27, but soon twenty trains arrived bringing not only many more cases of cholera but thousands of persons who had been exposed to it. The exposed, to the number of 14,000, were quartered in a separate village and the disease did not spread. Only twenty new cases developed in the entire district and the nine survivors were not left carriers. The mortality among the 176 cholera patients in the isolation hospital was between 24 and 30 per cent. Anticholera vaccination was applied on a large scale and no untoward by-effects were observed and only three among the thousands vaccinated developed cramps in the legs during the first few days afterward and two others had fleeting urticaria.

Wiener has had extensive experience with cholera in Africa and Asia and calls attention to certain symptoms on the part of the nervous and vascular systems and the skin which are seldom mentioned in the text-books, such as the cramps in the upper arm, keeping the elbow at an acute angle, and the predilection for the knee-elbow position. He never knew a patient to recover who had these symptoms. Symmetrical pains in the toes or limbs, congestion of the conjunctiva, and trophic disturbances in the legs were also common. He reports that not another case of cholera developed by the sixth day after anticholera vaccination of 28,000 persons at Keryermezo, in which there was a camp of prisoners and an isolation hospital in his charge. His experience confirms the value of Rogers' method of infusion of hypertonic salt solution, but he prefers for a drink a 1 or 3 per thousand solution of hydrogen dioxid, rather than of potassium permanganate as Rogers recommends.

63 *Emetin in Treatment of Hemoptysis. (Valore del chloridrato d'emetina nel trattamento dell'emottisi tubercolari.) B. Nicola.

61. **Three-Day Fever.**—Zannini states that in his province in northern Italy there has been a recent epidemic of this disease, nearly all in men, no children. The symptoms are a suddenly developing fever, from 39 to 41 C. (102 to 105.8 F.) intense headache, with localized and general pains, insomnia, congestion in the conjunctiva and pharynx, and in about a third of the cases bradycardia and leukopeny. The fever subsides after three days but great weakness is left and in a few instances there was some mental confusion for a time. This infection has been proved to be transmitted by the bite of a nocturnal gnat, *Phlebotomus pappatasii.* Quinin and tonics are the reliance in treatment. The same principles should be applied in prophylaxis as for malaria.

63. **Emetin in Treatment of Tuberculous Hemoptysis.**—Nicola reports twenty-one cases of hemoptysis in tuberculous patients all treated by subcutaneous injection of about 0.04 gm. of emetin, repeated after an interval of twelve hours; in some of the cases the first injection was 0.06 gm. and the second was 0.04, with an interval of only three hours. In one case 0.32 gm. of emetin was given fractioned in thirty-four hours without result. In another, four injections of 0.06 gm. within twenty-four hours finally conquered the tendency to hemoptysis. Analysis of the various cases teaches that a good result can be counted on only when the hemoptysis occurs in the early stages of tuberculosis, and there is not much loss of blood, or in the cases with high blood-pressure and unstable vasomotor system. In all his cases of this kind the tendency to hemorrhage was definitely arrested by the emetin in from ten to forty-eight hours. On the other hand, when the hemorrhage was the result of passive venous congestion or of an ulcerative process with abnormally low blood-pressure, emetin not only failed to arrest the hemoptysis but induced symptoms of mild toxic action when the dosage was pushed.

69 Causes of Error in Determination of Proteins in the Urine. (Di un reperto singolare, come contributo alla conoscenza della cause di errore nella ricerca della proteine nell'urina.) E. Cavazanni.
70 *Sulphur Reaction in the Urine with Cancer. (Del comportamento del solfo organico urinario nei tumori maligni. Reazione di Salomon-Saxl.) M. Capella.

67. **Permeability of Infant's Intestine for Cow's Casein.**—Modigliani and Benini tested the blood for protective ferments, using for the test the serum from rabbits treated by repeated parenteral injections of casein from cow's milk. In time their serum acquired casein-precipitating properties. Applying this biologic-test technic they obtained a positive response every time with serum from bottle-fed infants showing symptoms of gastro-intestinal disturbance on cow's milk. Positive findings were obtained also in sick new-born babies given a little cow's milk. In older, breast-fed infants with acute intestinal disturbance, the response was negative when they had been given a little cow's milk. Healthy infants at any age never gave a positive response. The experiences reported demonstrate the specific nature of the reaction and that the intestines become permeable for the casein in abnormal conditions of various kinds. They suggest further that the alien casein thus getting into the circulation may do much damage in different ways, especially on the liver.

70. **The Sulphur Reaction in the Urine with Cancer.**—Capella applied the Salomon-Saxl test in twenty-one cases of certain cancer, eleven with various other affections, and five healthy controls. (The technic was described in The Journal, 1912, lix, p. 738.) He obtained a positive response in only 48 per cent. of the cancer cases, so he thinks the test is of comparatively little differential value.

73 *Lead Meningitis. (Meningite asettica di origine saturnina.) L. Preti.

73. **Lead Meningitis.**—Preti was treating a painter for his ninth attack of lead colic, which soon subsided under hot baths, pilocarpin, etc., but was followed by paresis of the legs, which also gradually subsided in a couple of weeks. Ten days afterward various joints and muscles became painful and in the course of a few days fever developed suddenly, with intense headache, pain in the back of the neck, the Kernig sign, Cheyne-Stokes breathing, and other signs of severe acute meningitis, the patient finally becoming unconscious. The cerebrospinal fluid was under high pressure but sterile. The patient recovered consciousness after 25 c.c. of the fluid had been withdrawn, and recovery proceeded rapidly. Nearly all the symptoms had disappeared by the end of the week. About 20 c.c. of fluid was then withdrawn by lumbar puncture. It was still under considerable pressure, but the specific gravity had dropped from 1.010 to 1.004, the albumin from 0.5 per cent. to traces, and the former traces of sugar had almost disappeared. Culture media and animals inoculated anew confirmed the aseptic character of the meningitis. Leukocytes were found in the fluid each time but they were of normal shape and aspect.

81 *Formation of Uric Acid in Man. III. (Bildung der Harnsäure beim Menschen.) J. P. Chrom.

81. **Production of Uric Acid.**—To show the practical importance of the research reported, Chrom relates that ten years ago he had a patient, a married woman of 55, who for thirty-five years had suffered from depression, headache and insomnia with, latterly, hallucinations and sensations of oppression. She had tried all kinds of treatment to no avail. Her appetite and bowel functioning were good and nothing objective could be found except an unusual amount of uric-acid crystals in the urine. This started him to investigate the mechanism of the production of uric acid and the ratio between the H_2SO_4 and the æ-H_2SO_4. He found it remarkably low, not over 4-1. Under suitable dietetic measures he succeeded in raising this ratio to 7-1, and as he accomplished this all her symptoms disappeared. He never got the ratio above 9-1, but she has been in perfect health during the last few years. The ratio at the last examination was 63-1.

He has apparently established that this ratio between one-half of the amount of uric acid and the total amount of the ethereal sulphates is proportional to the ratio between their molecular values. He produces evidence to show that as the conjugated sulphates are formed, the normal transformation of uric acid is interfered with and in such a way that the uric acid becomes refractory to the oxidation processes in the body, and the organism has to cast it out unoxidized. If oxalic acid is supplied to the organism, this splits the uric acid so that it becomes oxidizable. Other substances which seem to act in the same way are volatile fatty acids, and the livelier the putrefaction processes going on in the intestines, the more fatty acids are generated. Tables are given showing under seventeen headings the metabolic findings during two months on a special ration; first rye bread and margarin and then with prunes, potato and sugar. Other tables show the findings with other rations, but all seem to confirm his conception of the mechanism of the production of uric acid, namely, that the fatty acids are instrumental in splitting the uric acid in such a way that it can be oxidized. The ratio index ran up highest when cauliflower was eaten daily for a week, reaching 16.2-1. The next highest ratio was on a diet of 2,400 gm. purées; 450 gm. white bread; 180 gm. margarin; ½ liter milk; 360 gm. tea, and 360 gm. coffee. A high ratio was also evident on a diet of 900 gm. white bread; 150 gm. margarin; ½ liter milk; 260 gm. tea, and 360 gm. coffee. The ratio averaged lowest on a diet of nothing but 1,000 gm. fine white bread and 125 gm. margarin.

83 *Ultimate Outcome of Traumatic Neuroses. (Om traumatiske Neuroser og deres senere Forløbsamt om deres Forhold til Erstatningsspørgsmaalet.) A. V. Neel. Concluded in No. 52.

83. **Traumatic Neuroses.**—Neel reviews the experiences of accident insurance societies in 189 cases of traumatic neuroses. The trauma had injured the head in sixty-eight cases but in 106 there did not seem to be any organic injury and the traumatic hysteria was due in large part to the indemnity factor. In fifteen cases there were actual neurasthenic neuroses, mostly the result of fright, and this group, he declares, is all that should strictly be called traumatic neuroses.

THE HISTORY OF OPIUM AND SOME OF ITS PREPARATIONS AND ALKALOIDS *

DAVID I. MACHT, A.B., M.D.
Instructor in Clinical Medicine and Lecture Assistant in Pharmacology, Johns Hopkins University
BALTIMORE

If the entire materia medica at our disposal were limited to the choice and use of only one drug, I am sure that a great many, if not the majority, of us would choose opium; and I am convinced that if we were to select, say half a dozen of the most important drugs in the Pharmacopeia, we should all place opium in the first rank. If we were to inquire, however, into how much the great majority of the medical men know about the history of this wonderful product of plant life, which, when judiciously employed, has proved such a boon to suffering humanity, if we were to ask about the origin of some of our most familiar remedies—laudanum or paregoric, for instance—I fear the information gleaned would be meager. It is doubtful whether it is even generally known that opium, so widely used in China, is not indigenous to that country, but was introduced there at a comparatively late date. This were apology enough for a brief historical sketch on the subject, but a glance at the history of opium and its derivatives from the earliest time to the present may teach us more. If the aim of the history of medicine is not altogether the recitation of interesting anecdotes, but rather to trace the progressive development of our noble art and science, then is the history of no other drug more calculated and better fitted to illustrate the gradual transition from the obscurity and mysticism of the ancient *Dreck-Apotheke* or polypharmacy and kakopharmacy to the rational therapeutics of the present day.[1]

EARLY HISTORY

The medicinal properties of poppy juice date from a remote period, and yet not so far back in antiquity as we might expect, for the earliest definite and authentic references to it are found only in the Greek and Latin literatures. Of course, recalling the mystic rites and highly developed culture of the ancient Egyptians one is inclined to imagine that the narcotic properties of opium were known to them; but the investigations of Unger (1857) have failed to trace any acquaintance with opium in Ancient Egypt, and Dr. Ember, of the Semitic Department of this university, tells me he knows of no reference to it in Egyptian literature. According to some Hebrew scholars, there is a reference to poppy juice in the Bible. In several passages in the Old Testament the word *rôsh* is mentioned in connection with the word *la'anah*, wormwood or absinthe (Jer. viii 14, ix 14, etc.). *Rôsh* in these passages is in the authorized version rendered hemlock. *Rôsh*, however, in Hebrew is the word for "head," and so it has been taken by later scholars to mean poppy-head, and *me-rôsh*, or the juice of *rôsh*, rendered by Jewish interpreters as "poison water," is taken to mean the juice of the poppy. This interpretation fits well enough in the context, and further support is given it by the fact that the Latin for poppy-heads is *caputa*. Professor Haupt is convinced that *rôsh* means the poppy, and so also is Professor Post, who is considered an authority on the flora of Palestine. In the Talmud we have one reference to opium, under the name *ophion* (Jerusalemic Talmud, Tr. Abodah Zarah, 40a), but that word was clearly borrowed from Greek.

In regard to Sanskrit, Prof. M. Bloomfield of the Sanskrit department of this university tells me that opium is not at home in India, and so in the classical Hindoo literature (Brahmanical, Buddhist, Jinist) there is found no reference to it. From the time of the Mogul Conquest on there appears a word *Khash-khash* which means poppy-seed, and *Khash-khasha-rasa*, juice of the poppy. In this it is easy to recognize our modern word *hashish;* and so it seems that at that early date the narcotics opium and cannabis indica were confused with each other.

In modern Sanskrit lexicons there are found the names *aphena* and *ahi-phena* appiled to opium; *aphena* strictly means "foam," and *ahi-phena*, "serpent's foam." As these words for opium do not occur in any literary document, Dr. Bloomfield suspects that they are the English opium "sophisticated by what is known as popular etymology."

The original home of the poppy was in Asia Minor. From there it was carried to Greece at a later period.

The name opium is derived from the Greek *ὀπός* "juice." From this word were later formed the Hebrew *ophion* already mentioned, and more particularly the Arabic *af-yun*, which has found its way into other Asiatic languages. The Chinese name for the drug *o-fu-yung* (and its modifications *ya-pien* and *opien*) are not of native origin, but are all derived from the Arabic.

---

* This sketch is intended to be an introduction to a pharmacologic study of some opium alkaloids carried on by the author and endorsed by a grant from the Council on Pharmacy of the American Medical Association.

[1] In the preparation of this manuscript the following authorities have been frequently consulted:

Geissler and Möller: Real Encyclopedie der Gesammten Pharmacie, Leipzig, 1886-1891.

Fluckiger and Hanbury: Pharmacographia or History of Drugs, 1874.

Rice: New Remedies, 1876, p. 229.

Jones, John: The Mysteries of Opium Revealed, London, 1701.

Thompson, C. J. S.: The Mystery and Romance of Alchemy and Pharmacy, 1892.

Jeffreys and Maxwell: Diseases of China, 1906.

It is not at all certain whether Hippocrates was acquainted with the juice of the poppy. According to Wootton, he refers to a substance called *mecon* to which he attributes a purgative as well as narcotic action. Some think that it was opium; others believe that he was referring to another plant. In any case, he made but very little use of the drug.

The first authentic reference to the milky juice of the poppy we find by Theophrastus at the beginning of the third century B. C., when he speaks of it as μηκώνιον (meconion).

Scribonius Largus,[2] in his "Compositiones Medicamentorum," about the year 40 of the present era, describes the method of procuring opium from the capsules of the poppy, and about the year 77 of the same century Dioscorides makes a distinction between the juice of the capsules which he called ὀπός and the extract of the whole plant or μηκώνειον, which he regarded as less active. He describes the method of incising the capsules, and refers to adulterations of the drug with the milky juices of other plants such as Lactuca, so that from his statements it is evident that the collection of opium was quite an industry in Asia Minor at that time. He also describes the preparation of a syrup of poppies or *dia-kodion,* which is the original of the syrup of poppies of the German and other Pharmacopeias to this day.

Pliny devotes some space to a description of opium and its medicinal use, and the drug is mentioned repeatedly as *lacrima papaveris* by Celsus in the first century and by numerous other Latin writers. Galen spoke enthusiastically of the virtues of opium confections, and the drug was soon so popular in Rome that it fell into the hands of shopkeepers and itinerant quacks.

The introduction of the drug to the natives of the East was through the Arabs, and in the first instance to Persia. Its introduction into India seems to have been connected with the spread of Mohammedanism and was favored by the Mohammedan prohibition of wine.

The Arabic physicians used opium very extensively, and even wrote special treatises on some of its preparations. The most celebrated of them, Abu-l-ali-ibn-Sina, more commonly known as Avicenna (980-1037), recommended it especially in diarrhea and diseases of the eye. Avicenna himself is said to have met death from an overdose of the drug. Serapio (about 1090) used it freely, and Maimonides and Averroes each wrote a treatise concerning the theriac, of which I shall have much more to say a little later.

The earliest mention of opium as a product of India is by the traveler Barbosa, in his description of the Malabar coast in 1511. A Portuguese historian, Pyres, in a letter to Manuel, King of Portugal, in 1516, speaks of the opium of Egypt and Bengal. It is from Egyptian Thebes that we have the terms "opium thebaicum" and the alkaloid thebain.

Opium is supposed to have been brought to China first by the Arabs, who are known to have traded with the southern parts of the empire as early as the ninth century. Later the Chinese began to import the drug in their junks from India. At that time it was used by them exclusively as a remedy for dysentery. It was not before the second half of the eighteenth century that the importation of opium began to increase rapidly through the hands of the Portuguese, and a little later through the famous East India Company. In 1870 the English established an opium depot in Lark's Bay, south of Macao, and the traffic rapidly increased, so that very soon the Chinese authorities began to complain, and in 1820 an edict was issued forbidding any vessel having opium on board to enter the Canton River. A system of contraband followed, then political friction between England and China, and the so-called Opium War, which culminated in the Treaty of Nanking (1842) by which five ports of China were opened to foreign trade, and in 1858 opium was admitted as a legal article of commerce. By that time the vice of opium-smoking had spread like a plague over the gigantic empire, and became so deeply rooted that, in spite of innumerable edicts and decrees, all efforts to check its growth have been powerless. A poor sort of missionary work by the enlightened West among the heathen Orientals!

I shall not spend here any more time in tracing the history of opium in China, or in dwelling on the horrors of the opium habit, with its frightful constipation and even more terrible diarrhea, and the physical and mental degeneracy to which it leads. Our object is rather to follow the use of opiates therapeutically, and in Europe.

Since the time of Galen, the use of opium was continued in a disguised form in various concoctions and confections containing so many ingredients that the distinction between the important and useless could not be discovered, and the value of the drug was overlooked, except by a few brighter minds.

The famous physician of the middle ages, Philippus Aureolus Theophrastus Bombast von Hohenheim, commonly known as Paracelsus (1490-1540), owed much of his success to the bold way in which he administered opium to his patients. He is said to have carried opium in the pommel of his saddle and called it the "stone of immortality." His followers were as enthusiastic as himself over the virtue of opium. Platerus of Basle in 1600 strongly recommended it, and Sylvius de la Boe, a famous Dutch physician, declared that without opium he could not practice. The celebrated chemist and physician Van Helmont, about 1640, used it so frequently that he was called Doctor Opiatus, and Sydenham about 1680 writes that "among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium."

THE FOUR OFFICINAL CAPITALS

No better illustration of the widely beneficent properties of opium and at the same time of the hopeless muddle of superstition, kakopharmacy and polypharmacy pervading the older materia medica and therapeutics, can be given than by a brief description of the four remedies which are sometimes known as the four officinal capitals, of which Wootton,[3] in his "Chronicles of Pharmacy," says, "There were writers who ventured to criticize some of the details of composition, or some of the uses made of these compounds, but the possibility of medicine existing without them was hardly contemplated previous to the eighteenth century." These four standbys or panaceas were the *mithridatium, theriaca, philonium,* and *diascordium.*

Mithridatium was a confection which derived its name from Mithridates VI or the Great, king of

---

[2] Largus, Scribonius: De Compositione Medicamentorum. 1786.

[3] Wootton: Chronicles of Pharmacy, 1910.

Pontus in Asia Minor, born about the year 134 B. C., who was one of the most troublesome foes the Roman Republic had to deal with. He was finally defeated by Pompey. This personage is said to have been a student of poisons, and was accredited with having invented or concocted an alexipharmac or antidote as a protection against them, which was named mithridatium after him. The legend goes to say that when conquered by the Romans, to escape capture he poisoned his wife and daughters and then took poison himself; but according to the story he had so successfully immunized his body to all sorts of poisons that his efforts at suicide proved unsuccessful and he had to call on one of his soldiers to dispatch him. Hence the origin of the term "mithridatism" or immunization against the effects of a poison through gradual administration of small doses of it. As the king of Pontus was accredited with having possessed especial skill in the production of medicines, his conquerer, Pompey, took care to ransack his medical writings and secure whatever he could. Thus, whether from Mithridates or not, a panacea bearing his name found its way into Roman literature and became very popular. Various modifications of it were later made, the most important of which was the so-called theriaca.

Theriaca was invented by Andromachus, the physician of Emperor Nero, and was devised as an improvement on mithridatium, which until then was the great antidote of Roman pharmacy. The most important difference between the two was the addition of vipers. The word "theriaca' comes from the Greek θηρίον, wild beast, or serpent, and has reference to its use as an antidote against snake bites. According to Galen, the virtues of this panacea were the following:

> It resists poison and venomous bites, cures inveterate headache, vertigo, deafness, epilepsy, apoplexy, dimness of sight, loss of voice, asthma, coughs of all kinds, spitting of blood, tightness of breath, colic, the iliac poison, jaundice, hardness of the spleen, stone, urinary complaints, fevers, dropsies, leprosies, the troubles to which women are subject, melancholy and all pestilences.

Though all this may seem a huge joke, all these virtues were accepted down to the seventeenth century, and many learned treatises were written on the subject. For some centuries various cities such as Constantinople, Cairo, Genoa and Venice gained the enviable reputation of manufacturing the most efficient theriaca. Later Venice overshawdowed them all; and the Venice theriaca, or as the word became corrupted, Venice *treacle*, was for a long time famous, and is found in the London Pharmacopeia as late as 1745. Our present word "treacle" is derived from this confection; in earlier English works, however, treacle signified much more than molasses, and was used metaphorically for the divinest blessings.

I am now going to quote the ingredients of theriaca, as given by Galen, first to illustrate the curious conglomeration of an enormous number of useless drugs, and secondly to point to the presence in it of opium, to which probably a great part of its virtues were due. The ingredients of this, as well as of mithridatium, were given in Greek verse, in order that they might be better remembered.

ELECTUARIUM THERIACALE MAGNUM

Root of Florentine iris, licorice, 12 ounces each; of Arabian costus, Pontic rhubarb, cinquefoil. 6 ounces each; of Ligusticum meum, rhubarb, gentian, 4 ounces each; of birthwort, 2 ounces; herb of scordium, 12 ounces; of lemon grass, horehound, dittany of Crete, calamint, 6 ounces each; of pennyroyal, ground pine, germander, 4 ounces each; leaves of laurus cassia, 4 ounces; flowers of red roses, 12 ounces; of lavender, 6 ounces; of St. John's wort, 4 ounces; of lesser centaury, 2 ounces; saffron, 2 ounces; fruit of amyris opobalsamum, 4 ounces; cinnamon, 12 ounces; cassia lignea and spikenard, 6 ounces each; Celtic nard, 4 ounces; long pepper, 24 ounces; black pepper and ginger, 6 ounces each; cardamoms, 4 ounces; rape seeds, agaric, 12 ounces each; seeds of Macedonian parsley, 6 ounces; of anise, fennel, cress, seseli, thlaspi, amomum, sandwort, 4 ounces each; of carrot, 2 ounces; *opium*, 24 ounces; opobalsamum, 12 ounces; myrrh, olibanum, turpentine, 6 ounces each; storax, gum arabic, sagapenum, 4 ounces each; asphaltum, opoponax, galbanum, 2 ounces each; juice of acacia and of hypocist, 4 ounces each; castor, 2 ounces; Lemnian bole, calcined vitriol, 4 ounces each; trochises of squill, 48 ounces; of vipers, of sweet flag, 24 ounces each.

Triturate the balsams, resins and gums in a sufficient quantity of wine to form a thin paste, and incorporate the whole with 960 ounces of honey.

Philonium was another famous antidote, invented by Philon of Tarsus, who is supposed to have lived in the early part of the first century of the present era. It is conjectured from an obscure passage in Pliny that this antidote was prescribed against an epidemic of colic or dysentery which occurred in Rome in Philon's time. Philonium was the original of the confection of opium which remained in the English pharmacopeias until 1867. In the Pharmacopeia Londinensis of 1746, the ingredients of philonium are given as follows: white pepper, ginger, caraway seeds, strained opium and syrup of poppies, the proportion of opium being 1 grain in 36 grains of the confection.

Diascordium, the last of the four officinal capitals, was a medicinal compilation by Hieronymus Frascatorius, a famous physician and poet of Verona in the early part of the sixteenth century, and is given in his book "De Contagio et Morbis Contagiosis." It was originally devised as a preventive of the plague. In the eighteenth century it became a popular household opiate and was frequently given to children for soothing purposes. The original formula, which was adopted in the first London Pharmacopeia in its integrity, mentioned among its principal ingredients cinnamon, cassia wood, scordium, dittany, galbanum, storax, gum arabic, *opium*, sorrel, gentian, Armenian bole, Lemnian earth, pepper, ginger, and honey. Later some of the ingredients were dropped, and the Edinburgh Pharmacopeia made it more astringent by adding catechu and kino. The mangled remains of this famous panacea are represented by the British and U. S. P. Pulvis Catechu Compositus, and Pulvis Kino Compositus.

LATER USES OF OPIUM

The compound powders of catechu and kino just mentioned are not the only relics of ancient opium compounds remaining in the British and our own pharmacopeias. The commonest pharmaceutic preparations of opium still in use are of antique extraction, and it may be of interest to devote a few words to them at this place.

Our tincture of opium or laudanum dates from Paracelsus (1490-1541). Paracelsus probably applied the name "laudanum" to several medicines, all of which contained opium. Thus one historian describes a *pill mass* which he designates as laudanum of Paracelsus, and which consisted of one-fourth of its weight opium, to which were added henbane juice, mummy, salts of pearls and corals; bone of the heart of a stag, bezoar stone, amber, musk, and essential oils.

Another laudanum, known as anodynum specificum of Paracelsus, was obtained by digesting opium, with orange and lemon juice, frog's sperm water, cinnamon, cloves, ambergris, and saffron. So much for the more ancient laudanum. The laudanum of the early London pharmacopeias was a pill mass, made of a mixture of opium, wine, saffron, castorum, diambrae, ambergris, musk, and oil of nutmeg. The principal liquid preparation of opium used in England a little later was the so-called Sydenham's laudanum. The formula was given by Sydenham in his work on dysentery in 1669-1672, and called for the following ingredients: strained opium, saffron, cinnamon, clover, and canary wine. About the same time, that is, at the end of the seventeenth century, another preparation known as Rousseau's laudanum was much in vogue on the Continent. This differed from the other laudanum in being a fermented compound, and was named after a Capuchin monk by the name of Rousseau. This holy man was sent from Rome to Paris to learn medicine preparatory to mission work in Asia, but became enamored with the subject and settled in Paris to practice the art of healing. He became a favorite with Colbert, the minister of Louis XIV; rooms and laboratory were provided for him in the Louvre, and Louis ordered the Faculty of Medicine to give him a degree.

The name "laudanum," attributed to Paracelsus, is supposed to be derived from the Latin *"laudandum,"* "something to be praised." According to some philologists it is related to gum labdanum or ladanum, from which a stomachic cordial was prepared in the middle ages. Others regard it as an abbreviation of the two words *laudatum opium*. Still others endeavor to find in it a corruption of the word *anodynum* with the article prefix, that is, *l'anodynum,* or *the* anodyne, and some latter-day punsters humorously refer to it in bad Latin *Lauda non!* "do not praise," which conveys more truth than poetry.

In the early part of the eighteenth century another celebrated opiate was the so-called "black-drop." Its inventor was one Edward Runstall of Auckland, and it was also known as Lancaster or Quaker's black drop. A formula for its preparation was as follows: Opium ½ pound; verjuice, 4 pints; nutmegs, 1½ ounces; saffron, ½ ounce. Boil, add two spoonfuls of yeast and set in a warm place for six to eight weeks; then decant, filter and put in bottles. This preparation was three times as strong as laudanum, and is the forebear of the English Acetum Opii.

Our other familiar friend and popular household anodyne, paregoric, originated with the elixir asthmaticum of Le Mort, professor of chemistry at the University of Leyden from 1702 to 1718. A modification of Le Mort's formula given in the London Pharmacopeia of 1721 was as follows: honey and licorice root, of each, 4 ounces; flowers of benjamin and opium, of each, 1 dram; camphor, 2 scruples; oil of aniseed, ½ dram; salt of tartar, 1 ounce; spirit of wine, 2 pounds. In the London Pharmacopeia of 1746, the name of it was changed to Elixir Paregoricum. In that of 1888 the official name became Tinctura Opii Camphorata. This preparation was also known as Tinctura Camphorae Co., and in the German Pharmacopeia as Tinctura Opii Benzoica. The word "paregoric" comes from the Greek παρηγορικός, which means "soothing" or "consoling."

Our official opium pills, or Pilulae Opii, are not a modern product but are descended from the old English Pilulae Soponis Co., or Pilulae Soponaceae, which in their turn are an adaptation of the long famous nostrum known as Matthew's Pills or Starkey's Pills. Starkey was a physician who invented them, and Matthew was a vender who sold them. The pills consisted of opium, soap of tartar, and a number of other trivial ingredients.

No account of the history of our opiates can be said to be complete without a reference to Dover's powder, and its originator, the adventurer and knight errant of English medicine, Thomas Dover. I shall not dwell long on the life of this interesting individual, especially as an account of him by Osler[4] has already been published. Born at Barton on the Heath in Warwickshire in 1660, he studied medicine, and in his youth lived at the house of the famous Thomas Sydenham. Many have probably read of how he later joined a privateering party, and led a life of adventure, roaming around the world; how the ship in which he was sailing rescued Alexander Selkirk, the man who lived alone on an island for over four years and who became the prototype of the famous Robinson Crusoe. When he returned to London and settled down to practice, Dover[5] wrote his "Ancient Physician's Legacy to his Country." In this work, in the chapter on gout, he gives the recipe for his "diaphoretic powder" in the following words:

> Take opium, 1 ounce; saltpeter and tartar vitriolated, each 4 ounces; liquorice, 1 ounce; ipecacuanha, 1 ounce. Put the saltpeter and tartar into a red hot mortar, stirring till they have done flaming. Then powder very fine. After that, slice in your opium; grind to a powder and mix. Dose, from 40 to 60 or 70 grains in a glass of white wine posset, going to bed, covering up warm, and drinking a quart or three pints of the posset while sweating. In two or three hours at furthest the patient will be free from pain.

This will suffice for the commoner opium preparations.

THE ALKALOIDS

Let us now turn from this region of pharmaceutic romance, superstition and mysticism, to some of the achievements that characterize the pharmacy of the nineteenth century, and which mark the beginning of rational therapeutics.

As is well known, throughout the middle ages it was the great ideal of all chemists, or rather alchemists and pharmacists, to search after essences, or quintessences of things, after the philosopher's stone, the elixir of life, etc., and it is natural to find that of all popular drugs opium should be the one especially tortured to give up its essence. Therefore the various laudanums and extracts of opium, and preparations known as magisteria opii, were products of activity exerted in that direction.

Toward the end of the eighteenth century it was a universal belief that plants could elaborate products of only an acid or neutral nature, and that alkalies were substances of a very different character, related more to the metals and exhibiting metallic properties. It was not until the beginning of the nineteenth century, with the discovery of the alkaloids, that this conception was shattered, and it is significant that the first alkaloid to be discovered was the chief active principle of opium—morphin. The honor of this epoch-making discovery belongs to a German, Friedrich Wilhelm Adam Sertürner. Sertürner was born July 19, 1783, in Paderborn. He became an apothecary and chemist at Einbeck in Hanover, Germany, where he did his most important work, and moved later to Hameln, where he died, Feb. 20, 1841.

---

[4] Osler, W.: Bull. Johns Hopkins Hosp., 1896, vii, 1.

[5] Dover, Thomas, M. B.: The Ancient Physician's Legacy to His Country, London, 1762.

Sertürner began his investigations of opium in 1803, and published the first report of his studies in 1805, when he announced his discovery in opium of an acid, *Opium-Saüre*, which he later named "meconic acid," and which he explained was combined with an alkaline base which he called morphium. In a second communication, in 1816, he gave a detailed account of his work, and described the chemical as well as the pharmacologic properties of morphin, which he tested out on himself, and came near losing his life.

"I flatter myself," he wrote, "that chemists and physicians will find that my observations have explained to a considerable extent the constitution of opium, and that I have enriched chemistry with a new acid (meconic) and with a new alkaline base (morphium), a remarkable substance which shows much analogy with ammonia." Sertürner's discovery excited so much interest, and its importance was regarded as so great, that in 1831 the Institute of France awarded to him a prize of 2,000 francs "for having opened the way to important medical discoveries."

Next in importance to morphin in point of quantity, the opium alkaloid narcotin was discovered really before morphin, in 1803, by the French pharmacist Derosne, who obtained crystals of what proved to be narcotin while diluting a sirupy aqueous extract of opium. These crystals became known as *sel d'opium* of Derosne. The basic or alkaloidal character of the body, however, was not established until 1817 by Robiquet, another pioneer in alkaloidal chemistry. The same Robiquet was the discoverer of the next very important opium alkaloid named codein, in 1832. The discoverer of the next opium alkaloid was another illustrious chemist, Joseph Pelletier, whose name is familiar to us from the active principle of male fern, pelletierin. Pelletier was born in Paris in 1788, and died there in 1842. A son of an apothecary, he was from his earliest days engaged in chemical and pharmaceutic studies, and later became a director of the school of pharmacy in Paris. He was the first to isolate a large number of alkaloids. In 1832 he discovered the opium alkaloids narcein and oxymorphin, and in 1835, with Thiboumery, another alkaloid, thebain. Pelletier was also the discoverer of strychnin, and together with Caventou, of brucin; quinin, and chinchonin, together with Magendie of the at present interesting emetin, together with Corriol of aricin, together with Thiboumery of pseudomorphin, together with Couerbe of picrotoxin, and together with Pelleton of berberin. Since his time opium has become a nidus for a large number of alkaloids, and promises to yield a few more. Up to the present, according to Winterstein and Trier,[6] opium has yielded besides protein bodies, sugar, gum, resin, salts, and organic acids, twenty-two different alkaloids of which the following is a list: morphin by Sertürner in 1804; narcotin by Robiquet in 1817; codein by Robiquet and narcein by Pelletier in 1832; thebain and pseudomorphin by Pelletier and Thiboumery in 1835; papaverin by Merck in 1848; cryptopin in 1857; gnoscopin in 1878 and xanthalin in 1893 by T. and H. Smith; codamin, laudanin, meconidin, and lanthopin by Hesse in 1870; laudanosin and hydrocotarnin in 1871, and protopin in 1872 also by the same investigator; oxynarcotin, by Beckett and Wright in 1875; tritopin by Kander in 1890; laudanidin by Hesse in 1894, and lastly pseudopapaverin and papaveramin by the same man in 1903.

Besides the primary opium alkaloids, a large number of derivatives of them have been made, which we need not enumerate here. Let me but mention apomorphin, apocodein, heroin, dionin, and peronin.

All these chemical individuals have been analyzed, their empiric formulas established, and an attempt, at least in case of some of them, has been more or less successfully made to determine their structure. Along with this chemical work, which forms one of the most brilliant chapters of modern chemistry, a great deal, though by no means complete or sufficient, physiologic and pharmacologic work has been done with them.

Only within the last few years, the work of Straub, Faust, Bürgi, Sahli and others has marked a still further step in our knowledge of their therapeutic properties. These authors have shown that not only have the various opium alkaloids individually definite pharmacologic actions, but that also still other effects can be produced by combining them with each other.

Thus if we trace the history of opium from its earliest beginnings to the brilliant researches of recent years, if we but compare the analytic and synthetic, chemical, physiologic and pharmacologic studies of the same old drug with the fantastic and puerile effusions on the subject of our medical predecessors, we cannot help being impressed with the long strides forward which medicine has made; yet, on the other hand, our very recent studies on opium and its alkaloids serve but to emphasize the more our meager knowledge of the subject and the still greater task before us.

As I close, I must recall the pregnant words of the philosopher: "And I saw indeed that wisdom hath the advantage over folly, as great as the advantage of light over darkness." "The wise man hath his eyes in his head, while the fool walketh in darkness"; but (and that is what we should all remember) "I myself perceived then also that the same occurrence may befall all of them." (Ecclesiastes ii: 13, 14).

One-Minute Biographs.—The subject of to-day's sketch is claimed equally by chemistry, biology, medicine, industry, agriculture and economics, and all are deeply indebted to him for substantial scientific contributions. Chemistry is his debtor for throwing a flood of light on the nature of isomerism, and thereby laying a secure foundation for our present conceptions of structural chemistry. Biology is his debtor for effectively disposing of the theory of spontaneous generation and for demonstrating fermentation as a vital phenomenon. Medicine is his debtor for establishing the relation of bacteria to disease, and for fundamental contributions to the science and practice of immunity. Agriculture is his debtor for his brilliant work in devising a protective vaccine against anthrax, a dread scourge of cattle and sheep. Industry is his debtor for epoch-making discoveries in fermentation which provided a sorely needed scientific foundation for the wine industry, and for his work in discovering the cause of the silkworm blight whose control saved the silk industry in France from destruction. Economics is his debtor for the knowledge which made possible the introduction of canned foods, a step which has wrought profound economic changes throughout the world. With all the world so largely his debtor, let us revere the name of Louis Pasteur, benefactor of mankind.—*Weekly Bull. Dept. Health*, New York City.

A NEW OPERATIVE TREATMENT FOR SELECTED CASES OF CEREBRAL SPASTIC PARALYSIS *

WILLIAM SHARPE, M.D.
Adjunct Professor of Surgery, New York Polyclinic Medical School
AND
BENJAMIN P. FARRELL, M.D.
Visiting Surgeon, New York Orthopedic Dispensary and Hospital
NEW YORK

This paper is merely the report of the operative treatment of sixty-five cases of spastic paralysis showing intracranial pressure by an ophthalmoscopic examination. These sixty-five operated cases are the ones selected as being suitable for the operation from the examination of 201 cases of spastic paralysis, that is, one in about every three cases examined. Although only a little more than a year has elapsed since the first operation, which was performed in June, 1913, yet our results have been so gratifying and even startling, that we feel justified in presenting the progress of the cases treated by us up to the present time. Naturally, sufficient time has not yet elapsed to permit us to say whether the improvement in our cases will be a permanent one or not; and yet, in view of the pathologic lesions producing this type of spastic paralysis, we do not see why the improvement should not become more and more marked as the children grow older.

Let us emphasize first, that we are *not* operating on the mentally deficient, the constitutionally inferior and idiots in the hope of restoring them to a normal mentality; and secondly, that we are not operating on microcephalic children in the belief that the brain will develop and become normal by enlarging their cranial capacity (a belief long exploded); and thirdly that we are not operating in cases of spastic paralysis due to a lack of development and malformation of the cortex of the brain and the pyramidal tracts—cases forming at least one-half of the total number of spastic paralyses—the so-called Little's disease, in which a cranial operation will do no good,* and from the very pathology of which a cranial operation can be of no benefit to the patient. On the other hand, we *are* operating in those cases of spastic paralysis giving a history of difficult labor with or without instruments, in which on opthalmoscopic examination the definite signs of increased intracranial pressure are to be seen on the fundus of the eye; that is, only those cases of spastic paralysis which show definite signs of increased intracranial pressure, whether this condition is associated with impaired mentality (and it very frequently is as the result of prolonged pressure on the cortex of the brain) or whether the size of the head is unusually small or unusually large. If in the latter cases there is an increased intracranial pressure, then that pressure should be relieved in the hope that the spasticity will lessen and the mentality be improved. Naturally, the most satisfactory and desirable cases for operation are the ones with slight impairment of the mentality, but these cases are rare when the intracranial pressure has been present for several years; much more commonly do we find a more normal mentality in those cases of lack of development and malformation of the pyramidal tracts, unless very extensive.

The condition of spastic paralysis results most frequently from a lesion of the brain occurring before birth, during birth or shortly after birth. It is characterized by more or less complete paralysis of the part affected, and is associated with a stiffness or spasticity depending on the extent of the involvement of the pyramidal tract; this hypertonicity produces muscular contractures and deformities, usually flexor in type, with a corresponding overstretching of the opposing muscular groups, usually the extensors. In mild cases, however, the spasticity may be so slight as to cause little or no deformity, but merely an awkwardness of the part affected. Frequently, athetoid movements of the arms and legs may be observed, and epileptiform attacks, commonly of the jacksonian type, may occur.

As the child grows older, not only do the spasticity and its resulting contractures increase in a large percentage of cases, but also the mentality of the child becomes impaired, and this impairment continues until the child may be considered a defective, or still further an imbecile, and only too frequently an idiot.

Little, if anything, has been done to improve permanently the condition of spastic paralysis, and we offer our observations in the hope that they may lead to a more satisfactory solution of the treatment of these cases. Our attention was first centered on the importance of relieving the increased intracranial pressure as a means of lessening the spasticity and improving the mentality of these children, by a decompression operation performed by one of us at the Nassau Hospital, Garden City, Long Island.

The case, referred by Dr. L. B. Rogers, was one of a child, aged 9 years, who after an easy delivery was apparently normal in every way until the ninth month of age, when it suddenly had a series of epileptic attacks; after these attacks had subsided, it was observed that there was a total left hemiplegia with exaggerated reflexes; the left arm and left leg became spastic and gradually assumed the flexor contractures so typical of these spastic cases. Three years ago, the patient had another series of convulsions and since that time these convulsive seizures of greater and lesser severity have continued almost daily. The mental impairment was moderate. Every method of treatment had practically been given up as useless. Last June, another series of convulsions began and during the four days preceding the examination of the patient, 302 attacks had occurred; the child was in a condition of status epilepticus—one convulsion following another; the almost continuous administration of chloroform was of little value. In addition to the typical left spastic hemiplegia, the patient had at this examination double choked disks, as revealed by an ophthalmoscopic examination—that is, a high intracranial pressure; the pulse was 54 and the respiration was very irregular and of the Cheyne-Stokes type. As artificial respiration and oxygen were being used, a right subtemporal decompression was advised in the hope that a relief of the increased intracranial pressure might improve the condition of the patient. The operation was performed at the Nassau Hospital, Garden City, June 18, 1913. No anesthetic was necessary—the patient being unconscious. On incising the dura, which was exceedingly tense, the cerebrospinal fluid spurted to a height of 6 inches; the cortex was edematous and swollen, and on enlargement of the opening upward, a fibrous mass, apparently the residue of an old cortical hemorrhage, was exposed, lying on the cortex and extending upward beneath the margin of the decompression opening. As the condition of the child was bad, I decided to remove the mass at a later operation. Owing to the mere relief of the intracranial pressure, the child became conscious at the end of the operation and an uneventful recovery occurred, the child leaving the hospital on the eleventh day after operation. The striking feature of the case, however, was the gradual lessening of the spasticity and of the contractures of the face, arm and leg, and this improvement continued until the child began using the leg freely and the left arm and hand for picking up articles for the first time in its life; there was also a definite mental improvement. The improvement in this case has been continuous.

---

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the author's reprints. A copy of the latter will be sent by the author on receipt of a stamped addressed envelope.

* The preliminary report of this work appeared in The Journal Nov. 29, 1913, p. 1982; at that time, the operation had been performed in only twelve cases.

The thought then occurred, "Why not do a decompression operation in those selected cases of spastic paralysis having a possible hemorrhage on the brain and showing any signs of intracranial pressure?" And so we began having the eyes of spastic children examined carefully with an ophthalmoscope for signs of increased intracranial pressure. It was very surprising to ascertain that of the cases examined, a large number did show mild though distinct signs of intracranial pressure—that is, a dilatation of the retinal veins, and a hazy edematous blurring of the nasal margins of the optic disks; many of them showed even mild signs of old secondary optic atrophy—rather whitish disks and the physiologic cup shallow from scar tissue formation. We then began to select for operation such cases having these definite signs of increased intracranial pressure, especially the extreme cases and the ones which had received the usual treatment of tenotomies, tendon lengthenings, alcohol injections, braces, massage, etc. Since then, we have operated in 65 cases, most of them being of the extreme type, and the results have been very gratifying. Of these 65 cases 34 were diplegics, both arms and legs being affected; 11 were paraplegic, only the legs being involved, while the remaining 20 cases were hemiplegic—the leg usually being more affected than the arm of the one side. Epilepsy in its various forms was present in 26 of these 65 cases; the improvement in 7 of these 26 epileptic patients has been complicated because the epilepsy has continued but in a less severe degree.

Six of our patients operated on have died and each of them within ten hours after the operation; four of these were under 2 years of age, of the extreme diplegic type, emaciated and therefore very poor operative risks; it seems that in them any alteration of the high intracranial pressure and circulation was sufficient to upset the patient—the temperature rising to 108 degrees within two hours after the operation; possibly, a too rapid escape of the cerebrospinal fluid interfered with the circulation of the basal ganglia and therefore the high temperature resulted. We are now controlling this loss of cerebrospinal fluid by elevating the head and shoulders of the patient according to the rate of flow and with much better results; it is an interesting observation that the temperature in these cases can be either raised or lowered by elevating or lowering respectively the head and shoulders.

Not only has there been a lessening of the spasticity of the arms and legs affected in these cases selected for operation, but there has been a definite amelioration of the mental condition of the patient to such a degree that we obtain the cooperation of the child in the carrying out of the after-treatment—a very important advantage of this operation. Naturally, the younger the patient is at the time of operation, the better the prognosis; that is, the longer the general and local increased intracranial pressures have persisted, just so much more will the delicate nerve cells be compressed, their blood-supply interfered with and therefore the cells themselves impaired.

The ideal time for the operation would be immediately after birth; then, merely a small opening need be made to allow the subdural blood to flow out in liquid form with little or no resulting impairment of the cortex. However, it is extremely rare for a definite diagnosis to be made at this early date—the impairment usually not being ascertained until several months later when the child is from 9 to 12 months of age. It is to be hoped that routine ophthalmoscopic examinations of the fundi in suspected cases following difficult labor will be of great assistance.

METHOD OF PROCEDURE

In those cases of spastic paralysis of the hemiplegic, paraplegic or diplegic type, with a definite history of difficult labor with or without the use of instruments, in which, on ophthalmoscopic examination, signs of intracranial pressure are shown in the dilated retinal veins and a blurring and haziness of the optic disks, especially of their nasal halves, a large right subtemporal decompression is performed to relieve the intracranial pressure. If the intracranial pressure is extremely high and remains high after the operation, a left subtemporal decompression is performed the following week, the operative recovery requiring only a week or ten days.

The operation itself consists of a vertical incision over the side of the head from 2½ to 3 inches in length extending from the parietal crest down to a point overlying the zygomatic arch and just anterior to the external auditory meatus; that is, to the lowermost point of the cranial cavity. The fibers of the temporal muscle are separated longitudinally and then a small opening in the squamous bone, made by the Doyen perforator and burr, is enlarged by rongeurs to a diameter of from 2 to 3 inches. The dura is now incised in a stellate manner, allowing the brain to expand, and in this way the increased intracranial pressure is relieved. The dura is *not* resutured and the bone is not replaced.

The usual pathologic findings are definite supracortical fibrous or cystic formations resulting from a cortical hemorrhage occurring at birth. These pathologic lesions are treated according to the individual findings—removed, punctured, the interior touched with some mild corrosive to cause an obliteration (great care being taken that no excess of the corrosive fluid escapes over the cortex) and very frequently, merely let alone; that is, more damage to the cortical cells may be done by endeavoring to remove the lesion and therefore it is wiser not to attempt it. The decompression operation is performed merely to offset the effects of the pressure of this hemorrhage with cystic formation, and the resulting spasticity and mental impairment. In four cases, the hemorrhagic cyst was cortical and subcortical; naturally, the local nerve cells and their fibers must have been damaged, so that a physical improvement cannot be expected in that part of the body controlled by the cells or fibers destroyed; however, the cells and fibers at the periphery of the lesion are merely impaired functionally by the local pressure of the cyst and the cystic formation, so that the functional impairment in these cases has improved very much.

The after-treatment, briefly, consists in the correction of deformities by tendon lengthenings if necessary, or merely stretchings of the contracted muscles, the maintenance of corrected positions through the employment of especially adapted braces, skilled massage and faradism, particular attention being given to the weakened and overstretched muscle groups. A careful, systematic course in muscle training is carried on daily.

The improvement in our cases selected for operation has been so marked—not only a lessening of the spasticity, but also a definite amelioration of the mental condition of the patient—that we believe a cranial decompression is indicated in those cases of spastic paralysis showing intracranial pressure by the ophthalmoscopic examination; of those cases of spastic paralysis which we have examined, about 40 per cent. have shown signs of intracranial pressure, and are, therefore, in our opinion, cases that can be very much improved; all of our operated cases had previously had the routine orthopedic treatment of massage, muscle training, tendon operations, etc., with little or no permanent improvement. The operation of cranial decompression is not a formidable procedure for one trained in neurologic surgery; all of our patients have improved (four only slightly), and we have had six deaths. The anesthetic should be administered by an expert; cyanosis and coughing are very dangerous complications, especially after the dura has been opened. Dr. C. S. Hunt used a mixture of ether and oxygen in all of our cases reported in this series, and in only two of them was any difficulty encountered; fortunately, the dura had not been opened. Dr. Hunt has observed the tendency of patients to become conscious as soon as the dura is incised and the intracranial pressure relieved; it is important to deepen the anesthesia, therefore, just before the dura is incised in order to prevent coughing, etc.

For lack of space, we report in this paper only every sixth case in which operation was performed, since the preliminary report in November, 1913, until May, 1914; the record of each case in detail will be published later.

Case 12.—Erma, aged 26 months. Diagnosis: Left spastic hemiplegia. Right supracortical hemorrhagic cyst. Operations: First, right subtemporal decompression; *second*, left subtemporal decompression.

History.—Admitted to Stern's Private Hospital, Sept. 29, 1913. Referred by Dr. George E. Brewer. Family history negative. Four older children well and strong. Personal History: Fifth child; nine months' baby; difficult labor requiring the use of instruments. Patient remained "quiet" for three days, then began to have convulsive twitchings of head to the right, lasting from three to five minutes; then quiet, possibly for the entire night. Since then, irritable "spells," crying for five hours at a time. Paralysis and flexor contractures of the entire left side of the body, including the face. No convulsions since. Poor appetite; constipated with much mucus in stools. Has never attempted to walk or talk; apparently oblivious to its surroundings. Past Treatment: Massage, electricity and general hygiene. No improvement; spasticity and flexor contractures becoming worse.

Examination.—Typical left spastic hemiplegia of face, arm and leg. Leg flexed and adducted; fingers clenched, especially thumb. Right eye diverges slightly. Poorly nourished child with definite mental impairment. Fundi: Dilated retinal veins and blurring of nasal halves of optic disks, especially the left disk, which is distinctly pale. Reflexes all increased on left side; left Babinski. Unable to talk a word. Has never walked or attempted to walk or crawl. Wassermann test negative.

First Operation.—Oct 8, 1913. Right subtemporal decompression. Usual incision and bone removed; no complications. Dura very thick—⅛-inch—and under marked tension. Cerebrospinal fluid spurted half an inch—a large amount escaping. The pia-arachnoid adhered to the dura, and when the dura was widely incised, a large bluish cyst an inch in thickness extended upward beyond the superior border of the decompression opening where the cortex appeared normal; this cyst extended downward to the base of the skull. It was bluish white and contained many new vessels. The cyst was punctured and a portion of its outer wall excised; much straw-colored fluid escaped so that the underlying cortex now became convex instead of concave; the cortex was pale but otherwise normal. Usual closure; no complications. There was some oozing of cerebrospinal fluid from the lower angle of incision for eight days (the longest in any case). On the second day after operation, it was noticed that the left hand was no longer clenched. All sutures removed on the seventh day after operation. Oct. 24, 1913, sixteen days after operation, the patient was discharged surgically.

Nov. 1, 1913, twenty-three days after operation, there was much improvement. Patient is now using left hand and tries to pick up things (right hand being tied). Is walking some (supported). Says "Ida" (the name of her nurse). Notices objects and her surroundings.

Dec. 1, 1913, fifty-three days after operation, there is great improvement. Uses left hand; can extend fingers. Walks well, but still needs a "finger-support." Says "Papa, Mama, Daddy" and a number of other words.

Dec. 20, 1913, seventy-three days after operation, the child is walking alone; drags left leg slightly. Decompression area is tense; fundi still reveal dilated retinal veins and some blurring of disk margins.

Jan. 15, 1914: Still improves, especially mentally; can now say several more words. Difficult to advise second operation on account of the great improvement, but it will relieve the pressure effects of the cyst still more.

Second Operation.—Jan. 24, 1914. Left subtemporal decompression. Usual incision and bone removed; no complications. Dura rather tense, but not so thickened as on right side. When the dura was incised, much cerebrospinal fluid escaped; an old hemorrhagic cyst formation extending down over upper one-fourth of the decompression opening was exposed; it was very shallow, however, and had been practically absorbed, little more than a thickened discoloration being present, so that there were no clinical signs of its presence. (Mighty interesting in that the paralysis clinically indicated a hemorrhage only on the right cortex—the hemorrhage over the left cortex being practically absorbed). Usual closure. All sutures were removed on the sixth day after operation; the child was discharged surgically Feb. 8, 1914, 12 days after operation. Treatment: massage and exercises as before operation.

Feb. 24, 1914: Walking, but left leg still drags. Mentally much brighter. Fundi: Optic disks pale but clear; retinal veins not enlarged.

May 4, 1914: Patient uses left leg very well now; impairment of left hand much less so that she uses it now. Mentally very bright. Has learned a number of German words from her nurse.

July 10, 1914: Improvement continues both physically and mentally.

Sept. 2, 1914: Marked improvement. Patient is walking with but a slight limp and uses the left hand fairly well. Speaks several small sentences now. Child is becoming well nourished; no digestive disturbances.

Remarks.—The rapid improvement in this case was simply amazing. It seems that children aged 2 years or less improve much more quickly than the older ones; this is what we should expect from the pathology of the condition—the cortex not being primarily damaged but merely its function impaired by the pressure of the overlying hemorrhage and resulting cyst formation. Naturally, the longer it remains, the greater the impairment.

Case 18.—Willie, aged 8 years. Diagnosis: Mild spastic diplegia. Supracortical hemorrhagic cyst. Operations: First, right subtemporal decompression; second, left subtemporal decompression.

History.—Admitted to the New York Orthopedic Hospital, Jan. 4, 1914. Referred by Dr. R. A. Hibbs. Family history negative. Two brothers and two sisters all well. Personal History: Third child; nine months' baby; very difficult labor requiring the use of instruments. Child "semiconscious" for one week. Scarlet fever, whooping-cough and diphtheria as a child. At 10 months of age, it was noticed that child was unable to stand and that it did not try to walk. When 2 years of age, child would drag the left foot, which had become stiff as well as the left hand; this stiffness has increased. Rather stupid and apathetic; memory is poor. No convulsions. Past Treatment: Massage and exercises; tenotomy of left Achilles tendon. No permanent improvement.

Examination.—Typical spastic diplegia, especially affecting the left side, with flexor contractures. Reflexes all increased, greater on left side; double Babinski (interesting observation in view of the lesion found at operation). Right leg was used rather awkwardly. Left internal strabismus. Fundi: Definite dilatation of retinal veins and distinct blurring along the nasal margins. Mentally impaired. Simon-Binet test: Mentally, a child of 5 years of age. Moving picture, Oct. 12, 1914.

First Operation.—Jan. 5, 1914. Right subtemporal decompression. Usual incision and removal of bone, which was very spongy, thick and vascular. Dura under high tension and very vascular; when it was incised a hemorrhagic cyst was exposed, at least 1 inch in thickness, pressing down on a pale anemic cortex. Much cerebrospinal fluid escaped under tension. Outer wall of cyst removed. Usual closure; no complications. Postoperative recovery negative. All sutures removed on the sixth day after operation. Spasticity of left arm and leg lessened and patient seemed brighter mentally. Decompression area was tense.

Second Operation.—Jan. 31, 1914. Left subtemporal decompression. Usual incision and removal of bone, which was not so vascular or spongy as on the right side. Dura under tension, and on being incised, the upper half of the exposed cortex was covered by a cystic formation half an inch in thickness; many adhesions. (Cause for Babinski on the right foot and also the awkwardness of the right foot. Other than this, no signs of the hemorrhage on this side clinically.) Usual closure; no complications. All sutures removed on the seventh day after operation.

Feb. 21, 1914: Condition at Discharge: Spasticity very much improved; mentally much brighter. Treatment: Massage and exercises as before the operation. March 6, 1914, Moving picture.

June 7, 1914: Marked improvement mentally and physically. Patient walks with only a slight limp; very little spasticity, though left Babinski still persists. Mentally, much brighter. July 27, 1914, moving picture.

Sept. 9, 1914: Improvement in every way. Was irritable formerly, but now has an even disposition—does not cry as he used to. Walks very much better—scarcely a limp. Better in school; has skipped one grade. Memory better. Reads better. Talks better—expressing himself better. Formerly left arm would hang dead, now he uses it at table and in carrying things. No headache. No convulsions. Left eye, formerly "crossed," now straight so that it is not noticeable.

Decompression openings are half closed with new bone formation; slight bulging. Left arm does not differ from the right—apparently normal. Knee jerks: Left greater than right; no Babinski can be elicited. No adductor spasm. Simon-Binet test of mentality: A child of 7 years of age.

Remarks.—The mental improvement has been a most gratifying one in these cases; besides making it possible for these children to take care of themselves better, the cooperation of the patient is obtained in carrying out the after-treatment of the exercises of muscle training, etc.—a very important factor in their treatment. The improvement of both convergent and divergent types of strabismus has been observed in a number of our cases.

Case 24.—Theodore, aged 12 years. Diagnosis: Right spastic hemiplegia. Left supracortical hemorrhagic cyst. Operations: First, left subtemporal decompression; second, right subtemporal decompression.

History.—Admitted to Polyclinic Hospital, Jan. 18, 1914. Referred by Dr. John A. Wyeth. Family History: Three sisters and two brothers alive and well; three died at birth, all labors being instrumental. Personal History: Youngest child (the ninth). Nine months' baby; instrumental delivery. Left eye was swollen and completely closed for several weeks after birth. Child cried from birth up to 8 months of age. Always slept with right eye open. Walked at the age of 3 years with stiffness of right leg; right arm also stiff. Talked at 12 months—has always been "smart." When 1 year old, patient had five convulsions in one day; unconscious; it was then noticed that the right side was paralyzed. When 3 years of age, patient had one short convulsion; never has had any since. Eyesight blurred and very poor.

Past Treatment: A patient of many hospitals—massage, exercises, tenotomies—with no permanent improvement.

Examination.—Well-developed white child. Typical right spastic hemiplegia with flexor contractures. Reflexes: Right increased; right Babinski. Flexor contractures of right leg at knee; 1 inch shortening of right leg. Fundi: retinal veins dilated; entire nasal halves of optic disks obscured. Disks pale with shallow physiologic cups due to new tissue formation; a mild secondary optic atrophy. Moving picture, Oct. 12, 1913. Simon-Binet test, Jan. 18, 1914: Mentally a child of 9 years of age.

First Operation.—Jan. 19, 1914. Left subtemporal decompression. Usual incision; much bleeding in rongeuring bone, apparently due to sinuses in bone, and to adhesions of dura to bone. Dura tense, but not much cerebrospinal fluid escaped. Very dark-reddish hemorrhagic clot on cortex, ½ inch in thickness, extending beyond the bony margins of decompression. Large cortical vessels. Usual closure; no complications. All sutures removed on the seventh day after operation.

Second Operation.—Jan. 29, 1914, ten days after first operation. Right subtemporal decompression. Usual incision; moderate bleeding in bone. Dura under fair pressure. Cortical vessels enlarged; pia-arachnoid "sweated." At upper area of cortex, definite signs of old hemorrhage—even on this side homolateral with paralysis—practically all absorbed and thus showing no clinical signs of its presence; numerous adhesions were severed between arachnoid and dura. Usual closure. All sutures removed on the sixth day after operation.

Feb. 22, 1914: Condition at Discharge: Arm and leg straighter. Can extend right wrist and right fingers. Walks with a limp due to shortening of right leg. Treatment: Massage and exercise, as before operations. March 6, 1914, moving picture.

April 18, 1914: Much improvement, especially in the arm; easily bends right hand at the wrist.

June 7, 1914: Improvement continues. July 27, 1914, moving picture.

Sept. 9, 1914: Marked improvement. "Uses arm much better; can grasp things and use them, which was impossible before the operation. Patient can see much better than before. Is not irritable and nervous." Mentally "very bright." No convulsions. A much more intelligent looking child.

Moderate flexor contracture of right leg with apparent anatomic shortening of the tendon; a tenotomy may be necessary; walks better. Patient can now extend the right wrist; uses the fingers much better. Decompression areas tense; partially covered with a layer of bone which bulges slightly. Reflexes increased on the right side; no Babinski. Fundi:

Retinal veins normal; some new tissue formation about the disk margins; disks rather pale. Simon-Binet test: Mentality is that of a child of 11 years of age.

Remarks.—Although this patient is 12 years of age, yet his improvement has been very definite. Naturally, the younger the children, the greater the improvement to be expected from an early operation. The oldest case has been of a man aged 21; his improvement has been less marked than the younger patients having lesions of similar extent and pressure.

Case 30.—Martha, aged 10 years. Diagnosis: Spastic diplegia of extreme type. Supracortical hemorrhagic cyst. Operation: Right subtemporal decompression.

History.—Admitted to Polyclinic Hospital, March 24, 1914. Referred by Dr. Royal Whitman. Family history negative. Three younger children well and strong. Personal History: First child; nine months' baby; difficult labor requiring the use of instruments. Entire head contused; laceration of scalp behind left ear extending forward to top of head. "Doctor thought child would die." Blue for one week; could not swallow; comatose. On the third day, general convulsions began, lasting two hours until child was thought "dead." Gradual improvement until 2 years of age. From 2 to 7 years of age, patient had "spasms"—became "blue around mouth," and twitching of left side of body until entire body became stiff and rigid—more on right side; no loss of consciousness. These spells lasted two or three minutes and occurred only when child was irritated or frightened. Patient has never walked. No diseases of childhood. Constipated during past three years. Past Treatment: All kinds of treatment; braces at 2 years of age for one year. Osteopathy for one year; electricity for one year. Massage, exercises and gymnastics for past five years; no improvement.

Examination.—Typical spastic diplegia of extreme degree with flexor contractures of arms and legs; left side worse; extreme adductor spasm. Poorly developed. Speech is very difficult to understand. Respiration is noisy and difficult because of a laryngeal spasm. Right pupil larger than left. Fundi: Dilated retinal veins; marked blurring of nasal halves of optic disks. Tongue large and protrudes; continuous dribbling and drooling of saliva. Reflexes all increased, left possibly more; double Babinski. Mentality much impaired. Simon-Binet test: A child of 6 years mentally. Moving picture, March 6, 1914.

Operation.—March 26, 1914. Right subtemporal decompression. Very difficult case for anesthesia; impossible to pass tube into larynx because of spasm. Usual incision; bone vascular and spongy. Dura was much thickened and very tense so that cerebrospinal fluid spurted out under high pressure. A hemorrhagic supracortical cyst was exposed extending beyond the decompression opening; it tended to protrude on account of the very high pressure. While a small portion of the outer wall of the cyst was being incised the child "went bad"—respirations became labored and spasmodic, and brain pulsated feebly about 30 or 40 per minute. Heated oxygen; artificial respiration; hot coffee by rectum; improvement. Usual closure in haste. While applying dressings and bandage, child again ceased to breathe and it seemed that child was dead; edema of lungs apparently. After ten minutes of artificial respiration, rhythmic tongue traction, oxygen, atropin and camphor in oil, the child improved; patient was "blue"—no corneal reflex—pupils widely dilated and no pulse for half an hour, but child gradually rallied. Three doses atropin, 1/100 grain, 5 minims of camphor in oil and 3 ounces of hot black coffee by rectum *after child reached the ward.* Six hours later, child was in good condition. Conscious. Temperature, 100. Pulse, 130. Respirations, 20. After the operation respiration slightly improved. All sutures removed on sixth day after operation.

April 5, 1914: Condition at Discharge: Ten days after operation, respiration quiet now and not difficult. Spasticity much lessened; patient can use the hands much better. Treatment: Massage and exercises as before the operation.

May 10, 1914: Patient walking with finger-support but with difficulty; less spastic. Speech much improved.

July 27, 1914, moving picture.

Sept. 14, 1914: Much brighter mentally. Legs and arms much more limber. Walks alone 20 to 25 feet. No convulsions. Less irritable and restless. Less spasms of legs and arms. Can go up and down stairs alone now, which she could not attempt before. Talking improved but the breathing is about the same. Has not had massage for past two months but has improved right along.

Marked lessening of the spasticity and contractures; left Achilles tendon still shortened—undoubtedly an anatomic shortening of tendon itself owing to its long contracture; a tendon lengthening is advisable. Reflexes are still increased; double Babinski not so definite. Fundi: Retinal veins still slightly dilated and some edema still remains along the nasal margins of the optic disks. Marked improvement mentally. Simon-Binet test shows a child of 7 years of age.

Remarks.—A second decompression on the other side of the head is advisable in this case to lessen further intracranial pressure. The operation has been delayed in the hope that the respiration will still improve and thus lessen the risk of the operation.

Case 36.—Sidney, aged 32 months. Diagnosis: Spastic diplegia. Supracortical cystic formation. Operation: Right subtemporal decompression.

History.—Admitted to Polyclinic Hospital, May 3, 1914. Family History negative. One sister, aged 5 months, alive and well. Personal History: First child; nine months' baby; difficult labor—"three days and three nights"; non-instrumental. Child has been "weak" from birth; no convulsions. Child did not lift its head until 16 months of age. Has never talked or walked. Cries constantly and moves arms and legs continuously when awake; "never quiet." Does not understand; does not notice. Very "rigid" at times. Little strength in legs; more strength in arms. No convulsions. Fontanels not closed at 26 months. Child becoming "stiffer" and more "foolish." Past Treatment: Massage, electricity, exercises, etc., at several hospitals; no improvement.

Examination.—A typical case of spastic diplegia. Child lies in bed "stiff and straight"—eyes turned up to the ceiling; frequent jerking of arms and legs. Cries constantly. Reflexes: Knee jerks increased; double Babinski present. Fundi: Dilated retinal veins; nasal halves of optic disks obscured. Mentally: Apparently an imbecile. Moving picture, March 6, 1914.

Operation.—May 7, 1914. Right subtemporal decompression. Usual incision and bone removed; no complications. Characteristic "cracks" in bone which oozed freely. Dura moderately tense; not thickened, although whitish and rather pale. Cortex bulged through dural opening and much cerebrospinal fluid escaped; edematous pia-arachnoid ½ inch in thickness, forming a sort of "blanket" over cortex. Cortex pulsating normally at end of operation. Usual closure; no complications.

Recovery uneventful. All sutures removed on the sixth day after operation. Child much quieter.

May 14, 1914: Condition at Discharge: Seven days after operation, child cries only at times. Legs do not seem so stiff. Reflexes still increased; double Babinski present. Fundi: Retinal veins less dilated; only the nasal margins of the optic disks are blurred. Treatment: Daily massage and exercises as before the operation.

July 10, 1914: Marked improvement, both physically and mentally. Child is now trying to walk; seems to notice his surroundings.

July 27, 1914, moving picture.

Sept. 15, 1914: Improved in every way. Now walks alone. Says a number of words. No convulsions. Mentally very much better; now plays with toys; cries very infrequently.

Decompression area bulging slightly; tense. Reflexes: Knee jerks increased; no Babinski now present. No adductor spasm. Fundi: Retinal veins less dilated; no edema of the optic disks but some new tissue formation along its margins.

Remarks.—The improvement in this case is most apparent. For a child of 32 months of age which has never talked or walked, and then four months after the operation to be walking alone and even talking a number of words, is truly remarkable. As there are still signs of increased intracranial pressure as shown by the tense decompression area and by the ophthalmoscopic examination, a bilateral decompression is advisable. The absence of a definite walled-off cyst at the site of the decompression opening and merely an edematous pia-arachnoid of varying thickness producing, with its many adhesions, a cystic formation or blanket overlying the cortex has been observed in a number of our cases; the relief of the general intracranial pressure, however, apparently suffices.

Case 42.—Mollie, aged 7 years. Diagnosis: Left spastic hemiplegia. Supracortical cystic formation. Operation: Right subtemporal decompression.

History.—Admitted to Polyclinic Hospital, May 10, 1914. Referred by Dr. John A. Wyeth. Family history negative. Two younger children well and strong. Personal History: First child; nine months' baby; breech delivery; very difficult labor but no instruments used. Baby "dead" for half an hour; artificial respiration. Nursed with difficulty; cried continuously. When 8 months old, it was noticed that child did not use its left arm and left leg, which were "stiff." At 3 years of age, child began to walk but only a few steps and then would fall; would trip constantly. Cannot run even now, trips frequently; left leg drags. No convulsions. Child feeds itself, but is unable to use left hand. Patient was not allowed in public schools as authorities said it was "crippled"; the School for Crippled Children refused to admit it because patient was "nervous." Past Treatment: Massage, exercises and electricity during past four years; no improvement. Moving picture, March 6, 1914.

Examination.—Typical left spastic hemiplegia with flexor contractures. Reflexes increased on left side; left Babinski. Fundi: Dilated retinal veins; distinct haziness of nasal margins of optic disks. Mentality impaired; speech fair. Simon-Binet test: Mentally a child of 4 years of age.

Operation.—May 11, 1914. Right subtemporal decompression. Usual incision and bone removed; no complications. Dura tense but not vascular or apparently thickened; no adhesions. Cerebrospinal fluid spurted 2 inches and much fluid escaped. Cortex edematous, with many adhesions, producing a cystic formation half an inch in thickness; large cortical veins extended downward vertically over temporosphenoidal lobe. Cortex tended to bulge under such great tension that bony opening was enlarged upward 1 inch and dura likewise opened; cortex protruded so much that a ventricle puncture was attempted but not successful. Usual closure; no complications. All sutures removed on the seventh day after operation.

May 24, 1914: Condition at Discharge, thirteen days after operation: spasticity has lessened. Brighter mentally. Treatment: Massage and exercises as before operation.

July 6, 1914: Marked improvement. Patient walks with but a slight limp, the heel touching the floor. Uses the left hand well. Mentality much improved; speech good. July 27, 1914, moving picture.

Sept. 14, 1914: Improvement continues both physically and mentally. Walks much better; does not fall now as formerly; very slight limp. Mentally brighter; more observant. Simon-Binet Test: A child of 5 years of age. Uses left arm well. No convulsions. "Another child," mother says.

Decompression opening not closed; bulging slightly. Knee jerks: left greater than right; no Babinski. No adductor spasm; no shortening of the Achilles tendon. Fundi: Negative; optic disks have assumed distinct margins; normal pinkish color.

Remarks.—Here again, the improvement has been very rapid. Within four months, the child is walking with the heel touching the floor, the left arm is being used and the mentality has so changed that a Simon-Binet test records an improvement of one year. In this case, the unilateral decompression has apparently relieved the intracranial pressure to such an extent that a bilateral decompression will not be necessary.

CONCLUSIONS

Naturally, we do not believe that all cases of spastic paralysis should have a cranial decompression; in some mild cases tendon lengthenings alone are sufficient, and this is especially true in the absence of mental impairment. But those selected cases of spastic paralysis, particularly of the hemiplegic and paraplegic types, which show signs of increased intracranial pressure by an ophthalmoscopic examination, are the cases that can be very much improved by such a procedure. The cases of agenesis and maldevelopment of the cortex of course *cannot* and *do not* show signs of increased intracranial pressure, and are therefore easily excluded by an ophthalmoscopic examination; besides, the cases of lack of development of the cortex and pyramidal tracts are frequently premature babies, being born the seventh or eighth month, so that a careful history is very important.

We are having moving pictures taken of the patients before operation, and at regular intervals after the operation, in order that the physical impairment of posture and gait may be accurately recorded.

Likewise, a Simon-Binet test of the mentality is being recorded before operation and at regular intervals after operation; the mental improvement in our cases has been very impressive.

A lumbar puncture is being made before operation in order to estimate the intraspinal pressure as a means of corroborating the signs of increased intracranial pressure as shown by an ophthalmoscopic examination.

A Wassermann test of both the blood and cerebrospinal fluid is made in all suspicious cases.

We wish to repeat that this paper is merely a report of work being carried on to improve the condition of selected cases only of spastic paralysis. It is by no means a cure, and possibly the improvement in our selected cases is only a temporary one—we cannot tell. But from the pathology of these selected cases in which operation has been performed and the general continuous improvement which has resulted and is still progressing, we feel justified in making a report of the work in the hope that it may throw some light on the treatment of this very pitiful condition.

OCCURRENCE OF RETURN CASES OF SCARLET FEVER AND DIPHTHERIA

EXPERIENCE OF THE CHICAGO DEPARTMENT OF HEALTH SINCE THE INTRODUCTION OF A SYSTEM OF CLASSIFIED QUARANTINE

G. B. YOUNG, M.D.
Commissioner of Health
CHICAGO

In the fall of 1913 the department for the first time published a complete handbook for the bureau of medical inspection, and in that connection made quite extensive changes in the methods hitherto employed in connection with quarantine.

Owing to unavoidable delays in connection with the budget, etc., the changes were not put fully into effect until March 15, 1914.

Our experience with classified quarantine from March 15 to November 1 has been quite instructive. As a preliminary explanation let me give a summary of the methods of quarantine now enforced by the department.

> The result sought is to avoid the imposition of all restraint upon the family of the patient when consistent with effective isolation of the patient and "carriers," the object being, in brief, to quarantine the public out and to quarantine the patient in. To this end the following rules will be enforced:

lated individual is exposed to infection, that is, if live bacteria find their way into his body, they are readily destroyed and will not multiply. Naturally, if the army of invaders is excessive, or the defense too slight, infection will arise in spite of the prophylactic measure. Fortunately, such instances are exceptional. The protection is therefore explained on a bacteriolytic, and to a less degree, on a bacteriotropic basis. From clinical experiences it has been shown that immunity persists even after these immune bodies cannot be demonstrated any longer (Cole[13]).

The *prophylaxis attained by the injection of Besredka's living sensitized typhoid vaccine*, cannot, if sensitization is complete, be explained on identically the same principles, for, as soon as the sensitized bacteria enter the normal system, they combine with the complement of the blood and are broken up. The agglutinating and bacteriolytic antibodies and the complement fixation bodies are therefore either not produced at all or only in very small quantities; consequently, the reliance for protection must be placed on the bacteriotropic or phagocytic activity, stimulated by the liberated central substance of the broken-up bacteria, the so-called endotoxin. The fact that the bacteria are alive does not necessarily mean that they are harmful, because, as was mentioned above, they are destroyed by the organism immediately after injection. The relative excellence of the sensitized method over the original Wright method has not been definitely established, but the fact that Besredka and Metchnikoff[14] strongly advocate it, is an important point in its consideration.

It may be in place here to consider a problem which has suggested itself to me, but which I have thus far been unable to carry out. If the injection of ordinary vaccine causes mainly a bacteriolytic reaction, and the administration of sensitized vaccine mainly a bacteriotropic response, would it not be advisable in prophylactic immunization to inoculate individuals with both sensitized and non-sensitized vaccines? In this way a combined form of immunity would be attained. As experimental basis for this suggestion I have shown that if the serum from rabbits immunized with non-sensitized bacteria is mixed in equal quantity with the serum from rabbits immunized with sensitized bacteria, this mixed serum was more curative for mice infected with typhoid bacteria than equal quantities of either serum alone. Naturally it will be necessary to establish the best method for such mixed immunization; whether the two vaccines should be administered separately and at different times or whether they should be given at the same time, as would be accomplished also by an incompletely sensitized vaccine.

In the therapy of typhoid fever the use of the ordinary non-sensitized vaccines has not met with as favorable results as for purposes of prophylaxis. Up to the present time several thousand cases have been treated (Watters,[15] Horner[16]), but the beneficial effects in the majority of instances are not sufficiently marked to warrant the employment of the vaccines as a routine procedure. Occasionally a striking crisis in the course of the disease is observed, but just as frequently an increase in the severity of the symptoms develops. Reports of instances in which the effects have been distinctly harmful (or even fatal) must also be considered.

When the biologic basis for the possible therapeutic value of vaccines in typhoid fever is asked, the answer is much more difficult and hypothetical than in the question of prophylaxis. Several factors are to be kept in mind. First, typhoid fever is a self-limited disease, running a typical clinical course and probably associated with definite phases of immunity to account for its characteristic picture and self-limitation. Second, the number of bacteria existing in a typhoid patient is very great; they circulate everywhere and stimulate the tissue cells continually, resulting in the formation of agglutinins, bacteriolysins, bacteriotropins, complement fixatives, etc.; these antibodies are apparently produced very slowly and are either not of sufficient number or of a nature suitable to overcome the infection quickly. It usually takes four weeks or more to ultimately accomplish this. The reason for this prolonged period may possibly be ascribed to the structure of the typhoid bacillus. As was said above, this bacterium belongs to a class of micro-organisms whose central substance, the so-called endotoxin, is liberated only after the bacillus has been broken up. This central substance also stimulates the formation of antibodies (antiendotoxins for purposes of designation) which are bacteriotropic in action and probably important elements in the curative process of typhoid fever.

Were it permissible to divide the phases of typhoid fever from an immunological point of view, as is usually done from the clinical aspect, one would assume that the first stage consists of the multiplication of the invaded typhoid bacilli. Then as a defensive reaction, the tissue cells stimulate the formation of antibodies (bacteriolysins, agglutinins and but few bacteriotropins). The next phase sees the numerous bacteriolysins attack the bacteria, sensitize them and with the aid of the complement the micro-organisms are broken up and their endotoxins liberated. The latter thus freed further stimulate the tissue cells with the result that other protective bodies (antiendotoxins) are produced in sufficient numbers to prevent any harmful effects and finally to help overcome the infection. Naturally, these very schematic stages are not sharply limited and do not fall within definite periods of time. Sluggishness or absence of the proper reaction on the part of the tissue cells at any stage is followed by a protraction of the disease or even death death by infection if the bacteria multiply and are no broken up due to insufficient response by the bacteriolysins, or death by intoxication if marked bacteriolysis has occurred, or has occurred so quickly that the liberated endotoxins are not in turn neutralized by sufficient antiendotoxins.

Keeping this explanation in mind, one can readily observe that the injection of *ordinary vaccines* in typhoid fever aims at nothing more than what th body is already doing with all its power, namely, th production of antibodies for the breaking up of th bacteria, the liberation of their endotoxins and th ultimate manufacture of antiendotoxins. There ma be cases in which the body cells are inactive and ar stimulated to activity and production of antibodie only after the inoculation of the vaccine. Here th ordinary bacterins are of undoubted aid.

As a general rule, however, it is best to relieve th sick body as much as possible of any active reactio During an infection the tissue cells are less responsiv than during health, especially if the disease be a severe and prolonged one. That is why an efficient serum (passive immunity) would be the ideal form of specific therapy. Sensitized vaccines possibly hold a position between serum therapy and ordinary bacterin treatment. In the first place, they might save the system from the strain of producing the primary antibodies for the destruction of the bacteria, and second, this provision might hasten the stage of liberation of the endotoxins and the stimulation of the antiendotoxins, an important step in the recovery from the disease.

[16] Horner: Boston Med. and Surg. Jour., June 25, 1914, No. 26.

With these ideas in view, I undertook the study of the effect of sensitized typhoid bacteria as a form of active immunity in the therapy of typhoid fever.

Preparation of Sensitized Vaccine.—Three strains of typhoid bacilli that had been isolated from the blood of patients at the hospital were used for preparing the vaccine. Agar cultures of each strain were grown for twenty hours; the profuse growths were washed off with sterile normal saline solution, about 2.5 c.c. for each agar slant. This mixed suspension was sealed in a sterile tube, which was then submerged in water at 60 C. for one hour. This generally sufficed to kill the bacteria. The sterility was tested in the usual manner. The exact total quantity of the emulsion was noted. The strength of the vaccine was standardized at this point of the preparation, that is, before rather than after the immune serum had been added, for I found it more difficult for purposes of standardization to obtain an even distribution of the bacteria (on the counting slide) after the bacteria had been sensitized (agglutinated). Wright's[17] classic method of standardization was employed.

For sensitization I used the immune serum obtained from the same three (then convalescent) patients from whom the bacteria used for preparing the vaccine were isolated. (Their serums had a strong agglutination and complement fixation titer.) In this way it was certain that the antibodies would certainly fit the bacteria, as they both came from the same source; in other words, complete sensitization was attempted. The same object can be accomplished by using the serum from an animal (goat or horse) that had been immunized with the strains of bacteria from which also the vaccine is to be made. The serum was inactivated at 56 C. for one-half hour before being added to the bacterial emulsion. Two c.c. of serum for each 1 c.c. of bacterial emulsion were used. The mixture under cover of toluol was left for twenty-four hours at incubator temperature not exceeding 37 C., and was frequently shaken. At the end of this time the agglutinated bacteria were gently stirred and then centrifugalized for five minutes. The supernatant fluid was pipetted off, more sterile saline solution added, the emulsion again shaken and again centrifugalized. Once more the supernatant fluid was removed and finally the same quantity of saline solution added as was employed before for washing off the bacterial growths from the agar slants. In this way the standardization estimated previously from a sample of unsensitized vaccine held good for the sensitized preparation. The concentrated emulsion after being stirred and shaken thoroughly to make an equal, fine suspension, was finally diluted with one-half per cent. phenol solution so that each cubic centimeter contained 2,500 million sensitized typhoid bacteria.

Dosage.—The dosage of typhoid vaccines for therapeutic purposes is far from definitely established. As a general rule, however, it may be said that bacteria can be given in much larger doses when sensitized than if non-sensitized. The author found that guinea-pigs inoculated intraperitoneally with double the lethal dose of non-sensitized dead typhoid bacilli would die within ten hours, while the same quantity of sensitized bacteria was well tolerated. Similar results were recently obtained by Cecil.[18] No fixed therapeutic dose of either non-sensitized or sensitized typhoid vaccine has been adopted. In the present series of cases, 500 millions of sensitized bacteria were employed as the standard dose, both for the first and subsequent inoculations. Naturally, one had to be guided by (a) the severity of the illness, (b) the age of the patient and (c) the reaction from the inoculation. Thus, very sick individuals were given only 250 million bacteria. The dosage in children should be regulated according to the weight, 150 pounds being taken as the weight corresponding to 500 million bacteria.

Frequency of Inoculations.—Usually two to four inoculations were necessary until the temperature became normal; as a rule, one inoculation (250 millions) was administered during convalescence with the aim of preventing a relapse. The interval between inoculations was five to seven days, or even longer. It must be remembered that with non-sensitized bacteria, the larger the dose of vaccine, the longer must the interval between the inoculations be. This rule does not apply as strictly to sensitized vaccine, nevertheless 500 million bacteria is a large dose, and more frequent repetition was not deemed advisable. Future experience should guide us in this direction.

Reactions from Inoculation.—Both local and systemic reactions were exceedingly slight. Sensitization in general tends to diminish local reactions.[19] This has been demonstrated for the tubercle bacillus by Fritz Meyer, who uses a sensitized bacilli emulsion (S. B. E.), and also by Citron for the bacilli of mouse typhoid and swine pest, in which instances marked infiltration following the inoculations was avoided by sensitization of the micro-organisms. Besredka noted only very slight local reactions following the prophylactic inoculation of sensitized typhoid bacilli. In my cases a small, red, infiltrated area about the size of a quarter usually appeared around the points of injection within twenty-four hours after the inoculation and persisted for one to two days. In some cases the local reactions were larger, about 3 inches in diameter, but never were they as severe as is observed after the prophylactic administration of the ordinary vaccine. As for systemic reactions, no definite manifestations of a negative phase, that is, increase in the severity of clinical symptoms, were evident.

Results.—In a consecutive series, seventeen cases of typhoid fever were treated with the sensitized vaccine as soon as the diagnosis was definitely established. In the majority of instances this was the second week of the disease. The usual other indications in the treatment of typhoid fever, such as sponge baths or tub baths, rectal irrigations, etc., were not neglected. Of this series, only one patient died. The latter had developed a large, deep, spreading abscess of the thigh and scrotum requiring operation. Four patients had relapses. One patient had several very severe intestinal hemorrhages, the first following about thirty-six hours after the first vaccine inoculation. The subsequent vaccine inoculations, however, were well borne, so that it would be unfair to assume the principle of *"post hoc ergo propter hoc."* With this possible exception, no manifestations of a negative phase were observed and no other complications noted. Only in two out of the seventeen cases did the temperatures subside acutely, reaching normal forty-eight to seventy-two hours after the vaccine inoculation; in the great majority, the temperature did not go any higher, but began to show remissions, coming down to normal gradually. It would be futile to tabulate the results of the treatment in reference to any other individual symptoms, as such detailed differences should only be based on a very much greater material. On the whole, the impression was gained that the inoculated patients ran what might be termed mild courses with comparatively few complications. I am fully aware how guarded one should be about the results of any form of specific therapy in a disease like typhoid fever. Normally, all types of illness may exist. Clinicians have frequently observed that during some typhoid seasons the patients will present mild infections without any special treatment whatever. One could attribute beneficial effects to vaccine treatment with certainty only if rapid improvement or crisis in the course of the disease would set in soon after the inoculation. Such acute changes can be expected more often by treatment with a specific *serum* than with a *vaccine*, for by the former (passive immunization) antibodies are injected ready for neutralizing the poison; while in the latter instance, the antibodies must first be manufactured by the tissue cells. This ever-existing factor in vaccine therapy makes it absolutely necessary to start the treatment in typhoid fever as early in the course of the disease as possible, at a time when the reactive power of the individual is still responsive and unimpaired by the infection.

[18] Cecil: Paper read before the New York Serological Society, Oct. 9, 1914.

[19] It is interesting to note in this connection the recent finding of Jobling that addition of homologous serum to bacteria lessens the occurrence of anaphylaxis, an observation already made by me in 1910.

SUMMARY

In summary it may be said:

1. The treatment of typhoid fever by sensitized typhoid bacteria offers a more rational therapy from an immunologic point of view than by the ordinary non-sensitized vaccine.

2. The repeated inoculation of large doses of sensitized vaccine even in very sick patients, was not attended by any harmful effects or a distinct negative phase; the general course of the disease seemed milder and the complications less; the occurrence of a crisis in the infection took place in a small percentage of cases, the improvement usually being gradual. Perhaps more striking results will be attained by a larger number of smaller doses more often repeated.[20]

---

[20] The patients referred to were treated in 1911, but publication was deferred until a series could be treated by smaller and more frequently repeated doses. This was not, however, possible.

Geographic Distribution of Diseases.—In certain diseases, of which the cause or means of spread is unknown, morbidity reports show their geographic distribution and varying prevalence and the conditions under which cases occur. This information has great potential value in attempts to ascertain their causes and means of spread.—John W. Trask, Supplement No. 12, Public Health Reports, April 3, 1914.

GUIDES IN VACCINE THERAPY

HORACE GREELEY, M.D.
BROOKLYN

Since the opsonic index variation method proved to be practically unsuited as a guide in the general application of vaccine therapy, most users of vaccines have not attempted to discover individual indications as to dosage, but have established a general routine initial dose, to be increased by a certain amount at a certain interval, and have persistently carried out their program as long as the treatment was adhered to. For this reason one object of the present article is to gather and describe such symptoms and manifestations as there is reason to believe give clue to that which takes place in the body following vaccine administration, and which may reliably guide to individual case variation of both dose and interval.

In general there has been a tendency to overdo and abuse this form of treatment which, in many instances, when properly handled, proves of immense value; and through frequent bungling and total disregard of the principles involved there is great danger that it will be brought into disrepute with the profession at large. To aid in counteracting this I am offering the record of my experience and interpretation of results obtained by other physicians for whom I have prepared vaccines, and I feel certain that the facts noted will be found so much in line with observations which all who have used these agents must have made—although, perhaps, they may not have paused to analyze them — that their truth and value will be readily understood, and may help in guiding aright others with less experience in this line.

It has been truly said that it is as wrong as it is useless to attempt to convince through argument, but that one's duty is to offer evidence and let the unprejudiced convince themselves. This principle applies very strongly to those who, despite what one would think are insuperable objections, make use of stock vaccines. No one for a moment would imagine that an attack of measles, although known to confer great specific immunity, could aid in preventing or in overcoming a typhoid infection; and yet if we employ a stock vaccine, in at least ninety-nine instances out of a hundred we follow a similar procedure. Let any one who has fixed on a variety of stock vaccine for use in a given case look up the possible bacteriology of the disease process which he proposes to treat, and then calculate his chances of striking, even by name, the guilty organism, let alone the particular strain active — which may even be one as yet unrecognized by science — the last consideration a factor which so often confuses exact bacteriologic diagnosis and serum therapy, but which is entirely avoided in vaccine treatment when autogenous products are used.

The fact that a given stock is composed of a number of strains cannot reassure, since at least all but one would be given needlessly and could not but burden, if they did not seriously injure, the patient's reactive mechanism — as in the case of the rabbit dosed with colon bacilli in order to render him susceptible to organisms to which he is normally immune, an effect which could be produced by the use of any stock vaccine on the market. Besides, the polyvalence of most vaccines relies solely on difference in source and not on actual known biologic differences of their constituent micro-organisms, so that many are polyvalent in name only. Furthermore, not entirely understanding what makes a difference in strain, or even the number of such that may exist, or, in fact, that they may not be as illimitable as the variations in the conditions affecting their cultivation, we can easily imagine the great odds that possibly exist against hitting the nail on the head with a dose of stock vaccine even in a disease in which the infecting organism has been named. A striking example, to be recalled in this connection, of the necessity for recognizing and allowing for differences is supplied by Flexner's experience with cerebrospinal meningitis, in which one antimeningococcus serum was found entirely ineffective when used to combat an infection with what was evidently a meningococcus of different nature, although morphologically and culturally identical, and which also, in turn, could be employed in the production of a serum specific for itself but totally without affinity for the other.

Although stock vaccines are thought to be cheaper and more readily obtainable than autogenous, such is not the case, for should it be desired to administer vaccine treatment it is rarely proposed to use less than ten separate injections per patient, and since such doses in the stock vaccines on the market cost 50 cents apiece (in separate syringes, the most popular form, and which, on the average, contain one dose each), there will be a total expense of at least $5, and then we are not considering the fact that any reasonable system of resistance-raising would require that two syringes (necessitating a double puncture, usually) often be used to make up most of the doses called for by the scale determined on, since no series of containers to be had is graduated in such increasing strengths as may advantageously be used, one after the other—even supposing that variation according to symptoms was not attempted.

The cheapest form in which stock vaccines in unit doses may be bought ordinarily is in ampule sets of four or of six, costing 25 cents per dose; but all vials of each set contain the same dose, which is either 100, 250 or 500 million bacteria, according to the set purchased, so that it is difficult to see what use could be made of a single set, while if all three sets were bought the cost would be at least $3, and the nuisance and waste of using part of an ampule at one time, and the whole of one and a fraction of another the next, so great as to make this form of no practical use. Besides, even by using all three sets, one ampule after the other, only three increases in dosage could be effected. Another form in which stock vaccines may be had, though usually only on order to the druggist, is a vial of 10 c.c., most frequently standardized at 100 million organisms per cubic centimeter and costing $3.50. Even with this a ten-dose graduated course, beginning with 1 c.c. and increased 10 per cent. each time, could not be obtained from one bottle of such a size.

These facts are recounted for the benefit of those who think that a stock vaccine is cheaper than an autogenous, the usual cost of which is $5, and which is always supplied in a quantity much greater than would ever be required, which keeps at room temperature for many months and whose dosage is easily measured with the ordinary hypodermic syringe. Such vaccines can also, of course, be put up in a series of single-dose ampules, with doses measured to order, but this is undesirable, since, as I shall show later, the size of any dose after the first should be regulated by a consideration of the effects of the preceding one.

The time required to secure stock vaccine is certainly not less in the long run than that lost in waiting forty-eight hours for the autogenous preparation, since a patient would hardly be kept waiting while the druggist was sent or telephoned to for a supply; and since this must be renewed later, sometimes through order on the wholesaler, the nuisance and time lost is often greater.

Another factor which is not unworthy of consideration is that the public each year is becoming more and more exacting as to the care and attention the medical man gives to his case, and a patient's first thought on being treated with a vaccine is of its modus operandi. When this has been explained the question next arises as to what determined the choice of organism; and when the patient learns, as he surely will soon or late, that this was mere guesswork when exactitude was possible, dissatisfaction and distrust arise. Further, since even with an autogenous vaccine of the trouble-making bacteria, improvement and cure is sometimes difficult to effect and long deferred, the physician himself, knowing full well the chances of missing the mark with a stock vaccine, is apt soon to lose confidence, switch about to another variety or discard the method entirely in disgust. On the contrary, everything connected with the procedure of bacteriologic diagnosis and the making of a special vaccine from the patient's own germ inspires confidence in both patient and physician, and even if the treatment should not prove so effective as hoped (which may rarely happen in suitable and well-managed cases), both would feel satisfied with the scientific accuracy of the effort.

I have sometimes known physicians to have a bacteriologic diagnosis made in a particular case and then to purchase and use a stock vaccine. Although such diagnoses are of variable difficulty and cost, there can hardly be an instance in which the additional preparation of an autogenous vaccine would involve appreciably more labor or expense. The really economical plan would be to ask that a vaccine be prepared, and this would usually entail a determination of the infecting organism.

A person's powers over a particular infection, when his system has not previously dealt with it, must depend on the applicability of enzymes formed by his cells for other purposes — such as the reduction of normal tissue waste — to the digestion of the new protein presented in the form of the attacking organisms. When sufficient bacterial substance is distributed within the body to reach and react with all the main sources of such enzymes (the cells of the lymphatic system), the maximum immunizing processes are operating, and we should certainly keep hands off, so far, at least, as vaccine therapy is concerned. Such conditions always obtain in acute infections, in which the infecting agent exists in the blood or is so disseminated in the other tissues as to reach most of the body's reactive cells (those prominent in inflammation, both of lymphatic and connective tissue origin), or, at any rate, the greatest number of them whose simultaneous activity is compatible with safety to life. In association with such infections continued fever seems to be a positive indication of this full-capacity working, and a daily remittant undoubtedly means the same. An equivalent condition sometimes occurs without noticeable temperature elevation, especially in pulmonary tuberculosis, in which, as a result of a stimulus to the antibodies from an injection of vaccine, such a large amount of *partially* digested, and therefore especially poisonous — as with peptone — bacterial substance is freed from the disease focus as to injure the tissues generally and thus to depress the reactive mechanism, lowering, at least temporarily, the general resistance to further development of the infection. Such a condition usually exists when extensive areas are involved in a chronic process, and advanced pulmonary tuberculosis may be regarded as uniformly presenting it.

Apart from the foregoing, every troublesome or dangerous infection not amenable to specific treatment, either medical or surgical, should be considered for the *immunity-raising methods of vaccine therapy;* provided, of course, that we know and can artificially cultivate the infecting agent. As vaccine treatment relies entirely on the vigor of the elemental tissues for the response which can alone make it effective, nothing that can be done to improve the general health can be neglected during its administration; and, above all, particular care must be exercised not to overdose, lest general poisoning of the system, as mentioned above in connection with advanced lung tuberculosis, or from the direct effect of the products of a partial digestion of the vaccine, might result.

It is to be remembered that when we inject a vaccine our purpose is similar to that of the wise mother who gradually increases the amount of starch and other solid food administered to her weaning baby in order gradually to develop powers of digestion never exercised before, but whose special enzymes, as with those elaborated parenterally in the fight against invading parasites, must have existed in some degree, as previously stated, even if only in the inactive state of the "ogens" — pepsinogen, etc. Also, we must not forget that if we give an overdose we are apt to injure the reactive mechanism, destroy or cripple the specific enzyme-producing cells, as might the mother her child's digestion by overfeeding, and in a similar way, through the injurious effect of direct contact with decomposition products, and thus do actual harm. Furthermore, we should understand that the element of time required in which to digest a given amount is even more important with a meal of vaccine, hypodermatically administered, than with one of beefsteak fed in the ordinary way, since, should the previous meal not be out of the way, the tissues would certainly be subjected to more bacterial substance at once than that contained in the last dose, and the patient suffer the effects of overdosage, parenteral indigestion, previously referred to.

PRACTICAL GUIDES

Having considered the general principles involved, we may now turn to the actual practice of vaccine therapy. Premising that we have an autogenous vaccine, efficiently prepared, skilled selection of the organism from the patient's supply, controlled by smear and culture, and care in sterilization of vaccine so as not to destroy the specific nature of the bacterial protoplasm through the employment of too much heat, we should first look for proof that the organism constituting the vaccine is at least active in, if not entirely responsible for, the lesions that we are to attempt to heal. Any individual becomes what is called sensitized to an infecting organism soon after it or its products gain access to the general circulation, and as thi means that his lymph contains newly developed (a previously explained) enzymes peculiarly adapted t the disintegration of the special bacterial protoplasm involved, no sooner does such protoplasm find its way into his tissues than it is attacked and more or less completely digested. The symptoms arising from this process depend directly on the activity and quantity of such enzymes that may be available, no less than on the quantity of bacterial matter introduced. If these two factors are so related that immediate and complete disintegration of the bacterial matter takes place, no symptoms whatever occur. But if the digestive process proceeds relatively slowly, as with our gastro-enteric digestion of albumin, through albumose *and peptone to amino-acid,* the poisonous action of the intermediate products shows itself in symptoms of inflammation at the point of introduction (local reaction); in fever, increased pulse rate and malaise generally (constitutional reaction), and in increased congestion and cellular activity at the foci of disease (focal reaction). Here we should especially note that no symptoms would be produced by the *first,* or perhaps the first two or three, injections of strange bacterial protoplasm (soluble toxins, as of the diphtheria or tetanus bacillus, are not included), as contradistinguished to what may be called familiar bacterial protoplasm, but that if such injections were continued, even of non-pathogenic bacteria (as proved by Thiele, Embleton and others), the individual would become sensitized just as he does in the course of an infectious disease, and all three varieties of reaction would develop. For these reasons a focal reaction following the first, or at least the second or third dose is particularly to be desired and watched for as convincing proof of the culpability of the organism constituting the vaccine in use. Of course, careful note should be made of any local or any constitutional reaction (which, with the same reservation, are also pathognomonic) as both corroborative of the first and as indicative of the strength of the body's response.

In default of any such reactions, even after the third dose, local and constitutional responses cannot be taken as diagnostic, nor even a focal one, unless it be so distinct and apart from a general disturbance as to exclude the possibility that it might be due only to the general sensitization to the vaccine plus the increased irritability shown by any inflamed tissue.

Of course, since a reaction of any sort presupposes a certain amount of resistance, there will be found individuals whose specific response is so slight (notably in some cases of acne) that it is only with much difficulty that any reaction whatever can be obtained. While this state explains the original development of the malady and the failure of automatic cure, it is very difficult to deal with and markedly points to the limitations of active immunization — we *can supply* the specific stimulus, but as yet have to leave the response to the body. Abnormally low temperature (mouth) is often a concomitant, if not an actual indicator of this condition, and after an injection of vaccine it frequently falls and remains still lower for days and even weeks.

Before giving a first injection of vaccine we should have record of both the patient's daily range of temperature and of pulse, so that we may judge how the vaccine acts in these particulars. The temperature (morning and afternoon) record should be kept up during the entire course of treatment, and the pulse rate recorded just before each injection and at the height of any reaction that may occur. Needless to say, written record should be made of the amount of vaccine injected and the character, extent and duration of all reactions following.

As regards the size of the first dose, although each case must be a law unto itself, depending principally on the danger of inducing a painful or a debilitating reaction, either on account of the location or the extent of the pathologic process, it is rare that one smaller than 100 million organisms need be given. If no reactive response or no prolonged lowering of temperature results by the end of a week, a 25 per cent. increase may be given, and so on for three or four periods; but just as soon as the slightest sign of reaction is apparent the same dose must be repeated, over and over again if necessary, till it ceases to elicit noticeable response, which will be when the special enzyme produced is plentiful and powerful enough immediately and completely to reduce the bacterial protoplasm, as previously explained. After the fourth dose, or after a repeated dose, fails to elicit a reaction, the increase should never be greater than 10 per cent. A prolonged depression of temperature indicates, as stated, deficient reactive ability, and should be met by a reduction of at least 90 per cent. in the size of dose and a subsequent increase of not over 10 per cent. each time whenever the temperature retains its level in accordance with the general rule given above. The interval between doses should never be less than a week (possibly better results could be obtained with two weeks), since, besides avoiding cumulative overdosage, we must give any increased specific resistance developed time in which to act on the organisms in the focus of infection, else we shall lose at least early improvement, which will be much interfered with if we use up all or most of the new enzymes with dose on dose following in too rapid succession.

As to the place of injection: It is to be remembered that our object is to secure the aid of the as yet unaffected body cells in the production of antibodies, and as a hypodermic dose of vaccine in the arm, for instance, exerts its main stimulating influence on the tissues in the immediate neighborhood and along the lymphatics to and including the nearest chain of glands, and as the immunity and therefore special enzyme formation persisting over this area at the end of a week or more is certainly greater than that in the normal tissues elsewhere, the next dose should certainly be placed accordingly—in as new a field as may be available. I therefore suggest that, besides the arms, the thighs be used, so that even the same lymphatic chain would not be restimulated more than once every four weeks. It has been demonstrated that an intraperitoneal injection of a given dose of vaccine in animals subjected to the experiment has a much greater immunizing power than when administered anywhere else. This is undoubtedly due to the fact that here opportunity exists for contact with the greatest number of the cellular elements of inflammation — the main antibody producers—so that the given plan, as it widens the area of subcutaneous dosage, tends to a similar effect and result.

In a suitable case, if we follow out the foregoing rules, we are almost certain to obtain improvement after ten or twelve injections, and when this improvement has nearly reached cure we should stop all vaccine, at least for a month or two, since improvement is usually particularly marked just after the arrest of a course of appropriate vaccine therapy—a further indication of the necessity of avoiding too short intervals between doses.

DIABETES MELLITUS TREATED WITH FLUID CULTURES OF THE LACTIC ACID BACILLUS

REPORT OF FOUR CASES

ALFRED C. HENDERSON, M.D.
NEW YORK

Several references[1] have recently been made in medical literature to the successful treatment of diabetes mellitus by the administration of the lactic acid bacillus. It is desirable that the effects of this therapeutic agent should be confirmed; with this idea in mind, four patients were given the treatment.

The first three were observed at Gouverneur Hospital, service of Dr. John H. Huddleston. They were kept on a constant weighed diet for a considerable period before the treatment was begun. This diet was constituted as follows:

Breakfast: Three ounces of bacon; 2 eggs; 1 ounce butter; 1 ounce cheese; tea or coffee, with 2 ounces cream.

Midday: Ten ounces clear soup; 3 ounces lean meat; tea, without cream; 1 ounce cheese; 4 ounces vegetables (asparagus, beet-greens, cabbage, cauliflower, cucumbers, eggplant, lettuce, rhubarb, spinach, string beans, tomatoes or vegetable marrow).

Evening: Tea or coffee with 2 ounces cream; 3 ounces ham; 2 eggs; 1 ounce cheese; 1 ounce butter.

This diet is equal to a carbohydrate intake of 15 gm. Where the tables indicate a larger intake, the increased carbohydrate is in the form of white bread.

Continuing on the same diet, the patients were then given the lactic acid bacillus solution, the idea being to note any effect the medication might have on the disease as compared with the control periods. The subjects of these observations were kept in the same ward under the care of the same nurse. While in the hospital the urinary examinations were all made by one man. For the quantitative determination of glucose, Benedict's modification[2] of Fehling's method was used; for the qualitative demonstration of acetone, Legal's test; for diacetic acid, Gerhardt's ferric chlorid reaction.

Two of these three patients were treated in the metabolism division of the Vanderbilt Clinic, both before and after treatment at the hospital, and thus afforded additional data for observation. One of the three died while under treatment.

The protocol of a fourth case has been given me by Dr. H. O. Mosenthal.

PROTOCOLS

CASE 1.—H. B., man, aged 38, born in the United States. In 1910, three and one-half years previous to his admission to Vanderbilt Clinic, began to complain of great thirst and hunger, loss of flesh and strength. At that time he was circumcised on account of great itching under the foreskin. After the operation examination of the urine showed sugar. The patient was put on a moderately restricted diet by his physician, but did not improve; he lost weight, from 207 pounds in 1909 to 114 pounds in January, 1914, when he was admitted to Vanderbilt Clinic. From January 26 until April 20 he showed considerable improvement under dietary restrictions. April 29 he was admitted to Gouverneur Hospital and placed on the constant diet already quoted. The observations from May 8 to 15 serve as a control period, to contrast with the lactic acid bacillus period beginning May 15.

Case 2.—A. S., man, aged 23, Russian, cutter by occupation, was perfectly well until September, 1913, when sugar was found in the urine during an examination for life insurance. Soon afterward he began to feel weak, to pass a great deal of urine, and to have an excessive appetite. There was also some pruritus, dryness of mouth and obstinate constipation. He did not lose much weight. His physician at that time gave him fluid culture of lactic acid bacillus for two weeks, without improvement; later he spent a few weeks in Roosevelt Hospital, where he felt better on a restricted diet. From February 9 until April 28 this patient attended the Vanderbilt Clinic, with only moderate improvement in his condition. April 28 he was admitted to Gouverneur Hospital. Table 2 gives the result of the observations in his case.

Case 3.—D. B., man, aged 42, born in Holland, electrician, was brought by ambulance to the hospital in a semiconscious condition, supposed to be suffering from alcoholism. He was at first very weak and listless and could be made to talk only with difficulty; also his statements were contradictory. From what he said it appeared that he had not known that he had diabetes, but that for eight months he had noticed that he passed a great deal of urine, was very thirsty, had a voracious appetite, and had grown progressively thinner and weaker. He had been much troubled by boils in different parts of his body. This patient was in the hospital during the entire period of observation. The diet was begun April 16; the control days are tabulated beginning May 7, on which date the patient had improved sufficiently to be out of bed.

Case 4 (Dr. Mosenthal's case).—G. B., clergyman, aged 52, refused to give a detailed history, saying it was of no interest whatsoever. The following facts, however, could be obtained: Three years before the present data were obtained the urine could be rendered sugar-free on green days, but by no other diet; traces of acetone and diacetic acid were present. Since that time the disease has made rapid progress, especially when the age of the patient is considered.

* Patient died.

COMMENT

In Case 1, during the control period of five days, there was an average daily carbohydrate balance of 7 gm. of glucose; during the following seventeen days, when the lactic acid bacillus culture was administered, the balance was reduced to 3.2 gm. This is so trifling that a change for the worse that it may be concluded that in this case the medication produced no result. The same may be noted in regard to the slight increase in acetone and diacetic acid.

On the other hand, an immediate beneficial effect is seen to follow the reduction of the carbohydrate intake from 35 to 15 gm. The glycosuria dropped to zero and stayed there, the carbohydrate balance remaining at plus 15. In two days a simple, slight dietary restriction accomplished what the lactic acid bacillus solution failed to do in seventeen days.

The sugar tolerance in Case 2 diminished slightly, and traces of acetone appeared, while the patient was taking the treatment. As in Case 1, only trifling changes for the worse were noted. The course of the disease may be considered to have been unaffected by the treatment.

Case 3 was the most severe of the three cases. The urine showed an acidosis practically all the time the patient was under observation. June 13 there was a sudden change in the urinary findings. The sugar and acidosis disappeared and the patient remained sugar-free for the next six days, when he died; but the acidosis reappeared during the last three days. Coincident with the changes in the urine, the patient's general condition grew rapidly worse. He went to bed and stayed there, lost his appetite and became very weak. His weight dropped from 97 to 87 pounds. He died in diabetic coma after being unconscious for six hours. The disappearance of the sugar and acidosis cannot be regarded as anything but an antemortem change in metabolism such as is often seen in such cases, and not a change for the better. The development of coma points to a lack of improvement.

It was expected that there would be an improvement in the general condition of these patients during the first part of their stay in the hospital, on account of the rest, strict dieting and more regular life brought about by hospital routine. After this improvement was established, the lactic acid bacillus treatment was begun and continued for a considerable period. No improvement could be observed during this treatment, clinically or in the urinary examinations.

The methods used in the determinations in Case 4 were those yielding accurate results: for glucose, Benedict's modification of Fehling's test; for total nitrogen, the Kjeldahl procedure; and for ammonia, Folin's method. The lactic acid bacillus medication was followed conscientiously for a month. During that period no marked variation for the better or worse occurred in the glucose tolerance, as evinced by either the glycosuria or the glucose-nitrogen ratio. If any change could be noted it was that the disease was more marked rather than ameliorated. The same holds true of the acidosis as shown by the ammonia figures, both absolutely and those of the percentage of ammonia nitrogen of the total nitrogen. In contrast to this, the figures of January 11 and 16 show that an oatmeal diet in a severe case of diabetes of this kind can accomplish more in therapy than the lactic acid bacillus.

All the urinary analyses cited are taken from days having similar dietary restrictions. The lactic acid bacillus period shows no improvement over the control day, January 11, nor does the following period, April 5, give any evidence that the course of the disease has been favorably influenced.

TABLE 4.—RECORD OF URINE ANALYSES IN CASE 4

	Urine in 24 hours									
Date, 1913	Volume c.c.	Specific Gravity	Reaction	Glucose, Per Cent.	Glucose, Gm.	Total Nitrogen, Gm.	Ammonia,* Gm.	Per Cent. Ammonia Nitrogen of Total Nitrogen	Glucose-Nitrogen Ratio	
1/11	3,000	1.028	Acid	2.5	75.0	21.8	2.6	9.9	3.5:1	Second of 2 green days†
1/16	2,940	1.017	Acid	1.0	29.4	14.2	0.6	4.4	2.1:1	Second of 2 green days
2/15	2,340	1.025	Acid	2.2	51.5	14.5	1.8	10.7	3.6:1	Green day following strict day‡
2/22	3,000	1.023	Acid	2.4	72.0	18.6	2.1	9.4	3.9:1	Green day following strict day
3/8	3,120	.....	.....	2.9	88.9	20.6	2.4	9.8	4.3:1	Green day following strict day
4/5	4,140	1.020	Acid	1.8	74.5	16.1	3.2	16.4	4.5:1	Green day following oatmeal day

* The qualitative reactions for diacetic acid (Gerhardt's reaction) and acetone (Legal's test) were of maximum intensity throughout. Sodium bicarbonate was administered during the period of observation. The dose of this drug, however, was constant, and therefore would affect the ammonia output equally on each day, and would not invalidate comparative values.

† A period of three oatmeal days followed the specimen of January 11; the diminished output of glucose and ammonia, January 16, are evidence of the benefit derived therefrom.

‡ From February 8 to March 9, 16 c.c. of the fluid culture of lactic acid bacillus was given three times a day.

CONCLUSION

The conclusion drawn from these four carefully observed cases of diabetes mellitus is that no improvement was effected by the administration of the fluid culture of the lactic acid bacillus either as to the glycosuria or the acidosis.

The Phenomena of Sleep.—We are never unconscious during sleep; in sleep we have a transformed consciousness. Instead of the relation of the ego to his environment being maintained, as it is during waking hours, we have a complete change, in which the ego goes through thinking processes, but without the same feelings of relativity. Unquestionably thought continues; the direction of thought is altered. There is in dream consciousness hardly any, if any, effort to control the thoughts. The thoughts very largely control themselves. Our conscious life ought to consist of a continuously controlled and directed stream of thought by association. But in dream consciousness the thought is completely uncontrolled, and it is all done by spontaneous association. The attention is diffused and dim, extending over a very wide field, instead of a small and well-illuminated one. —H. Crichton Miller, *Medical Press and Circular*.

THE EFFECT OF GRAVITATION ON THE PRESENTATION AND POSITION OF THE FETUS

CHARLES G. BARNUM, M.D.
GROTON, CONN.

The presentation of the head of the fetus at the uterine outlet, at the time of birth, is so common and offers so comparatively easy a delivery, that since the earliest times it has been called the normal presentation. The statistics collected by Schroeder,[1] including several hundred thousand cases, give 95 per cent. of vertex presentations, and Pinard[2] gives about the same figures. These findings are for all periods of pregnancy; but if full term cases alone are considered, about 97 per cent. present the occiput. About 70 per cent. of the vertex presentations occur in the left, and 30 per cent. in the right position. Naegele[3] first pointed out that the vertex is usually directed anteriorly in left and posteriorly in right positions, so that the presenting part is usually found at one or the other extremity of the right oblique diameter of the pelvis.

The great frequency of cephalic presentations at the end of pregnancy was recognized by Hippocrates, but he believed that the child presented by the breech up to the seventh month, and then turned over and presented the head. This turning over at the end of the seventh month has been known as "The fetal somerset" of Hippocrates. But the more frequent examination of pregnant women has demonstrated the error of this idea, so that since the time of Smellie[4] and Baudelocque,[5] it has been generally believed that head presentations predominate throughout pregnancy. For many years it was considered that the presentation once determined was permanent, but in 1861 Hecker[6] and others demonstrated that it is not unusual for changes in presentation to occur even in the latter months of pregnancy. It has also been shown that these changes are usually from some other to the cephalic presentation, and that the presentation becomes more stable the nearer full term is approached.

Many theories have been advanced to account for the prevalence of head presentations, and spirited controversies have occurred between their advocates. These theories fall into three groups, namely, the gravitation theory, the theory of mutual accommodation between the fetus and the uterine cavity, and a group of theories which have been put forward in the belief that the fetus determines its presentation by its own active movements. The first two are the leading theories at present.

The gravitation theory, first mentioned by Aristotle,[7] attributes the dependent position of the head to the greater weight of that part. Perhaps the most notable advocate of this theory has been James Matthews Duncan,[8] although Veit,[9] Smellie,[4] William Hunter,[10] and others have also supported this view. Duncan showed that if a recently dead full term fetus, that had not breathed, be bound with threads so as to be retained in the intra-uterine habitus, and put into salt solution of about its own specific gravity, it floats obliquely with the head down and the right side lower than the left. He also separated the head from the body and found that it had a specific gravity of about 1.060, while the body had a specific gravity of about 1.050, thus clearly demonstrating the greater specific gravity of the cephalic part of the fetus, while the lower position taken by the right side of the fetus showed that the center of gravity of the whole fetus lay to the right of the midline. Veit[9] and numerous others have duplicated these observations.

Duncan[8] also clearly described the manner in which the gravid uterus is supported. In the erect subject it lies forward on the anterior abdominal wall and is inclined at an angle of about 30 degrees to the horizon, and when the woman is in dorsal decubitus it is not horizontal, but lying back on the posterior abdominal wall and brim of the pelvis it forms an even greater angle with the horizon. Thus the os is the lowest part of the uterus in all ordinary positions of the woman except the lateral recumbent.

Objections to the gravitation theory have been made by a number of able writers, among them Dubois,[11] Scanzoni,[12] and Sir James Simpson.[13] Simpson did some careful experiments with fresh fetuses, putting the fetus into a large vessel filled with water and allowing it to sink to the bottom. In such an experiment, he said, if gravitation is competent to account for cephalic presentations, it ought to cause the head of the fetus to fall first to the bottom of the vessel. He found, however, that, on the contrary, the fetus always turned on its back, and the region of the scapula first touched bottom. He therefore declared that the action of gravity would not tend to produce a cephalic presentation, but that the preponderance of that presentation was due to the accommodation of the fetal ovoid to the cavity of the uterus.

The findings of Duncan, taken together with a consideration of the general character of the anterior and posterior surfaces of the fetal ovoid, rather readily suggest the prediction of the results obtained in Simpson's experiment. For when the fetus is in the intrauterine habitus, the posterior surface of the fetal ovoid, formed by the back of the trunk and the back of the anteflexed head, is a fairly regular convex surface, and such a surface offers a relatively small resistance when making its way through a body of water. On the contrary, the anterior surface of the fetal ovoid presents the anteflexed head and the four extremities so folded on the body as to form an irregular rather concave surface, such as in passing through water offers appreciable resistance. This difference in the resistance offered by the anterior and posterior surfaces of the fetus would tend to cause such a rotation as was noted in the experiment. The location of the center of gravity to the right of the midline and nearer the back than the front of the fetus, as asserted by Duncan, would also tend to produce the same rotation. The greater density of the head should cause it to fal a little faster than the other parts of the fetus, were it not for its attachment to the rest of the body. Thus the cephalic end of the fetus should slightly anticipate the other end in its arrival at the bottom of the vessel, and the fetus should move through the water back foremost, both of which it evidently did.

Probably the ablest opponent of the gravitation theory is Schatz.[14] In 1900 he made criticisms of Duncan's work which do not seem to have been met. Schatz stated that by following Duncan's method of procedure.

> "The interesting observation was made, that fetuses of the first months of pregnancy swim with the head up and the rump end down. But the difference between the ends becomes less as pregnancy proceeds, and that at the sixth or seventh months of pregnancy the fetus swims horizontally, later toward the end of pregnancy with the head lower than the rump, and at the end of pregnancy the fetus swims with the long axis perpendicular." He remarks that: "These experiments remind one of 'the fetal somerset' of Hippocrates," which was the turning of the child from a buttocks to a cephalic presentation supposed to occur at about the seventh month; "also the experiments seem to give a very pretty explanation of the more recent observations, that toward the end of pregnancy the presentation becomes more constant and established. And yet," he went on to say, "The whole theory and its application are false; because in a body whose parts are of various densities, there is no fixed point on which the body will balance when immersed in solutions of different specific gravities."

He illustrates this point as follows:

> "If one take a body, for example a cube of one cubic centimeter volume with a specific gravity of 3, together with another cube of the same size but of a specific gravity of 4, and join them together to form a rectangular body, the heavy-point of the system of seven grams is at a point three sevenths of the distance from the center of the four gram cube toward the center of the three gram cube, when the body is in the air. If now the body should be put into water, each cube would displace one cubic centimeter of water, which weighs a gram, then the heavier cube would weigh three grams and the other two grams, and the heavy-point would be two-fifths of the distance from the center of the heavier cube toward the center of the lighter cube. If, again, the body should be placed in a solution of a specific gravity of 2, then each cube would displace two grams of the solution and the heavier cube would weigh two grams and the lighter cube one gram, and the heavy-point would be one-third of the distance from the center of the heavier cube toward the center of the lighter cube. Thus the greater the specific gravity of the solution in which the body is suspended, the nearer the heavy-point approaches the center of the heavier cube," or differently stated, the position of the heavy-point of such a body is dependent on the specific gravity of the solution in which it lies.

In the experiment of suspending the fetus in a solution of its own specific gravity, about 1.050, natural conditions are not reproduced, for the liquor amnii has a specific gravity of only 1.006 to 1.008, and the heavy-point of the fetus lying in it is not the same as it is in the heavier solution. To determine the effect of gravity on a fetus suspended in a solution of the specific gravity of the liquor amnii, Schatz proceeded as follows: He took a fresh full-term fetus, which had not breathed, and to each end of its long axis he attached a cord, the other end of which was attached to the pan of a good balance. The fetus was then lowered into the salt solution (specific gravity 1.008), and the length of the cords so adjusted as to bring the long axis of the fetus parallel to the beam of the balance. When these conditions had been established, the pelvic end of the fetus was found to sink to a lower position than the cephalic, and it was found possible to measure the excess weight on the pelvic side of the balance by putting weights in the pan on the other side. In consequence of this finding, Schatz declares that the experiments of Duncan prove nothing with regard to the statics of the fetus in a fluid of the specific gravity of the liquor amnii. The experiment has been verified by Williams[15] by putting the fetus suspended as above into a solution of its own specific gravity, when the head sinks as in Duncan's experiment, and then gradually diluting the solution to a gravity of 1.008. During the dilution the fetus slowly assumes the horizontal position, and then as the dilution progresses, the buttocks sink to the lower position.

The conclusion drawn from these experiments, that so far from being a factor in determining the cephalic presentation, the action of gravity if unopposed would regularly produce a breech presentation, is such a remarkable contradiction of the findings of Duncan, that a study has been made to determine if possible the correctness of the conclusion.

Experiments were conducted as follows: The fetus was bound with small cord so as to be retained in the intra-uterine habitus, and then put into a salt solution, the specific gravity of which was so adjusted that the fetus was freely suspended in it. The experiments of Duncan were thus duplicated, and the specific gravity of the solution was taken as the specific gravity of the fetus. If the solution were diluted, of course the fetus would fall to the bottom. To prevent this, the fetus was suspended by the use of a long balance beam with a cord hanging from each end. These cords were attached to the fetus much as described by Schatz, but instead of the cords being attached to the ends of the long axis of the fetus, they were attached to the ends of that transverse axis on which the fetus balanced, in the air, with the long axis horizontal. With such an arrangement one would expect that, whatever the specific gravity of the solution into which the fetus was lowered, a disproportionately large part of the weight of that part of the fetus having the lower specific gravity would be borne by the solution, and that in consequence the opposite end of the fetus would sink. Such was found to be the case. The observations were as follows:

Experiment 1.—A 5-months fetus was freely suspended in a solution of a specific gravity of 1.049. Neither end tended to sink to a lower position than the other.

Experiment 2.—A premature child, which had breathed, was freely suspended in a solution of the specific gravity of 1.046. Neither end tended to a lower position than the other, but the right side took a lower position than the left whatever the initial position in which it was placed.

Experiment 3.—A fresh full-term fetus, weight 2,530 gm., specific gravity 1.050, in salt solution took an oblique position with the head down, but neither side took a lower position than the other.

Experiment 4.—Of a 5-months fetus, specific gravity 1.044, neither end tended to take a lower position than the other, but the body without the head took a vertical position with the head end downward. The specific gravity of the head was 1.041.

Experiment 5.—In a 6-months fetus, of specific gravity 1.037, the specific gravity of the head was 1.041, that of the liver and limbs 1.047. Neither end of the fetus tended to take a lower position than the other, but the decapitated body was very decidedly inclined to lie on the right side.

---

[14] Schatz: Ueber den Schwerpunkt der Frucht, Zentralbl. f. Gynäk., 1900, p. 1033.

[15] Williams, J. W.: Obstetrics, 1909, Ed. 2, Chapter IX.

Experiment 6.—In a male child, length 50 cm., the weight of the fetus was 2,485 gm., specific gravity 1.054; weight of the head 795 gm., specific gravity 1.056; weight of the body 1,690 gm., specific gravity 1.053. In salt solution the head end of the fetus went down and the right side was lower than the left. The fetus then was balanced as described above and when lowered into water it took a position like that which it took in the salt solution of its own density.

Experiment 7.—In a male child, length 50.5 cm., the weight of the fetus was 2,600 gm., specific gravity 1.051; weight of the head 810 gm., specific gravity 1.054; weight of the body 1,790 gm., specific gravity 1.050. It took a position in salt solution of its own density with the head nearly vertically downward and the right side lower than the left.

Experiment 8.—A male child, length 49 cm., weight 2,830 gm., was freely suspended in a solution of a specific gravity of 1.051 in which it took a position with the head nearly vertically downward and the right side lower than the left. It was then balanced as described before, and it then took a similar position when lowered into water.

The length of the long axis of the fetus, while in the intra-uterine habitus, was found to be 29 cm., and the transverse axis, on which the fetus balanced in the air, was found to be 15.5 cm. from the cephalic pole.

Experiment 9.—A full-term child 3 days old, weight 2,005 gm., floated in water with the head directly downward. The length of the long axis, when the body was bound in intra-uterine habitus, was 27 cm., and the transverse axis on which it balanced in the air was 14.5 cm. from the cephalic pole.

These observations almost exactly duplicate those reported by Duncan,[8] and when we review the findings we should bear in mind Duncan's warning that most of the early fetuses have been dead for some time before birth, and that in consequence decomposition is likely to have altered the relative densities of the parts, so that we may easily discount the variations in the findings made in examining the premature subjects.

If now we examine the data from the foregoing experiments together with the observations made by Duncan,[8] Simpson,[13] Schatz[14] and Williams,[15] the following conclusions will be found consistent with each observer's results:

1. The cephalic part of the fetus has a higher specific gravity than the body.
2. The center of gravity of the fetus, in intra-uterine habitus, is nearer to the buttocks end than to the cephalic end of the long axis.
3. The center of gravity of the fluid displaced by the fetal body is even nearer to the buttocks end than the center of gravity of the body itself.

As indicated, in the illustration given by Schatz, the heavy-point, as he calls it, of a system of two bodies of unequal specific gravity, moves along a line from the center of gravity of the system to the center of gravity of the denser body, as the specific gravity of the solution in which it lies is increased.[4] This is due to the fact that, when two such bodies lie in a solution, a greater proportional part of the weight of the body, of the lower specific gravity, is supported by the fluid, and this disproportion becomes greater, the greater the specific gravity of the fluid. By the method of suspension used by Schatz, the effective support for the weight of the fetus is applied to the midpoint of the long axis, and his experiment shows that the specific gravity of the liquor amnii is not great enough to cause the heavy-point to move from the center of gravity of the fetus to the midpoint of its long axis, for the pelvic end takes the lower position. On the other hand, a solution which will support the fetus causes the heavy-point to move beyond the midpoint toward the cephalic pole, as is shown by the experiment of Williams. And in this movement of the heavy-point with the changing of the density of the solution, we find a complete explanation of the phenomena observed in Williams' experiment.

In my experiment the effective support for the weight of the fetus was applied to its center of gravity. The support was thus applied to the heavy-point, and immersion of the fetus in any fluid, not dense enough to float it, would cause the heavy-point to move from the point of support toward the heaviest part of the body, the head, with a resulting depression of that part, as was observed.

In view of these conditions, shall we say that the effects of the action of gravity is rather to produce a breech presentation than a cephalic? In both experiments with the lighter solutions, mechanical supports were used, and the results obtained were determined by the point of application of the support.

It is pertinent to recall that the center of gravity of the fetus was found to be nearer the pelvic end[14] and about 1 cm. from the midpoint of the long axis, so that if the point of support be moved even 1 cm. from the midpoint toward the larger end of the fetal ovoid, the action of the amniotic fluid, due to gravity, would cause the head to sink to the lower position. But would we not make a rather unreasonable supposition in supposing that the fetus during its intra-uterine existence has a mechanical support acting on any single point?

It may be helpful at this point to inquire just how great the effective weight of the fetus is when lying in the amniotic fluid, and how that weight is distributed. The specific gravity of the fetus may be taken as 1.050, and that of the liquor amnii as 1.008. Then 1.050 : 1.008 :: 100 : x, in which x equals the percentage of the weight of the fetus supported by the liquor amnii. $x = 96$ per cent. That is, only 4 per cent. of the weight of the fetus is unsupported by the fluid. In other words, in a 3-kg. fetus, the pressure exerted on the wall of the uterus by the fetus equals 4 per cent. of 3,000 gm., or 120 gm., equal to about 4 ounces. If in this fetus the head is found to have a specific gravity of 1.056, while that of the rest of the body is 1.048, then each cubic centimeter of the substance of the head will have, on an average, an unsupported weight equal to 1.056 gm. minus 1.008 gm., or 0.048 gm., and the body similarly will have an unsupported weight per cubic centimeter equal to 1.048 gm. minus 1.008 gm., or 0.040 gm. Thus the effective weight of the head is one-fifth greater per volume than that of the body. As a result of this condition of affairs, it seems reasonable to expect that the head will fall to a lower position more rapidly than the buttocks part of the fetus, whenever any movement of the mother or fetus causes a separation, however small, between the fetal ovoid and the inclined slippery surface on which it lies. The fact, that in a fluid the denser of a group of bodies falls to the bottom of the container when the vessel is shaken, has been taken advantage of from prehistoric times in the panning of gold. The particles of gold collect on the bottom of the pan under the gravel even though the gravel stones are larger and heavier than the individual particles of gold. The denser body exerts a greater force per unit area on the fluid under it, particularly if the fall be short, and therefore more rapidly makes its way to the bottom. Other factors also come into play in the panning of gold, but when bodies of approximately the same size and shape are considered, the relative densities of the bodies is the major factor.

The supposition that, when the fetus falls through fluid, the head will fall the faster and gain the lower position, would seem to call for the very condition which Simpson[13] failed to find in his experiments. For he found that when the fetus falls through water, the head does not fall the faster and first reach the bottom, but that on the contrary the region of the scapula does it. But it should be remembered that, as a body gains velocity in moving through fluid, the shape of the body becomes a major factor in determining the order of precedence of its parts. However, in the first instant of its fall, the velocity is so small that the shape of the body exercises very much less effect. In consequence, repeated short falls may produce an effect on the relative positions of the parts of a body rather different from that produced in the same body by a single fall of the same total magnitude. Thus we seem to be warranted in expecting that the effect of gravity on the denser head of the fetus would be like that on the gold in the pan, and that it would cause the head to take the lower position unless mechanically hindered.

The note has been made by Schatz[14] that the relative specific gravity of the poles of the fetus changes with the advance of pregnancy, the relative specific gravity of the two poles in early pregnancy being the reverse of that found in the mature fetus. It must be borne in mind that most of the early fetuses available are open to the criticism, made by Duncan,[8] that they have been dead for some time before delivery, and that degenerative processes have changed the relative densities of their parts. In this connection, we should consider the practical unanimity of opinion among those who have opened the pregnant uterus post mortem, that the cephalic is the common presentation at all periods of pregnancy. Among these observers is Hohl,[16] who said:

> We have examined a series of unopened ova, and have always observed that the embryo reposing in the liquor amnii lies with the head lowest. We have in a considerable number of autopsies of pregnant women, not advanced to the seventh month, never once seen the breech lying lowest, if the corpse had not been disturbed.

Vesalius, Paré, Smellie,[4] Hunter,[10] Baudelocque[5] and Velpeau[17] are observers reporting similar findings. More recently Edgar[18] has stated that "it is well established that the head is generally lower than the breech, even from the very first formation of the liquor amnii."

During the earliest months of pregnancy, the relatively small fetus is enclosed with a considerable amount of fluid in a globular sac. As the fetus is heavier than the fluid, it lies on the lower wall of the sac, as soon as the umbilical cord has become long enough to allow it. As long as the uterus has the globular form, the fetus can hardly be said to have a presentation, for it slides readily over the lower wall of the amniotic cavity with the changes in position made by the mother, and the arciform contour of the body of the fetus determines its adaptation to the curved surface on which it lies. As pregnancy advances, the cavity of the uterus becomes somewhat elongated, but the body of the fetus, for some time still, fills the cavity so incompletely as hardly to allow the participation of any agent other than gravity in determining its position in the cavity. But as the fetus comes to fill the uterus more completely, the walls of the uterus restrict its movements, and become a potent factor in preserving a longitudinal presentation.

That the action of gravity is a factor in determining the anterior or posterior position of the occiput, in cephalic presentations, has been fully demonstrated by Schatz.[19] In 1904 he reported a very long series of observations made on women in the later months of pregnancy. He found that the left occipito-anterior position is more common in the evening after the mother has been up and around than in the morning at the time of arising, while the right occipitoposterior position is more frequent in the morning than in the evening. This phenomenon he attributes to the weight of the liver lying on the right side of the fetus, which, tending to the lower position, comes forward during the hours when the woman is erect and tends to go backward when she lies down. These changes in position most readily occur in multiparas, because in them engagement does not occur until the beginning of labor. The predominance of the left occipito-anterior position over the right occipitoposterior is readily accounted for by the relatively greater activity of the mother in the erect posture, compared with her inactivity when lying down, so that the frequent jarring while the mother is up and about causes a more ready change in the position of the fetus.

Thus Schatz satisfied himself that gravity is an active factor in determining the usual positions found in cephalic presentations. Yet, because of a mistaken interpretation of the results of his experiment, which results were primarily determined by the point of suspension of the fetus, he concluded that the cephalic presentation itself not only was not attributable to the action of gravity, but that the tendency of the action of gravity to produce a breech presentation must be counteracted by some other force. But his objections fall to the ground unless we suppose that the fetus, in the uterus, has a *mechanical* support acting on it, the resultant of which is applied at some point nearer the head than the center of gravity. Such a support does not exist. And in view of the slight rocking of the fetus in the uterus, by its own and the mother's movements, it seems reasonable to believe that the denser cephalic pole of the fetus, like the gold in the pan, will find the lowest part of the container. Thus we confirm Duncan's conclusions.

In the study of the effect of the action of gravity on the presentation, it has seemed pertinent to inquire whether any light might be thrown on the problem by a study of the conditions prevailing during pregnancy in the lower animals. The processes of human physiology are the outcome of a gradual evolution, and we find in the lower animals examples of some of the stages of that evolution, so that it would be rather remarkable to credit gravity with being an agent in

bringing the heavier head of the fetus to the lower position occupied by the os uteri in the human subject, if in the four-footed animal, in which the os uteri is at the upper end of the uterine cavity, the action of gravity could not be found to assist in producing the habitual cephalic presentation, or at least did not have to be overcome in its production.

In the mare and the cow, the uterus resembles the human in type,[20] and cephalic presentations are the rule. The cornua of the uterus and the broad ligaments are attached to the dorsal wall of the abdominal cavity, and the uterus is in the upper part of the cavity when in the non-gravid state, but after the first of pregnancy the uterus is borne down by the weight of its contents so that it lies on the lower abdominal wall, and the cervix becomes its highest part.

The young of these animals come into the world with a much more advanced development of their limbs than does the human infant, and from the first they are able to run about. Again, the young animal has a head which is smaller in proportion to its body than is that of the human infant, so that we are in a measure prepared for the remarkable findings made by Ernst Bumm[21] in experiments with the fetuses of animals. He made experiments with fetuses of uniparous animals, after the manner followed by Duncan, and he found that when freely suspended in salt solution such fetuses take a position with the pelvic end lower than the head. This reversal of the relative specific gravities of the poles of the fetus, as compared to the condition found in the human fetus, coupled with a corresponding reversal of the positions of the os uteri, is remarkably consistent with the idea that the action of gravity plays a part in the production of the cephalic presentation both in human beings and in animals.

It may also be shown that the action of gravity tends to produce the normal position of the animal fetus. At birth the fetus normally presents with its convex back fitting into the curve of the mother's sacrum, that is, it has its back uppermost and its belly below.

A number of experiments were done with pig fetuses in various stages of development, and every one took a position with the belly side down, when placed in a salt solution of its own specific gravity.

CONCLUSIONS

I think it has been shown that the action of gravity contributes to the production of the cephalic presentation, and that the interpretation of Schatz' experiments was an error because of the manner in which the support was applied in those experiments. In support of the proposition that the action of gravity participates in the determination of the cephalic presentation, three main considerations have been brought forward:

1. The amount and distribution of the effective part of the weight of the fetus lying in the amniotic fluid.
2. The admitted contribution of the action of gravity to the production of the left occipito-anterior position, which is one of the most characteristic features of the cephalic presentation.
3. The very great probability that the action of gravity contributes to the production of the normal cephalic presentation and the normal position of the fetus in animals.

The subject matter of this paper was submitted as a graduation thesis at the Yale Medical School in June, 1911. I wish here to acknowledge my indebtedness to the late Dr. Otto G. Ramsay, professor of obstetrics and gynecology, under whose guidance this work was done.

THE NURSING INFANT

BRANCH CRAIGE, M.D.
EL PASO, TEXAS

The purpose of this paper is to offer some practical suggestions for the prevention and correction of those far too frequent nutritional disturbances of breast babies due to faulty feeding.

During the first few months of infancy, there is probably more milk than at any other time during the nursing period, and the digestive system of the infant is less developed. If then, at 1 month there is as much milk as at 6, and a 6-months-old baby gets enough for proper nourishment, it is quite evident that the infant under 3 months is apt to overeat.

The infant stomach at 2 weeks holds about ounces, at 6 weeks 2¼ ounces, at 8 weeks 3⅓ ounc By nursing every two hours, ten feedings in twen four, granting the baby will not take more than t normal stomach capacity (but he takes much mo for almost all infants eat till the stomach overflow at 4 weeks old he receives 20 ounces in twenty-fo hours.

The mother's weight, let us say, is sixteen times th of the baby. Then in the same proportion the moth would be taking 10 quarts of milk daily. I hav weighed infants of between 2 and 4 weeks, before an after feeding, and in three minutes have found th stomach containing more milk than there should b after from fifteen to twenty minute nursings. Th infant stomach is not emptied under two hours. Breas milk contains a much larger percentage of fermentative bacteria than cow's milk. Continually dilating a naturally delicate stomach, and mixing fresh food with fermenting residue, are almost certain to give rise to flatulent dyspepsia with all its accompanying distress. At 6 or 7 p. m. this discomfort is greatest, because of the day's accumulations.

This dyspepsia, which might be so easily prevented, manifests itself in either gastric or intestinal indigestion, or both, vomiting of sour or curdled milk, diarrhea or constipation, colic and loss of weight, and in many cases chronic indigestion which takes months of careful feeding to repair. The infant, a victim of physician, nurse, mother, grandmother or neighbor, "who has raised lots of babies," frets and whines most of the time. The mother, whose whole life is absorbed in the baby, is soon reduced to a nervous wreck, both physically and mentally, from worry, confinement and loss of sleep. This nervous condition imparts to the milk a disturbing element that no medicine can correct. And so the "vicious circle" is complete.

When the physician realizes this mutual disturbance, he must take a most positive stand and insist that the written instructions for mother and baby be rigidly carried out. The mother now becomes the patient. She must above all things have an abundance of sleep (if necessary, in a room apart from the baby), good nourishing food, rest and much exercise in the open air. A tonic must be given if necessary. Constipation must be corrected with cascara or some mild laxative. Her surroundings must be pleasant and there must be diversion and entertainment. I have often heard mothers say, "I have not been out of the house since the baby was born." In such cases, it is a good plan to give a 3 p. m. bottle, regardless of the age of the child. By so doing the mother may go out for some recreation without hurrying and worrying to be home at three. The milk will be much more abundant and of much better quality.

[21] Bumm, Ernst: Grundriss zum Studium der Geburtshülfe, 1902.

A mother worrying all day and staying awake all night cannot expect to secrete milk that will be a healthy food for her infant. It has been proved experimentally that a child, doing well on cow's milk, can be made sick when fed milk from the same cow after she has been fretted into a state of nervous exhaustion. Some babies may thrive on the stuffing plan, but it will be found that usually when a baby gains more than 8 ounces a week he does it at the expense of his digestion, and there is going to follow a period of indigestion with loss of weight. You will hear mothers say, "My baby is such a nervous baby." These babies for the most part have no constitutional nervous disease, but are simply nervous systems, impoverished with injudicious feeding, just as any other part of the body suffering with lack of nourishment. Improper feeding is not, of course, the sole source of trouble in infants. There are cases of constitutional diseases, or imperfectly developed digestive systems, that must be treated with appropriate drugs, combined with rational feeding.

When the father and mother are healthy, the mother leads a well ordered life, and the baby is normal at birth, by feeding every three hours from the beginning, at 6 and 9 a. m., at noon, and at 3, 6, and 9 or 10 p. m., depending on the mother's bed time, and once between 1 and 3 a. m., the baby will sleep and be happy and contented and gain systematically from 4 to 6 ounces a week, with satisfactory growth and development. This schedule does very well up to weaning time, provided the night feeding is discontinued after the third or fourth month. The mother will say that if she does not give the night feeding, the baby will cry. He certainly will cry, and cry hard too. But he can be trained to sleep from 9 p. m. to 6 a. m., provided the mother will not go to him when he cries. The nursings should be regular and the baby awakened on the minute and allowed to nurse until he falls asleep, or is satisfied. There are some dyspeptic babies who may do better on a four-hour schedule temporarily, and some premature or very weak infants on small feedings every two hours. The milk equilibrium is not usually established until about the sixth week, so one should not be discouraged too soon. Regular, strong nursings by a healthy infant can overcome many difficulties.

In the composition of the milk, aside from the nervous element, the fat and proteins are the only constituents apt to be at fault, and of these the fat content is usually the most variable and troublesome. Within the past year, I have found two cases in which the fat was about 1 per cent. In one of these, the baby cried almost constantly, and in the other the infant showed marked rickets. Three others showed 5, 7 and 8 per cent., respectively. In the latter cases the infants cried a great deal, and did not gain satisfactorily. The milk in every case was as far as possible the middle specimen. Cow's milk, cereals, red meat, exercise and fresh air, and plenty of sleep will almost always raise a deficient fat content, if it is not lower than 2 per cent. If a baby has colic after each feeding, is uncomfortable and sleepless, has facial eczema, or seborrhea of the scalp, vomits sour excoriorating mucus, has stools that smell sour and scald the skin and contain small easily mashed white particles intermingled with light green mucus, or has constipation with musty gray stools, the fat, assuredly, is too high. To reduce this fat excess is more difficult than to raise a deficient percentage. Fresh air and exercise, with a diet consisting of meat once daily, fruits, vegetables and liquid food but no alcoholic beverages, will accomplish much if the nursings are not too frequent.

Often the protein is the disturbing element, causing colic, constipation, or diarrhea with mucous stools containing tough, white curds in shape of bean- or peanut-like masses. Such a condition is usually found with mothers leading a sedentary life and eating much meat, eggs and highly seasoned food with a lack of fruit and vegetables.

In the foregoing are found the causes and, in a large measure, the prevention of colic, certainly one of the most distressing and annoying symptoms a physician is called on to treat. An attack of colic is unmistakable. The child cries violently, the abdomen is hard and distended, the knees are drawn up, and the hands and feet, which are never still, are cold from the intense intestinal congestion. The trouble may be either in the stomach, coming on soon after nursing, or in the intestines an hour or two later. Remembrance of this may help in relieving the infant. For the treatment of colic I have but little to suggest other than what I have already said about the mother's life and the nursing habits, for here certainly prophylaxis is better than treatment. Every mother knows all the mechanical remedies, such as hot applications, enemas, turning the baby over on his stomach, or holding him against her shoulder. It is often necessary to stop feeding entirely for twenty-four hours. Frequently, diluting the milk by giving water, lime-water, or barley-water, before nursing, helps. Nursing a few minutes and stopping a short while, or the use of the nipple shield may be beneficial. I have had some good results with peptonizing powder dissolved in warm water and given before each feeding. Carminatives, milk of magnesia, sodium bicarbonate, magnesium carbonate and bismuth subnitrate may often be used to advantage. In chronic cases, pulverized rhubarb or tincture of nux vomica sometimes gives relief. Sugar should never be used in the prescription for colic. Glycerin is a good substitute. In many cases the elimination of tomatoes, sour fruits and early vegetables from the mother's diet will prevent it. Where the condition has been long standing, improvement should not be expected to take place at once, for time must be allowed, both for the repair of the damage to the digestive tract, and more especially to the nervous system.

One of the commonest difficulties with which we have to contend is the quantity of milk. The indications of insufficient quantity are very definite. The breasts are flabby. When the baby nurses he never seems satisfied. Instead of nursing fifteen or twenty minutes and falling asleep, some fret and whine and pull at the nipple often for half an hour, while others give up entirely for a few minutes and then try again. The weight remains stationary or shows only a slight gain. There is no colic, no vomiting; the stools are scant, often with an olive-green tinge, and contain no bringing the heavier head of the fetus to the lower position occupied by the os uteri in the human subject, if in the four-footed animal, in which the os uteri is at the upper end of the uterine cavity, the action of gravity could not be found to assist in producing the habitual cephalic presentation, or at least did not have to be overcome in its production.

In the mare and the cow, the uterus resembles the human in type,[20] and cephalic presentations are the rule. The cornua of the uterus and the broad ligaments are attached to the dorsal wall of the abdominal cavity, and the uterus is in the upper part of the cavity when in the non-gravid state, but after the first of pregnancy the uterus is borne down by the weight of its contents so that it lies on the lower abdominal wall, and the cervix becomes its highest part.

The young of these animals come into the world with a much more advanced development of their limbs than does the human infant, and from the first they are able to run about. Again, the young animal has a head which is smaller in proportion to its body than is that of the human infant, so that we are in a measure prepared for the remarkable findings made by Ernst Bumm[21] in experiments with the fetuses of animals. He made experiments with fetuses of uniparous animals, after the manner followed by Duncan, and he found that when freely suspended in salt solution such fetuses take a position with the pelvic end lower than the head. This reversal of the relative specific gravities of the poles of the fetus, as compared to the condition found in the human fetus, coupled with a corresponding reversal of the positions of the os uteri, is remarkably consistent with the idea that the action of gravity plays a part in the production of the cephalic presentation both in human beings and in animals.

It may also be shown that the action of gravity tends to produce the normal position of the animal fetus. At birth the fetus normally presents with its convex back fitting into the curve of the mother's sacrum, that is, it has its back uppermost and its belly below.

A number of experiments were done with pig fetuses in various stages of development, and every one took a position with the belly side down, when placed in a salt solution of its own specific gravity.

CONCLUSIONS

I think it has been shown that the action of gravity contributes to the production of the cephalic presentation, and that the interpretation of Schatz' experiments was an error because of the manner in which the support was applied in those experiments. In support of the proposition that the action of gravity participates in the determination of the cephalic presentation, three main considerations have been brought forward:

1. The amount and distribution of the effective part of the weight of the fetus lying in the amniotic fluid.
2. The admitted contribution of the action of gravity to the production of the left occipito-anterior position, which is one of the most characteristic features of the cephalic presentation.
3. The very great probability that the action of gravity contributes to the production of the normal cephalic presentation and the normal position of the fetus in animals.

THE NURSING INFANT

BRANCH CRAIGE, M.D.
EL PASO, TEXAS

The purpose of this paper is to offer some practical suggestions for the prevention and correction of those far too frequent nutritional disturbances of breast babies due to faulty feeding.

During the first few months of infancy, there is probably more milk than at any other time during the nursing period, and the digestive system of the infant is less developed. If then, at 1 month there is as much milk as at 6, and a 6-months-old baby gets enough for proper nourishment, it is quite evident that the infant under 3 months is apt to overeat.

The infant stomach at 2 weeks holds about 1½ ounces, at 6 weeks 2¼ ounces, at 8 weeks 3⅓ ounces. By nursing every two hours, ten feedings in twenty-four, granting the baby will not take more than the normal stomach capacity (but he takes much more, for almost all infants eat till the stomach overflows), at 4 weeks old he receives 20 ounces in twenty-four hours.

The mother's weight, let us say, is sixteen times that of the baby. Then in the same proportion the mother would be taking 10 quarts of milk daily. I have weighed infants of between 2 and 4 weeks, before and after feeding, and in three minutes have found the stomach containing more milk than there should be after from fifteen to twenty minute nursings. The infant stomach is not emptied under two hours. Breast milk contains a much larger percentage of fermentative bacteria than cow's milk. Continually dilating a naturally delicate stomach, and mixing fresh food with fermenting residue, are almost certain to give rise to flatulent dyspepsia with all its accompanying distress. At 6 or 7 p. m. this discomfort is greatest, because of the day's accumulations.

This dyspepsia, which might be so easily prevented, manifests itself in either gastric or intestinal indigestion, or both, vomiting of sour or curdled milk, diarrhea or constipation, colic and loss of weight, and in many cases chronic indigestion which takes months of careful feeding to repair. The infant, a victim of physician, nurse, mother, grandmother or neighbor, "who has raised lots of babies," frets and whines most of the time. The mother, whose whole life is absorbed in the baby, is soon reduced to a nervous wreck, both physically and mentally, from worry, confinement and loss of sleep. This nervous condition imparts to the milk a disturbing element that no medicine can correct. And so the "vicious circle" is complete.

When the physician realizes this mutual disturbance, he must take a most positive stand and insist that the written instructions for mother and baby be rigidly carried out. The mother now becomes the patient. She must above all things have an abundance of sleep (if necessary, in a room apart from the baby), good nourishing food, rest and much exercise in the open air. A tonic must be given if necessary. Her constipation must be corrected with cascara or some mild laxative.

QUININ SOLUTION FOR BLADDER IRRIGATION

ELLICE McDONALD, M.D.
NEW YORK

In the course of fifteen years' experimentation in the treatment of cystitis in women, solutions of a great number of substances have been tried in the hope of discovering the ideal one. All the various silver salts have been tested. Two varieties of silver salts which have been made in my laboratory have been given a trial. Various oily substances, and combinations of germicides with oil, have also been investigated.

The requisite of an irrigating solution in cystitis in women is that it should be non-irritating, easily obtained, antiseptic, stimulating and healing to the inflamed surfaces.

Of all the substances used, quinin bisulphate best fulfils these requirements. It is easily soluble in water, is comparatively non-irritating and is distinctly antiseptic, much more so than the various irrigating solutions now used. It has been employed by me in cystitis in women for eight years. I first drew attention[1] to its use in 1908.

Quinin bisulphate has a phenol (carbolic acid) coefficient of 0.5, or is one-half as germicidal as pure phenol, and will inhibit the growth of fresh typhoid culture in the strength of 1:30,000. It may be used in irrigating in a strength of 1:2,000 without noticeable irritation.

It should be remembered that the antiseptic or growth-inhibiting action of a substance differs from the germicidal or bacteria-killing properties. The phenol coefficient, or the germicidal strength in terms of phenol, is the measure of the germicidal qualities. The antiseptic or inhibiting power of a substance must be measured by a comparison with other substances. The method which I have used in comparing the inhibiting qualities of substances is to take a measured amount of standard broth culture, 9 c.c., add to it 1 c.c. of twenty-four hour broth culture of typhoid bacilli, and to this then is added a certain proportion of the antiseptic substance to bring it up to the required strength to be tested, as for example, 1:30,000 of quinin bisulphate, which will inhibit. In this way one substance may be tested against another.

Mercuric chlorid will inhibit twenty-four hour typhoid in the strength of 1:50,000.

The more elaborate salts of quinin do not offer any advantage over the simple and easily obtained bisulphate. Chinosol (oxychinolin sulphate) has a phenol coefficient of 0.3, and will inhibit typhoid in the strength of 1:40,000. Thus, quinin bisulphate is a better germicide than chinosol, and differs but slightly from it in antiseptic qualities.

According to my experiments, mercuric chlorid will inhibit bacterial growth in a strength of 1:50,000; chinosol in 1:40,000; quinin bisulphate in 1:30,000.

The quinin bisulphate solution is useful for bladder irrigation and cystoscopic examinations. It is particularly satisfying to have such a strongly antiseptic solution through which to catheterize the ureters and so avoid infection.

174 West Fifty-Eighth Street.

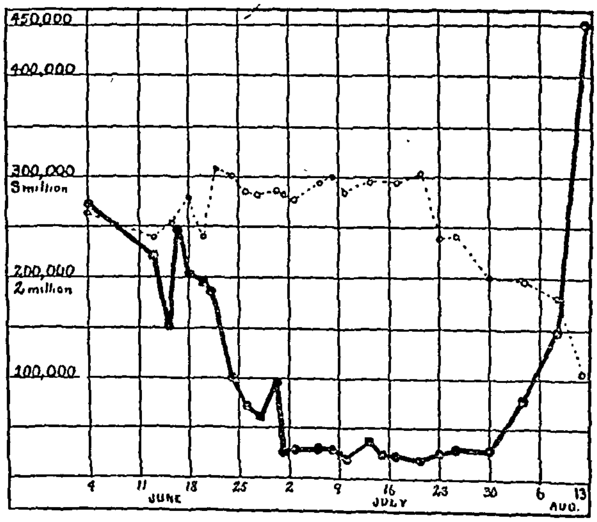
A CASE OF SPLENOMYELOGENOUS LEUKEMIA TREATED WITH BENZOL

CLARENCE F. GRAHAM, B.A., M.D., PROVIDENCE, R. I.
House Officer, Rhode Island Hospital

In view of the present interest in the benzol treatment of leukemia, the following clinical report may not come amiss, both because of the immediate benefit from the use of the drug and from the later acute recurrence in the course of the treatment.

History.—The patient, Mrs. M. B., a native of Rhode Island, was admitted to the Rhode Island Hospital, June 3, 1914, complaining of shortness of breath, general weakness and an abdominal tumor. Two years previously she had been under treatment in the same hospital for uterine hemorrhage, cough and general weakness. At this time she had a red cell-count of 3,712,000, a white cell-count of 120,000 and a hemoglobin of 29 per cent., with the characteristic blood-picture of splenomyelogenous leukemia. The spleen was then found enlarged to the umbilicus. After six weeks of Roentgen-ray treatment the red cell-count had become normal, though the white cell-count remained high, and the spleen had receded to the costal margin. The patient's family history was negative. She had suffered from the usual diseases of childhood, and her health had been poor for the last seventeen years. For six months before her admission she had coughed a great deal, though without hemoptysis, and had lost weight. She suffered constantly from gastric disturbance, together with pain in the precordial and left epigastric regions, and had been extremely dyspneic for two months before admission. For two years the patient had been annoyed by swelling of the legs whenever she was about, and for a year previous to her admission she had noticed a gradually increasing mass in the abdomen. Two years ago she had had severe uterine hemorrhage over a period of two months, and had been twice curetted. The onset of the present illness cannot be definitely dated, since it had been only an aggravation of the symptoms already present, with the addition of frequent nosebleeds and a profound nervous depression.



Curves of blood-counts: solid line, white cell-count; broken line, red cell-count.

Physical Examination.—The patient is a poorly developed and greatly emaciated woman of 40, propped up in bed and extremely dyspneic. The expression is anxious and pained, and the general condition seems almost hopeless. The skin is sallow and pale, and the mucous membranes are anemic. The chest is poorly formed, with small expansion. Respiration is rapid and labored, and evidently painful. The percussion note is everywhere resonant; the breath sounds are vesicular, with numerous moist râles over the whole chest. The point of maximum cardiac impulse is in the fifth interspace 7 cm. to the left of the midsternal line. The left border of the heart is 9 cm. to the left, and the right border 4.5 cm. to the right of the midsternal line. There is a loud, blowing systolic murmur at the apex. The pulse is rapid, of low tension and markedly irregular. A firm mass, evidently the enlarged spleen, occupies the whole left side of the abdomen, coming to the right of the midline just above the umbilicus and extending into the pelvis. The hilic notch can be felt at the umbilicus. The splenic tumor is decidedly tender on palpation. Both legs are slightly edematous to the knee; the knee-kicks are normal. There is no general glandular enlargement.

The blood examination on the day after admission showed: Red blood cells 2,610,000 (corrected for the white count); white blood cells 270,000; hemoglobin 60 per cent.

Differential count—Wright's stain—250 cells:

	No.	Per Cent.
Polymorphonuclear neutrophils	55	22
Polymorphonuclear basophils	0	....
Polymorphonuclear eosinophils	3	1.2
Small mononuclears	3	1.2
Large mononuclears	1	0.4
Neutrophilic myelocytes	183	73.2
Basophilic myelocytes	2	0.8
Eosinophilic myelocytes	3	1.2

The predominating white cells were myelocytes, ranging in size from 3.5 to 16.8 microns, with clear rounded or indented nuclei, and a finely granular protoplasm. No nucleated reds were found on this first examination.

Treatment and Results.—The patient had nearly expired as a result of the journey to the hospital, and her grave condition made it impossible to move her to the Roentgen-ray room for treatment. As no portable Roentgen apparatus was available, it was decided to try the benzol treatment. As soon as her condition had been somewhat improved by digitalis and rest, the administration of benzol (benzene, C_6H_6) was begun, and at the same time Fowler's solution was given in the usual way. The benzol, mixed with equal parts of olive oil, was administered in 10-minim capsules after meals, and was well tolerated with only occasional complaint of slight heart-burn. The initial dose corresponded to 15 minims of the benzol daily, and this was later increased to 45 minims daily.

The accompanying curve shows the course of the red and white counts from the time of the patient's admission. Up to the time when the benzol was begun there had been a drop in the white cell-count, possibly because of the arsenic, which was started before the benzol. Shortly after the administration of the benzol was begun, there occurred the usual initial rise in the white cell-count; then following this came a rapid and steady reduction in the leukocytosis. Hand in hand with this reduction came a slight increase in the red cell-count, while the patient's general condition improved greatly. By the end of a month she was sitting up in a chair, no longer dyspneic, and was rapidly recovering her appetite. The spleen was entirely to the left of the midline, with its lower edge at the iliac crest, and had become hard and no longer painful on palpation.

The differential count, July 3, was as follows:

	No.	Per Cent.
Polymorphonuclear neutrophils	84	42
Polymorphonuclear basophils	0	....
Polymorphonuclear eosinophils	0	....
Small mononuclears	2	1
Large mononuclears	20	10
Myelocytes	60	30
Transitionals	25	12.5
Nucleated red cells	4	2
Normoblasts	3	1.5
Unclassified	2	1

It was noted that the nuclei of the myelocytes were becoming more and more granular, and that the distinction between myelocytes and transitionals was increasingly hard to draw. Myelocytes of the type found in the first smear, with clear nuclei, were no longer to be seen. A few polychromatophilic and stippled red cells were found in this preparation, perhaps indications of the toxic effect of the benzol or of the arsenic.

For three weeks this improvement continued, and the patient even asked to be moved into the ward. Then, July 24, her temperature abruptly rose, and on the 27th she complained of pain in the left side. An area of extreme tenderness was discovered on the enlarged spleen, probably corresponding to a fresh infarct. The red cell-count had already fallen a little, and the white cell-count had risen. From this time her failure was rapid. July 30 the red count had fallen to 2,000,000 and the benzol was discontinued. Recourse was had to the Roentgen ray, but the patient developed the signs of an acute leukemia, and within thirteen days of the withdrawal of the benzol died with a white count of 456,000.

I wish to acknowledge the kindness of Dr. Henry A. Cooke in permitting the publication of this case record.

CLOSURE OF PYLORUS. CASE REPORT WITH SUGGESTION AS TO TECHNIC

Richard A. Barr, M.D., Nashville, Tenn.

History.—Miss G., white, aged 28, was admitted Nov. 30, 1914.

Family history unimportant. Patient had typhoid fever seven and one-half years previous to admission. Nothing else of interest in previous personal history.

Patient had stomach trouble ever since the attack of typhoid fever. This began with sour stomach and gas formation. Later she began having colic. The pain was epigastric and usually came on about 4 p. m. She would have these attacks of pain every day for a few days or even a few weeks, and then she would have no more for a varying length of time. At the time of this report she had had no attack for eight months. She had until two weeks prior to admission a burning spot in her back at the angle of the right scapula. This had been present for two years, but disappeared at the time mentioned and a dull ache began in the same place with a tendency to radiate around her chest to the ninth or tenth costal cartilage. She had never vomited and had only had nausea two or three times in the seven years. No jaundice, no constipation. Her attacks were worse in winter. There were times when eating crackers relieved the pain, but no period during which pain always came with an empty stomach. Her mornings were always free of discomfort. There was no period when pain followed the taking of food.

Three years and again two years prior to admission she had an attack diagnosed as peritonitis, which began with epigastric pain, and each attack kept her in bed for some weeks.

Physical Examination.—Physical examination was almost negative, except that the patient was thin. She was not emaciated and her skin was clear.

Blood: Hemoglobin 85 per cent. W. B. C. 11,500. R. B. C. 4,960,000.

Urine normal.

Stomach contents after ordinary test meal showed reduced acidity, but free hydrochloric and free lactic acid.

Diagnosis.—Chronic calculous cholecystitis with probable ulcer of duodenum.

Operation.—Operation disclosed plainly marked chronic appendicitis, indurated ulcer duodenum and apparently normal gall-bladder.

Appendectomy and posterior no-loop gastrojejunostomy were done, and then the pylorus was occluded by a variation of the Biondi method.

The necessity of occluding the pylorus in parapyloric ulcers without stenosis is now well established and the difficulty of accomplishing this occlusion, except by division and closure of the two ends, is equally well known. Timidity often causes us to try some less difficult procedure in hope of securing a good result, but we should only be deterred from making a complete and permanent occlusion by the special features of the individual case. In this case I mobilized the pylorus by ligature and division of the omentum. While I was doing this I decided to try a little technical procedure that I have several times thought of as being applicable in these cases.

I made a vertical incision through the peritoneal and muscular coats of the duodenum between the ulcer and the pyloric vein, so called. This wound I stripped back from the underlying mucous coat, and then dissected loose posteriorly the exposed cylinder of mucous membrane, which was easily cleared for about an inch. The mucous membrane was then doubly ligated near the center, with just space enough between the two ligatures to allow for cutting through with knife or scissors. The mucous membrane was divided between the ligatures and a purse-string of catgut run around the base of each stump in the angle where it joined the other coats of the intestine. This suture was placed rather in the muscular coat than in the mucous membrane itself. The stumps were then umbilicated and the purse-strings tightened and tied, just as is done in disposing of the stump of the appendix. The serous-muscular wound was closed with two rows of sutures, the peritoneal coat being turned in against the muscle of the posterior wall of the duodenum.

While handling the stumps one of the ligatures slipped off. The mucous membrane was seized with forceps and inverted without further effort at ligation. I am rather inclined to think that this would be the preferable routine method, except for possible hemorrhage from the cut edge of the mucous membrane, and this could certainly be controlled by proper care in placing the purse-string sutures.

I am sure that this idea is a good one and simplifies closure of the pylorus very considerably. It can be carried out without dividing the omentum, as there is no necessity for mobilizing the pylorus. It produces such a long gap, free of mucous membrane, that the continuity of the lumen of the bowel is not likely ever to be reestablished.

A longitudinal incision may be used in the serous-muscular coat instead of the vertical incision which I employed, and would have some advantages, but would cause more hemorrhage.

Ligation of the exposed cylinder of mucous membrane at both ends with removal of intervening section, followed by careful closure with inversion of the serous-muscular structures so as to obliterate the space left vacant, could be more easily done, and would probably be satisfactory though not so pleasing technically.

The patient made an uneventful recovery.

POISONING BY MERCURIC CHLORID PRESENTING UNUSUAL FEATURES

Horatio C. Wood, Jr., M.D., Philadelphia

The following case seems worthy of record because of the size of the dose of mercuric chlorid, the delay in onset of symptoms, and the prolonged suppression of urine.

J. M., aged 43, a man of splendid physique, walked into the accident ward of the Medico-Chirurgical Hospital and stated that he had taken mercuric chlorid tablets (presumably 7½ grains each) by mistake. According to his statement about an hour and a half previously he had taken five tablets but had felt no evil effects until an hour later, when he began to have some nausea and had vomited on his way to the hospital. He was at once given milk and eggs, the stomach washed out and apomorphin injected hypodermically. He was then put to bed, milk and eggs continued, and enteroclysis employed. As there did not appear to be any absorption of the water from the colon the enteroclysis was discontinued after a few hours and hypodermoclysis substituted. The treatment consisted in the administration of demulcents, 4 ounces of milk every two hours, 4 ounces of water by mouth every two hours, hypodermoclysis ranging from a pint to a quart in twenty-four hours, dry cupping over the loins, hot packs twice a day, and toward the end stimulants and anodynes as indicated.

On the second day the nausea and vomiting disappeared (I believe it was as much due to the apomorphin which had been given, as to the poison) and did not become manifest again until the seventh day. During these five days the patient made no complaint of pain and did not seem in any way to feel ill. The temperature ranged between 99 and 101 F. from his admission till the eighth day, when it dropped slightly below normal and from then ranged between 97 and 98 until death.

On the sixth day he complained of some pain in swallowing and his stomach rejected some of the water which he drank. On the seventh the pain in swallowing was more marked, the pharynx was found intensely congested and there were one or two small ulcers on the mucous membrane of the mouth. The ulcerations extended in breadth and depth, and on the tenth day a large part of the pharynx was necrotic. On the eleventh day some dulness, with bubbling râles, was noted at the base of the left chest. Despite stimulation the quantity of fluid in the lungs increased and he died of pulmonary edema on the twelfth day.

The most interesting feature in the case, aside from the slowness of the onset, was the almost complete suppression of urine for a period of about a week. The accompanying table shows the daily quantity of urine.

TABLE SHOWING DAILY QUANTITY OF URINE

Day	Quantity, Ounces	Specific Gravity	Amount of Albumin
1	1½	1.020	Large
2	⅛	?	Large
3	none		
4	none		Moderate
5	½	?	
6	⅝	1.012	Small
7	1	1.014	Small
8	4		
9	9	1.014	Small
10	11		
11	14	1.010	Trace

In a period of 120 hours, therefore, he had secreted less than 2 ounces of urine, despite the fact that he was drinking nearly 2 quarts of liquids and receiving daily nearly another quart hypodermically. There was, however, no evidence of any dropsical accumulation either in the extremities or chest. Some was lost through the bowels although the purging was by no means violent. From the sixth day, the quantity of urine increased daily—despite the fact that the amount of fluid ingested was less because of the difficulty in swallowing which developed about this time—until the day before his death, when he passed 16 ounces.

Holland (Peterson and Haines, Toxicology, 1914, ii, 391) says that after the swallowing of corrosive sublimate "The onset is never delayed half an hour," and I have been unable to find any case in the literature in which symptoms have not appeared promptly. Although we have no definite knowledge in this case of the exact time intervening between the taking of the poison and the onset of symptoms, there was no apparent reason to doubt the statement of the patient. The above quoted remark as to the onset of symptoms in mercuric chlorid poisoning is at least open to question.

It is of interest to note, also, the entire absence of any symptoms suggestive of uremia, either headache, high blood-pressure, urinous odor to the breath or disturbed intellection, despite the fact that the kidneys had practically entirely ceased functioning for nearly a week. Dobsenz (New York Med. Jour., July 26, 1913) reports a case of mercuric chlorid poisoning in which only 10 drops of urine were passed in five days, the patient eventually recovering.

Health and Safety in Metallurgical Plants.—In the metallurgy of iron and steel alone there are more than 150,000 men employed; 30,000 to 35,000 persons are injured and a considerable number are killed each year. In all the branches of the mining industry that are conducted above ground there are 1,300,000 employees, and not less than 100,000 are injured and a considerable number killed each year. In addition, the health conditions in many of the metallurgical plants are bad and the health of a larger number of persons is permanently impaired by the injurious conditions to which they are exposed.—Report of Director, Bureau of Mines, 1914.

space 7 cm. to the left of the midsternal line. The left border of the heart is 9 cm. to the left, and the right border 4.5 cm. to the right of the midsternal line. There is a loud, blowing systolic murmur at the apex. The pulse is rapid, of low tension and markedly irregular. A firm mass, evidently the enlarged spleen, occupies the whole left side of the abdomen, coming to the right of the midline just above the umbilicus and extending into the pelvis. The hilic notch can be felt at the umbilicus. The splenic tumor is decidedly tender on palpation. Both legs are slightly edematous to the knee; the knee-kicks are normal. There is no general glandular enlargement.

The blood examination on the day after admission showed: Red blood cells 2,610,000 (corrected for the white count); white blood cells 270,000; hemoglobin 60 per cent.

Differential count—Wright's stain—250 cells:

	No.	Per Cent.
Polymorphonuclear neutrophils	55	22
Polymorphonuclear basophils	0	....
Polymorphonuclear eosinophils	3	1.2
Small mononuclears	3	1.2
Large mononuclears	1	0.4
Neutrophilic myelocytes	183	73.2
Basophilic myelocytes	2	0.8
Eosinophilic myelocytes	3	1.2

The predominating white cells were myelocytes, ranging in size from 3.5 to 16.8 microns, with clear rounded or indented nuclei, and a finely granular protoplasm. No nucleated reds were found on this first examination.

Treatment and Results.—The patient had nearly expired as a result of the journey to the hospital, and her grave condition made it impossible to move her to the Roentgen-ray room for treatment. As no portable Roentgen apparatus was available, it was decided to try the benzol treatment. As soon as her condition had been somewhat improved by digitalis and rest, the administration of benzol (benzene, C_6H_6) was begun, and at the same time Fowler's solution was given in the usual way. The benzol, mixed with equal parts of olive oil, was administered in 10-minim capsules after meals, and was well tolerated with only occasional complaint of slight heart-burn. The initial dose corresponded to 15 minims of the benzol daily, and this was later increased to 45 minims daily.

The accompanying curve shows the course of the red and white counts from the time of the patient's admission. Up to the time when the benzol was begun there had been a drop in the white cell-count, possibly because of the arsenic, which was started before the benzol. Shortly after the administration of the benzol was begun, there occurred the usual initial rise in the white cell-count; then following this came a rapid and steady reduction in the leukocytosis. Hand in hand with this reduction came a slight increase in the red cell-count, while the patient's general condition improved greatly. By the end of a month she was sitting up in a chair, no longer dyspneic, and was rapidly recovering her appetite. The spleen was entirely to the left of the midline, with its lower edge at the iliac crest, and had become hard and no longer painful on palpation.

The differential count, July 3, was as follows:

	No.	Per Cent.
Polymorphonuclear neutrophils	84	42
Polymorphonuclear basophils	0	....
Polymorphonuclear eosinophils	0	....
Small mononuclears	2	1
Large mononuclears	20	10
Myelocytes	60	30
Transitionals	25	12.5
Nucleated red cells	4	2
Normoblasts	3	1.5
Unclassified	2	1

It was noted that the nuclei of the myelocytes were becoming more and more granular, and that the distinction between myelocytes and transitionals was increasingly hard to draw. Myelocytes of the type found in the first smear, with clear nuclei, were no longer to be seen. A few polychromatophilic and stippled red cells were found in this preparation, perhaps indications of the toxic effect of the benzol or of the arsenic.

For three weeks this improvement continued, and the patient even asked to be moved into the ward. Then, July 24, her temperature abruptly rose, and on the 27th she complained of pain in the left side. An area of extreme tenderness was discovered on the enlarged spleen, probably corresponding to a fresh infarct. The red cell-count had already fallen a little, and the white cell-count had risen. From this time her failure was rapid. July 30 the red count had fallen to 2,000,000 and the benzol was discontinued. Recourse was had to the Roentgen ray, but the patient developed the signs of an acute leukemia, and within thirteen days of the withdrawal of the benzol died with a white count of 456,000.

I wish to acknowledge the kindness of Dr. Henry A. Cooke in permitting the publication of this case record.

CLOSURE OF PYLORUS. CASE REPORT WITH SUGGESTION AS TO TECHNIC

Richard A. Barr, M.D., Nashville, Tenn.

History.—Miss G., white, aged 28, was admitted Nov. 30, 1914.

Family history unimportant. Patient had typhoid fever seven and one-half years previous to admission. Nothing else of interest in previous personal history.

Patient had stomach trouble ever since the attack of typhoid fever. This began with sour stomach and gas formation. Later she began having colic. The pain was epigastric and usually came on about 4 p. m. She would have these attacks of pain every day for a few days or even a few weeks, and then she would have no more for a varying length of time. At the time of this report she had had no attack for eight months. She had until two weeks prior to admission a burning spot in her back at the angle of the right scapula. This had been present for two years, but disappeared at the time mentioned and a dull ache began in the same place with a tendency to radiate around her chest to the ninth or tenth costal cartilage. She had never vomited and had only had nausea two or three times in the seven years. No jaundice, no constipation. Her attacks were worse in winter. There were times when eating crackers relieved the pain, but no period during which pain always came with an empty stomach. Her mornings were always free of discomfort. There was no period when pain followed the taking of food.

Three years and again two years prior to admission she had an attack diagnosed as peritonitis, which began with epigastric pain, and each attack kept her in bed for some weeks.

Physical Examination.—Physical examination was almost negative, except that the patient was thin. She was not emaciated and her skin was clear.

Blood: Hemoglobin 85 per cent. W. B. C. 11,500. R. B. C. 4,960,000.

Urine normal.

Stomach contents after ordinary test meal showed reduced acidity, but free hydrochloric and free lactic acid.

Diagnosis.—Chronic calculous cholecystitis with probable ulcer of duodenum.

Operation.—Operation disclosed plainly marked chronic appendicitis, indurated ulcer duodenum and apparently normal gall-bladder.

Appendectomy and posterior *no-loop* gastrojejunostomy were done, and then the pylorus was occluded by a variation of the Biondi method.

The necessity of occluding the pylorus in parapyloric ulcers without stenosis is now well established and the difficulty of accomplishing this occlusion, except by division and closure of the two ends, is equally well known. Timidity often causes us to try some less difficult procedure in hope of securing a good result, but we should only be deterred from making a complete and permanent occlusion by the special features of the individual case. In this case I mobilized the pylorus by ligature and division of the omentum. While I was doing this I decided to try a little technical procedure that I have several times thought of as being applicable in these cases.

ings, and the Cheyne-Stokes respiration disappears with the improvement in the circulation.

Small doses of morphin cause dilatation of the cutaneous vessels through the action on the vasomotor centers, increasing the actions of diaphoretic drugs which may be administered with it. Dilatation of the cutaneous vessels from any cause may cause erythema, and this sometimes follows the use of morphin or opium. While small doses cause this cutaneous dilatation, large doses have the opposite effect, the skin appearing pale because of the constriction of the peripheral vessels and dilatation of the splanchnic, due to vasomotor depression.

Morphin stimulates the centers in the medulla which are concerned with vomiting with varying degrees of intensity. Emesis may result even with moderate doses, or where the narcotic action is delayed after large doses in man. Vomiting cannot be induced during deep narcosis; hence this symptom is commonly absent in the late stages of morphin poisoning, while nausea, at least, is a more common symptom with moderate amounts. This emetic action of morphin is of some importance in connection with its use in strychnin poisoning, in which morphin is sometimes recommended.

The convulsant action of morphin is not usually seen in man because he succumbs to the narcotic action before the effect on the cord can be developed, but children occasionally show hyperexcitability, or even convulsions, after poisonous doses of opium. The convulsant action of codein is more pronounced than is that of morphin relatively to the narcotic effect. Toxic doses of opium probably contain enough narcotin to add materially to the convulsant action of the morphin present.

Therapeutic doses of morphin have little direct action on the heart except that they may depress the accelerator mechanism, permitting the vagus to exercise increased control over the heart-rate; the action is commonly utilized in therapeutics. The slowing which follows morphin is not always necessarily attributable to this direct action, for it may follow the relief of pain and anxiety, and the resulting rest and sleep.

The nauseant action of morphin is accompanied by some increase in the secretion of the bronchial glands, which is probably due in part to the excretion of the drug by them.

The pupils are not acted on by morphin directly, the miosis which is seen in morphin poisoning being due to the central action; it appears to be analogous to the miosis which occurs during sleep. This is worthy of attention because it is sometimes stated that the degree of antagonism between morphin and scopolamin can be estimated by changes in the size of the pupil. The actions are so different that little importance should be attached to the state of the pupils when morphin and scopolamin are used together.

It is very well known that morphin and opium lessen or abolish peristalsis and relieve pain in the gastro-intestinal tract. In this we have an example of the local analgesic action of morphin, but this is an exception to the rule and it is not seen elsewhere. Even here morphin does not relieve all pain by its local action. It abolishes sensory impulses from the mucous surface of the stomach, but not from the serous.

The behavior of the movements of the stomach after morphin depends on the dose and mode of administration, the gastric movements being increased by small doses, and the pylorus caused to contract firmly by somewhat larger ones, administered in such a way that they enter the circulation with a minimum of local action, as with subcutaneous injection, the effect being due to vagus stimulation.

Many investigators have endeavored to explain the direct and indirect influence of morphin on the gastrointestinal tract, but there is still much to be learned on the subject.

Morphin does not interfere directly with the secretion of urine, but in larger doses it causes the sphincter of the bladder to contract, preventing urination; hence it is often necessary to empty the bladder by means of a catheter during morphin poisoning.

Morphin is absorbed readily from the gastro-intestinal tract, and more rapidly after subcutaneous injection. Opium is used in the form of a pill when it is desired to retard absorption in order that the local action in the stomach and intestine may be prolonged, the colloidal matter delaying the absorption of the alkaloid.

Various explanations have been offered for the alleged greater action of opium than of an amount of morphin equal to that which it contains, but there is no satisfactory evidence that opium has any advantages over morphin except those just mentioned, which insure its increased local action.

Morphin is fixed in the liver of some animals in considerable amounts, and a small proportion may pass into the urine, though testimony on this subject is conflicting; the kidneys are probably negligible as excretory organs when one is seeking to hasten elimination during morphin poisoning.

It is of the first importance that morphin is excreted into the stomach after it has entered the circulation, but it is probable that this excretion is not very active after the first hour following the absorption of the drug into the circulation. It is sometimes stated that the excretion into this organ goes on for many hours, but it is probable that in such cases absorption has been prolonged.

It is surprising that we know so little about the rate of elimination of morphin by previously healthy man in view of its obvious importance in medicolegal cases. Since cumulation does not occur when morphin is taken several times daily by habitués, we must suppose that they, at least, are capable of destroying or excreting the drug fairly rapidly.

Morphin is not dangerous to the infant in the uterus, since it does not breathe through its lungs, but it is dangerous to administer it to the mother at such a time that it will be in the fetal circulation at the time of birth, as it depresses the respiratory center and may cause death. It is excreted in the milk of the nursing mother, and may give rise to poisoning of the infant in that way.

The odoriferous principle of opium is excreted in the urine and may afford a clue in cases of suspected poisoning.

TOXICOLOGY

Few drugs have assumed greater toxicologic importance than opium and morphin, as the various tables of death by poisoning attest.

Habitués become careless and in many instances have taken overdoses with fatal effect. Morphin has been dispensed by error for quinin in many instances.

The administration of soothing-sirups to infants has been a prolific source of fatal poisoning. Morphin is a favorite method of suicide because of the painless death which it causes, but it is not so frequently used for the murder of adults as some of the more rapidly acting poisons, because the symptoms are apt to attract attention and treatment is so commonly successful. It is more commonly used for the murder of infants, however, and unfortunately, statistics on this score are probably of little value.

The importance of determining from what part of the cadaver any morphin was recovered may be illustrated by the following: A woman was found dead in a bath-tub of water. The person accused of her murder maintained that the dead woman had taken morphin as a preliminary to self-destruction by drowning. Morphin was found in the gastro-intestinal tract, but the chemist had not examined the duodenum and the ileum separately, and could give no information as to the source of that part of the recovered morphin. Fortunately, he recovered a notable amount from the gall-bladder, showing conclusively that it had been absorbed; it seemed so improbable that the woman could have carried out the purpose of drowning herself after the morphin she had taken had been absorbed into the circulation, that the accused was led to confess.

The fatal dose of morphin varies so widely with the circumstances attending its administration that it is impossible to convey an accurate idea of the fatal dose in a single sentence.

It is often stated that infants are extraordinarily susceptible to all opiates, but several pediatrists have recently stated that very small children frequently take opium and morphin very well. It is not advisable for the general practitioner to disregard the almost universal testimony on this subject until we know more about the conditions under which opium and morphin may be given to infants with safety.

Reference to the pages of The Journal during the past few years will disclose the fact that many deaths have followed the administration of soothing-sirups to infants.

Morphin is oxidized readily into the harmless oxydimorphin. This change may even take place in old pills of morphin which contain acacia as an excipient; it may occur in solutions which are kept for some time; and it is induced almost instantly by potassium permanganate, which is therefore of great value in destroying any morphin with which it may be brought into contact in the stomach. This change also probably takes place slowly in the body when morphin has been taken.

The treatment of morphin poisoning demands the washing of the stomach at frequent intervals as long as the washings give any evidence of containing morphin; the bowels should be emptied by vigorous means in order to remove any of the poison that may have been excreted into the intestine or which reaches it from the stomach. The patient should be kept awake if this is possible without resorting to violent means.

Efforts should be directed toward sustaining the respiratory center; this may be so depressed that the respiration is insufficient long before death, and one should not wait for actual paralysis before beginning artificial respiration. Caffein is a valuable stimulant both for the respiratory centers and for the cerebrum. The free use of atropin is sometimes advised, but this is evidently a source of danger. It would be better not to use more than one, or possibly two, therapeutic doses of atropin, and if stimulation still be needed resort should be had to caffein. Since the tonic contraction of the pylorus may prevent the passage of fluid into the intestine, antidotal drugs should not be administered by mouth, except such as are added to the water for washing the stomach.

The treatment of chronic morphinism cannot be detailed here, but it may be stated that other narcotics, such as belladonna, are usually substituted for the morphin until the painful stage of withdrawal has been passed. Relapses are common, but the treatment can be taken repeatedly, and an ultimate complete cure may be effected.

Morphin is decomposed at a temperature slightly above that at which it distils, and this is very near the temperature which obtains in the opium pipe. Hence the question has arisen whether the opium-smoker actually absorbs morphin or not; it seems probable that some morphin passes over with the smoke and, being inhaled, is absorbed.

(To be continued)

Therapeutics

PREVENTION IS GREATER THAN CURE

(Continued from page 437)

XVIII

Mumps

This is a highly infectious disease, with a long period of incubation, from two to three weeks. There is more or less of it always present in most cities, and there are likely to be epidemics of it in certain seasons of the year, more particularly, perhaps, in the spring and fall. Children and youth, especially boys and young men, are the most susceptible to it. Infants and adults are not so likely to have it. Possibly adults are less likely to have it because they have been rendered immune by unrecognized mild attacks in childhood.

While the typical localization of this infection is in one or both parotid glands, the submaxillary glands may be coincidently involved, or may be the only glands involved. As simple and harmless as this disease generally is, it may cause very high temperature, sudden cardiac failure, and frequently in young boys and male adults a complication, or metastasis, of orchitis, which is always serious. In girls the mammary glands or the ovaries may show metastatic inflammation.

The complication of inflammation of the sexual glands is frequently attributed to the patient's taking cold. While chilling may be a factor in causing such complications, young men especially who remain in the house or even in bed may develop this complication of orchitis, and the danger of such a complication is greater after puberty than before. The peculiar interrelation of the parotid gland and the testicles or ovaries is biologically interesting, but has not been explained. Other complications are diarrheal attacks with bowel cramps, and in rare instances serious meningitis occurs. It is rare that more than one testicle is affected. This is exceedingly fortunate, as this testicle may be long hypertrophied and later atrophy and become permanently sexually insufficient. It is probable that the same history is true of an ovarian complication, and may be an undiagnosed cause of some forms of ovarian pain and dysmenorrhea.

The parotid glands in this affection seem to show no tendency to suppurate, but parotitis, whether the epidemic form or a complication of some other disease, may cause serious cardiac depression. Even with high temperature in epidemic parotitis the pulse will often be found abnormally slow, at least for the height of the temperature.

Any great amount of manipulation of the inflamed parotid gland in mumps should be condemned as tending to cause absorption into the circulation of depressant toxins or secretions. This caution is not unique, but is parallel with the danger from too much manipulation of a hypersecreting thyroid gland, causing absorption into the blood of cardiac depressants.

The prognosis when meningitis is present is serious. Deafness has been caused, and even an optic neuritis has been stated to occur. Sudden death occasionally occurs without any assignable cause, except a sudden upright position after a patient has been in bed. Albuminuria may be present with high temperature, and acute nephritis has occurred. Endocarditis is another rare complication.

The white blood count in this disease os more or less characteristic, there being a lymphocytosis, although the whole number of leukocytes may vary, early in the disease being below normal. Barach[1] states that there is a leukopenia due to a decrease in the polynuclear cells, both relatively and absolutely, all through the disease. On the other hand, Feiling[2] states that there is always a slight increase in the total number of leukocytes. Barach also states that the mononuclear cells are relatively and absolutely increased. As the blood returns to normal the eosinophils, which have been almost absent, return in their usual numbers. This blood count is very distinct from the leukocytosis that is apt to be present if the gland is infected secondarily and an abscess is liable to form, in which case there would be a polymorphleukocytosis.

Contagium from this disease is probably pretty direct, that is, by close contact; but the contagium may be transmitted from the very early stages of the disease to perhaps some time after the disease is in abeyance. It has not been shown that animals are affected by the disease.

A patient with the disease should generally be isolated, and the attack will often be milder if the patient remains in bed. Although the disease can be serious, it is generally so mild in children that it is sometimes a question whether other children of the same family should not be allowed to contract it, for the reason that one attack generally confers immunity for all time, and the disease is much more serious in adults, especially in young men, than in children. Of course, an infected child, even though very mildly sick, is immediately sent home from school. On the other hand, doubtless not a few children with very mild cases are unwittingly allowed to remain at school.

The disease generally begins in one parotid gland and quickly goes to the other, although not infrequently only one gland is affected. Occasionally the submaxillary or sublingual glands are the only ones attacked, and these cases may spread the mumps before the diagnosis is made. The inflammation in the first gland affected generally reaches its height in about four days, and the gland generally has returned to its normal size in from six to eight days. If the other gland is not quickly inflamed, but becomes inflamed later, the duration of the disease will be prolonged. The fever is generally mild, but it may be very high, and in such instances there is always likely to be more or less cardiac depression.

The same care of the child's surroundings in school should be given as in other contagious diseases to prevent the infection of others. The nurse or the mother should understand that infection is doubtless contained in the mucus and secretions of the mouth and throat; consequently infection will be given by close contact, as by kissing, by handkerchiefs, eating utensils, pencils, bedclothing, etc.

TREATMENT

The disease is so mild that it may not require any special treatment. Pain in the infected glands is rarely severe, and is modified by dry warmth or simple absorbent-cotton applications, and by any oily application, the latter to relax the tension of the skin over the swollen gland. For this purpose olive oil may be used, or petrolatum, or an ointment may be made with 10 per cent. methyl salicylate in petrolatum. It is inadvisable to use ice or cold applications to the parotid glands in mumps.

The diet should be mild, the bowels kept free, and in simple cases medicinal treatment is not needed. If the fever is very high, one or two doses of antipyrin or acetanilid may be given, with the knowledge that cardiac depression readily occurs in this disease. Hot drinks, as hot lemonade or hot tea, with a little alcohol in some form for its physiologic action in dilating the peripheral blood-vessels and promoting perspiration, is a satisfactory method of reducing the temperature. Tepid sponging may be of benefit, and hot sponging should be given the patient daily if he is too ill for a hot bath.

If a testicle is affected, the lesion is generally an orchitis, or it may be an epididymitis. Ice and cold applications are inadvisable in this metastasis from mumps. Warm, moist applications often relieve pain; but if the testicles are kept elevated and surrounded by absorbent cotton, and if perhaps some oil or fat, such as petrolatum, is applied, the inflammation will probably go away as rapidly as by any other treatment. Strapping is inadvisable in this complication. Any massage, or the rubbing in of any ointment or other preparation in this kind of orchitis, or to the parotid glands, is inadvisable in mumps. Ichthyol applications in from 10 to 20 per cent. strength, either in petrolatum or in olive oil, or glycerin and water, have been largely used locally in this inflammation. Lead and opium wash has been frequently used; but the less this inflamed gland is manipulated, the better.

If the mammary gland becomes metastatically inflamed, the treatment is about the same as that for the parotid. If it is decided that the ovary is inflamed, but little can be done, except absolute rest and the administration of a sedative if there is pain. If there is much pain from any of these inflamed glands, morphin or codein may be advisable if it seems unwise to give a coal-tar analgesic.

PLASMA REMOVAL—PLASMAPHAERESIS

Reference to text-books will make evident that venesection is by no means an entirely discarded practice. Bloodletting as a professional procedure is known to have been carried out long prior to the era of Hippocrates, who speaks of it as having been frequently performed. Hippocrates and Galen had advised copious bleeding largely from the arm on the affected side in pleurisy and pneumonia. That practice was gradually abandoned as Greek traditions were lost sight of, and finally the Arabs substituted something entirely different, the pricking of a vein in the foot in order to let blood flow drop by drop. The ancient Greek practice was later revived by a Parisian physician named Brissot; but it was "the modern Galen," Jean Fernel, who was especially responsible for the revival of bleeding during the first half of the sixteenth century. Something of the subsequent history of the time-honored but often debatable venesection of later medical practice is known to most physicians. The admitted harmful consequences of a serious procedure of this sort finally led to its almost universal abandonment a generation or two ago. There are now signs of a revival of interest in the discreet use of bloodletting.

To remove more than one-third of the circulating blood is always fraught with danger. Even this quantity cannot be withdrawn with safety under various conditions. The drawbacks of venesection are dependent on both the immediate and the subsequent effects of the anemia which it produces. The danger of seriously reducing the oxygen-carrying capacity of the blood by the removal of a large number of erythrocytes in the blood withdrawn is admittedly a serious one, particularly in certain cases such as aneurysm, cardiac decompensation with low blood-count, and in various toxemias in which a venesection might be indicated. The loss of great numbers of blood-cells entails a prolonged effort on the part of the hemopoietic organs for regeneration.

The restoration of the liquid medium of the blood either from stores of reserve materials or by synthesis from the nutrient products absorbed from the alimentary tract seems to be a far easier physiologic performance than the regeneration of the cells of the blood. If, therefore, the withdrawal of fluid from the circulation could be carried out without the loss of these corpuscular elements of the blood, a decided advantage might be gained. At the Johns Hopkins Medical School, Abel, Rowntree and Turner[1] have attempted to devise a process by which this end may be attained. The underlying idea has been to undertake repeated removal of considerable quantities of blood, separating the corpuscles by vigorous centrifugalization, replacing the plasma by Locke's fluid, and reinjecting this together with the sedimented blood-cells. The preliminary experiments on animals have shown that it is possible to withdraw without apparent injury quantities of blood-plasma that exceed several times the maximum amount of blood that can be safely drawn by the usual method of venesection, provided the corpuscular elements of the blood, suspended in a suitable medium, be returned to the vascular system after each bleeding. The procedure has been termed plasmaphaeresis (from ἀφαίρεσις, a withdrawal).

It cannot be emphasized too strongly that this interesting work is as yet entirely in an experimental stage. Whether or not it shall become applicable to human conditions remains to be learned. Meanwhile it may not be vain to speculate on the prospects involved. The possibility of increasing or decreasing (if only temporarily) the volume of fluid in the vascular apparatus, or of removing an excess of deleterious substances with the plasma, suggests a way for the use of a method of this kind in cases in which bleeding has hitherto been contra-indicated because of the attendant anemia; it would appear doubly advantageous for the patient in most of those instances in which venesection is now being done with good result. What has actually been accomplished in the preliminary trials on dogs shows that it is quite possible to withdraw by repeated bleedings, in a single day, a volume of blood more than twice that ordinarily contained in the body with no apparent injury to the subject if only the corpuscles are returned after each bleeding.

To put the method to a severe test, plasmaphaeresis was carried out on nephrectomized animals. Obviously, the removal of both kidneys, with the consequent suppression of renal excretory function, is a severe test for a therapeutic procedure. Nevertheless there was evidence of a relief of the symptoms consequent on bilateral nephrectomy by the withdrawal of plasma with its content of accumulated waste products. The improvement in the clinical condition of the animals thus treated was marked, and they lived longer than the untreated control subjects.

---

[1] Abel, J. J.; Rowntree, L. G., and Turner, B. B.: Plasma Removal with Return of Corpuscles, Jour. Pharmacol. and Exper. Therap., 1914, v, 625.

In the ordinary cases of plasma removal with return of the corpuscles there has been no evidence that the withdrawal of these considerable quantities of blood has a harmful action which is other than temporary. The urine has never become abnormal. It is, of course, not impossible that the resistance of the red corpuscles may be diminished by the change of medium to which they are subjected when the plasmaphaeresis is carried out on an extensive scale. Regeneration of plasma proteins is doubtless accomplished very promptly owing to a large "factor of safety" in this function. Fibrinogen is known to be regenerated very rapidly.[2]

One naturally reverts to the possibilities of application of methods like the one here outlined in human therapy. The Baltimore investigators remind us that centrifugated mammalian blood-corpuscles are said to retain their stability when kept on ice for four or five days and may then be reinjected and function normally.[3] In view of this fact a supply of human corpuscles *might possibly* be kept *in this manner* in operating-rooms for rapid injection in emergencies that would otherwise prove fatal.

In still another field, further applications suggest themselves. In the preparation of antitoxic serums, great economy might be effected in the use of horses if the method were found to be applicable, since, instead of bleeding a few liters every two weeks, many more might be taken in the same or even shorter intervals if the animal did not have to regenerate any morphologic elements.

RELATION OF IODIN TO THE THYROID AND OTHER TISSUES

Soon after the discovery of iodin in ever-present though small quantities in the thyroid gland, a search for the element was made in many other organs and tissues of the body. One investigator, Justus,[4] in particular, heralded the widespread distribution of iodin in the animal organism. The quantities reported were extremely small, being expressed in terms of hundredths of a milligram per hundred grams of tissue. This represents a degree of dilution at which methods of chemical analysis must be exceptionally exact and the technic unusually careful to lend any value to data of the magnitude mentioned. Nevertheless physiologists have become committed to the possibilities represented by minute amounts of active substances and the figures recorded by Justus have readily found their way into the literature.

It would not be surprising, after all, if an element as widely distributed in nature as is iodin, even though the absolute quantities are small, were to find its way into various parts of the living organism. When iodids are taken into the body they circulate widely and can be found in various places. The distribution may even be somewhat unlike in different parts of the system.[5] But ordinarily when the intake of iodid ceases, the element soon disappears from the tissues with the exception of the thyroids. In these glandular structures it is retained not in a readily diffusible form or in some loose chemical affinity, but rather in a unique organic combination that leaves no doubt of an active cellular process whereby a new iodin-bearing compound in the tissue results. The iodin becomes an integral part of some of the thyroid protein. This is something quite different from a mere deposition of the element such as occurs when iodids or other halogen compounds are being furnished freely to the individual.

These facts, including on the one hand the reputed widespread occurrence of iodin in the body, and on the other hand the apparently unique capacity of the thyroids to "fix" the element in a functional way, have raised the question as to the specificity of the latter phenomenon. Cannot iodin be "fixed" or organically bound by other cellular structures? Blum and Grützner,[6] who have devoted attention to the problem, conclude that the thyroids stand alone in this metabolic phenomenon among the tissues of the higher animals. Other organs may now and then exhibit the presence of iodin, but its occurrence there in contrast with the thyroids is irregular and uncertain; and it is found derived from the intake and in inorganic relations rather than in special organic combination. Even when iodids are administered freely the formation of iodized proteins has never been observed outside of the thyroid structures. These alone are entitled, in the light of our present knowledge, to claim a content of iodin as something physiologically characteristic. Iodin is therefore presumably not an essential component of every living cell.

THE CONDITIONS OF INDUSTRIAL ACCIDENTS

The enactment of laws in various states on workmen's compensation for injuries has aroused increased interest in the statistics and physical and psychic conditions of industrial accidents. The total number of these accidents is almost appalling. The lowest estimate places the fatal accidents to adult workers in the United States at 35,000 a year, with an additional 1,250,000 non-fatal accidents. The Massachusetts Industrial Accident Board, on the other hand, placed the number of workers killed by accident yearly at 75,000, which apparently includes not only adults, but also workers of all ages, while the number of injured of the same classes was placed by this Massachusetts authority at 3,000,000 or over. An earthquake in a foreign country that kills half this number of persons and maims one-fiftieth of those injured in our United States industries is spoken of as catastrophic.

Among the interesting elements of these accident statistics is the fact that a greater proportion of accidents occurs on Monday than on any other day of the week. Accidents are said to be due often to fatigue. As, after the day of rest on Sunday, workmen should be less fatigued than on other days, some other factor must be sought to explain this feature of the statistics. It has been suggested that the "blue Monday" accidents are really due to the fact that workmen take more spirituous liquor on Sunday, and thus become unnerved and more liable to accidents during the following twenty-four hours. There is, perhaps, something in this contention, though it has been disputed. In the Massachusetts Industrial Accident Board Reports, in which the official figures are given, there is scarcely more than one-twentieth more accidents on Monday than on Tuesday, while Tuesday is not much above the average in the number of accidents reported for other days. Saturday, of course, shows a noteworthy reduction, because of the half holiday in some trades.

By far the larger number of accidents occur at about 10 a. m. and 3 p. m. This fact is confirmed by the reports of two state boards, Washington and Massachusetts, which have secured rather careful records. As they represent the extremes of the country, the conclusions from their statistics would seem to be incontrovertible, though the fact is not what might naturally be expected. The State of Washington Industrial Commission[1] says, "These results seem to disprove the theory that fatigue is the prominent cause of accidents, because accidents are here shown to happen at the hours when the workmen are least fatigued." On the fatigue theory it might naturally be expected that most accidents would happen after 11 a. m. and 5 p. m. The actual hour of the high point of the curve of accidents shows how important are the facts and how necessary of proof the theories.

After much discussion, the tendency to speed up employment has been incriminated, as the predisposing condition for the occurrence of accidents. This desire comes over the workman when he is not yet fatigued, but has been employed for several hours. He starts the morning's work "cold," and as he warms to his work, the danger of mischance because of haste becomes greater. Just when the speeding up reaches a climax in the morning hours, most accidents happen. The same thing is true in the afternoon. Workmen feel sluggish after their lunch, but after an hour of work warm up again, and by about 3 o'clock they are doing their most rapid work, and are at the same time more subject to accident.

With regard to accidents among children, however, there is no hour of maximum. Accidents occur at all times, and they are comparatively much more frequent among children than adults. The United States Bureau of Labor reported that "there is clear evidence of great liability to accident on the part of children. Though employed in the less hazardous work, their rates steadily exceed those of the older co-workers, even when in that group are included the occupations of relatively high liability." This was said with regard to the Southern cotton mills, but the same thing is true of practically all industries in which children are employed.

The results of these accidents come to the physician. We are devoting much time to the prevention of disease, and we should be ready to give attention also to the prevention of injury. Virchow used to say that the ideal function of the physician, besides that of reliever of human ills, is to be the attorney of the poor for the prevention and relief of social ailments, and, above all, the prophylaxis of their physical consequences, whether in lowered health or in maiming injuries.

CULTIVATION OF LIVING TISSUES OUTSIDE THE BODY

The story of the cultivation of tissues outside of the living body has already lost much of its novelty. Though we can still easily count the time in terms of months rather than years, since the first demonstration of the development in vitro of isolated fragments made up of connective tissue cells, the fact has been established so conclusively and the technic developed so successfully that the cultivation of tissues in this way has already become a familiar practice in many laboratories. It is sometimes said that familiarity breeds contempt; but it may be wholesome at times to renew our acquaintance with the details of well-known scientific procedures and learn their present status. This is particularly desirable in the case of those persons who little realize the persistence and energy, the patience and forethought, which many of the permanent acquisitions of science demand on the part of investigators. We who share the results all too frequently fail to understand the laborious process by which success is attained. In this field the advice once given to an ambitious medical student may be reiterated: "Success is neither luck nor pull, but the longest, toughest job you ever tackled."

Not long ago Carrel[1] of the Rockefeller Institute for Medical Research called attention to the condition of a strain of connective tissue kept outside of the organism in a condition of permanent life. It was derived originally from a piece of heart extirpated from a chick embryo. The fragment pulsated for 104 days and gave rise to a large number of connective tissue cells which have since multiplied actively. The strain, after having undergone 358 passages, reached the twenty-ninth month of its life in vitro some time ago. It now appears that the proliferating power has in no wise diminished. During the third year of independent life of the connective tissue we are confronted with the remarkable fact that it shows greater activity than at the beginning of that period, and is no longer subject to the influence of time. Carrel remarks that if we exclude accidents, connective tissue cells, like colonies of infusoria, may proliferate indefinitely.

---

[1] Report of State of Washington Industrial Commission for 1912, p. 178.

[1] Carrel, Alexis: Present Condition of a Strain of Connective Tissue Twenty-Eight Months Old, Jour. Exper. Med., 1914, xx, 1; see also Jour. Exper. Med., 1912, xv, 516. Ebeling, A.: Ibid., 1913, xvii, 273. Carrel, Alexis: Ibid., 1913, xviii, 287.

In this connection it is interesting to note some recent results for human tissues reported from the same laboratory. It has been possible, for example, to keep human fetal tissue, derived from fresh cadavers, in a condition of independent life for several generations.[2] This has led to the attempt to cultivate human sarcomatous tissue in the same manner. The first essay in the direction of growing human malignant tumor in vitro was made in 1911 by Carrel and Burrows.[3] The tissues were kept in a condition of survival for a few days, but no real cultures were obtained. Losee and Ebeling[4] have now succeeded in keeping cultures of such tissue in a condition of active life in vitro for several generations. Their method may therefore prove of value in the study of the growth of human malignant tumor.

THE VIRULENCE OF THE ORGANISM GROWN FROM POLIOMYELITIC TISSUES

Work during the past one or two years in this country and abroad has indicated possible methods for the control of poliomyelitis based on the discovery of mild or abortive cases of the disease. Of still greater importance, perhaps, is the demonstration of the presence of the virus of the disease in healthy persons who have been in contact with cases of poliomyelitis. Previous reference has been made[5] to the great epidemiologic importance of "carriers" of the infection of poliomyelitis who may harbor the infective agent in their nasal mucosa, and yet have shown no symptoms of the disease. The successful cultivation of the causative organism, with the methods of cultivation devised by Noguchi, prompted the hope by students of the disease that we were on the eve of the announcement of the production of methods of active or passive immunization.

It has been established that the only sure method of immunization of monkeys against infection with poliomyelitis is by an attack of the disease, and that injections of emulsions made from poliomyelitic animals, unless followed by an attack of the disease, could not be relied on to immunize. Occasionally it happened, when great care was observed in the process, that an animal was found resistant, but that at times, just when immunity might have been inferred, the animal developed paralysis. From a recent paper by Flexner, Noguchi and Amoss,[6] it appears that somewhat the same experience is had with the organism when grown in cultures, and that successive injections of cultures devoid of virulence do not induce infection or immunity, which is evidenced by the absence of antibodies in the blood and failure to resist infection when active material was used for inoculation. In one series of experiments, it was found that the inoculation of cultures was ineffective at the first, or even second or third inoculation, but was effective at a later injection, although the same material failed to induce infection in a fresh monkey used as a control. The deduction was made that in the course of the successive inoculations, under certain conditions, the resistance of the monkeys was gradually lessened so that infection was finally accomplished.

It is possible that there may be another, or at least partial, explanation for the resistance at times, and a later developed susceptibility. Anderson and Goldberger,[7] in their studies of typhus fever, found a considerable variation in the infectivity for monkeys of different strains of typhus fever blood and, in addition, brought out the important fact that about 22 per cent. of monkeys failed to react to a first injection, and 3.5 per cent. to three or more successive injections of material proved to be infective at the time for other monkeys. As with poliomyelitis virus referred to above, they found that repeated inoculations of typhus virus, unless followed by a typhus reaction, conferred no appreciable resistance to infection. In any case, it is fairly evident, from the results so far reported, that attempts to produce immunity by the use of cultures of the organism of poliomyelitis have not given much promise.

The paper of Flexner, Noguchi and Amoss gives additional evidence of a most convincing kind in support of their contention that the organism grown by them is the specific etiologic factor in epidemic poliomyelitis. It is hoped that further work along the lines of the experiments reported will be continued, and that out of it may come results of value for use in immunization against this dreaded disease.

Current Comment

PRESENT STATUS OF THE VACCINE TREATMENT OF TYPHOID FEVER

The use of vaccines in the treatment of typhoid fever is still in the experimental stage. Numerous reports have been published on the subject in the last six years, but the results as shown by the death rate are not convincing. One difficulty is that the average mortality rate cannot be accurately determined because epidemics vary greatly in virulence. Some observers report a slightly lower death rate among patients treated with vaccines. Watters,[1] in an extensive review of 1,120 such cases, reports that the mortality is slightly lowered with vaccines, that the duration of fever averaged ten days less than in cases treated as usual, and that the percentage of relapse is diminished. In addition, the patients appeared brighter mentally, showed less depression and had lower temperature than ordinarily. All authors represented in this series agreed that the vaccines (bacilli killed by heat and injected subcutaneously) at least did not harm. It appears from the statistics that the dosage of the vaccines used has very little effect on the fever curve, leukocyte count or the mortality rate. As many deaths are reported with small doses as with larger ones. Some observers believe that early in the disease the treatment may prove beneficial in relieving the symptoms, whereas after the fourteenth day no such effect is obtained. On the other hand, striking results are announced by Ichikawa[2] from intravenous injection of sensitized bacteria. Living bacilli were treated with serum from typhoid convalescents, then washed, and finally suspended in salt solution with 0.3 per cent. phenol. In his cases he was able to produce a sudden drop in fever to normal, after a slight initial rise, and rapid retrogression of symptoms. He found that his typhoid vaccine was effective also in paratyphoid fever. The results reported by Ichikawa are so striking that further investigation is indicated. R. Kraus[3] also mentions the occurrence of crisis and rapid recovery after the intravenous injection of typhoid vaccines in typhoid fever. Ichikawa explains his results by saying that in typhoid fever only a small amount of antibodies is produced, so that not all the bacteria are killed. By the sudden injection of a large number of sensitized bacteria, the production of antibodies is greatly increased and all the bacteria are killed. In the ordinary subcutaneous injections, the introduction of the bacteria into the blood stream is retarded by local reactive processes, and consequently there is not produced the sudden stimulation necessary for the production of so large amounts of antibodies as might be expected. Recenly Gay and Claypole[4] have described a specific hyperleukocytosis on injection of typhoid bacilli in animals already immunized with this bacillus. These investigators also obtain a sharp specific leukocytosis with sensitized cultures in normal animals. Probably the explanation of the prompt effect described by Ichikawa in typhoid fever patients injected with sensitized vaccine is to be found in a specific hyperleukocytosis. Certainly this appears a much more likely explanation than the very complicated one advanced by Garbat.[5] The question of the occurrence of hyperleukocytosis in typhoid patients injected with typhoid vaccine will have to be determined, however, before any definite opinion can be formed as to the mechanism of the action of sensitized or other vaccine in typhoid fever.

THE HARRISON LAW AS APPLIED TO PHYSICIANS

An abstract of the Harrison bill and the regulations thereto appears in this issue, page 532. After three years' discussion, this bill has finally become a law, being signed Dec. 17, 1914, and becoming effective March 1, 1915. Its object is to limit the sale of habit-forming drugs to legitimate purposes by requiring a record of all transactions in such drugs. Any physician who dispenses or prescribes any drug preparations containing opium or coca leaves or any of their derivatives is required to register with the collector of internal revenue of his district and to pay an annual registration fee of one dollar. This is prorated for the period from March 1, 1915, to July 1, 1915, at 34 cents. Physicians dispensing their own drugs must use the blank prescribed by the commissioner of internal revenue in ordering their supplies, and must keep a record of all habit-forming drugs dispensed to patients. Physicians prescribing drugs must sign their full name and give their registration number with the name and address of the patient on each prescription. All persons having such drugs in their possession March 1, 1915, must make an inventory of such drugs showing exactly the amount on hand at that time. This inventory, which must be verified by affidavit, is kept by the individual and is not filed with the commissioner. One important point of controversy between the physician and the druggist is settled by the ruling of the commissioner of internal revenue. Only the original of prescriptions containing these drugs can be filled. The refilling of prescriptions is forbidden. Patients desiring an additional supply of such drugs must procure an original prescription from the physician. The law also requires a general registration of all physicians, dentists, druggists and veterinary surgeons, and only such persons will be allowed to dispense or prescribe these drugs. This law is a legislative experiment. Some time, many regulations and several amendments will probably be necessary before it can be reduced to smooth working order. In the meantime, physicians should at once take two precautions: They should make immediate application to the deputy commissioner of internal revenue of their district for registration, and they should make an inventory of all drugs and drug preparations in their possession containing opium or cocain, so that when the law goes into operation, March 1, each physician may have written evidence of the amount of these drugs in his possession at that time. Whether or not it will be possible to put so sweeping a measure into effective operation in so short a time remains to be seen; but physicians can give material assistance in the enforcement of the law, and can relieve themselves of any danger of embarrassment by taking these two steps at once.

HOSPITAL EFFICIENCY

In May, 1914, the Philadelphia County Medical Society appointed a committee[1] to consider "ways and means by which the efficiency of the hospitals in Philadelphia may be increased." This committee made an extensive study of the hospital situation in Philadelphia. The three reports of the committee embodying the results of this study, together with an introduction on "The Principles of Hospital Efficiency," by the secretary of the committee, are now issued in pamphlet form. One of the most important findings of the committee is that no standards as yet exist by which the efficiency of a hospital may be measured. The operating expense of one institution may be three dollars a day for each patient, and that of another, little over a dollar a day for each patient. Is the latter figure a credit or a disgrace? One dispensary physician may treat twice as many patients in an afternoon as his colleague working under the same conditions. Which one is accomplishing the most good? Standards of efficiency must be formulated and applied before such questions as these can be answered. Naturally, this lack of standards is reflected in chaotic conditions. For instance, the committee made a careful study of the record systems used in sixteen of the largest hospitals in Philadelphia. In eight of these, some systematic effort was being made to secure the completeness and accuracy of the records, the chief resident physician or the registrar finally checking the records. Four different systems of classification were being used in these eight hospitals. Only three of the sixteen hospitals were maintaining separate files for recording all operations performed in the hospital, grouping together all operations of like character, so that the number of all operations performed during a given period, with the results of each, could be quickly ascertained. The committee states that in 31 per cent. of the hospitals visited, the records were so kept as to be useless for scientific purposes. A number of recommendations are made for the improvement of record systems, the establishing of social service departments, the prevention of dispensary abuses, etc. In fact, the report contains many valuable suggestions for those who are interested in the improvement of hospitals, and deserves to be widely read.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ILLINOIS

Dinner to Dr. Steele.—Friends of Dr. Daniel A. K. Steele, dean of the Medical School of the University of Illinois, Chicago, gave a dinner in his honor, February 1, at the Hotel La Salle, at which about ninety were present. Dr. Charles S. Bacon presided as toastmaster.

Personal.—County Judge Scully has named the following advisory commission to assist in the hearing of lunacy cases in Cook County: Drs. Hugh T. Patrick, Peter Bassoe, and Harry L. Pollock, Chicago.——Dr. John B. Murphy, Chicago, was elected president of the Wisconsin Society of Chicago at the annual meeting, January 26, and Drs. Albert J. Ochsner and Edwin B. Tuteur, Chicago, were elected vice-presidents.

Tuberculosis Institute Meeting.—The ninth annual meeting of the Chicago Tuberculosis Institute was held January 28, and the following officers were elected: president, Dr. Theodore B. Sachs; vice-presidents, Dr. Robert H. Babcock and Mr. George W. Perkins; secretary, Mr. Sherman G. Kingsley, and treasurer, Mr. David R. Forgan. The institute passed a resolution opposing the proposed plan of incorporating the Municipal Tuberculosis Sanatorium in the consolidation bill, commending the efficient management of the board of directors of the sanatorium, and expressing its "emphatic opinion that the best interests of the tuberculosis problem in Chicago demands a continuance of the present administration arrangements of the Municipal Tuberculosis Sanatorium, and that the municipal tuberculosis sanatorium law be allowed to remain unchanged."

Foot and Mouth Disease Injunction Dissolved.—It is reported under date of February 2 that Judge Irwin of the Kane circuit court has dissolved the injunction prohibiting the slaughter of stock on account of the foot and mouth disease. At the annual convention of the Milk Producers' Association in Chicago, February 1, protest was made against the method of handling the disease by the federal and state officials, and particularly against the action of Governor Dunne in placing large dairy areas of the state under quarantine. It is said that from 3,000 to 4,000 cans of milk which daily come to Chicago are kept out by the action of the governor. The health commissioner, Dr. George B. Young, is reported to have asked Governor Dunne to rescind his action, the health commissioner promising to place at least fifteen inspectors on the work of inspection covering the prohibited area.

Chicago

Council Committee Approves Marriage Test Law.—The Chicago City Council Committee of Health on January 22, recommended the approval by the council and the enactment as a law of the bill providing that it shall be unlawful for any county clerk to issue a marriage license unless the applicants file a certificate, fifteen days before the issuance of the marriage license, that they are free from venereal disease.

Warning to Chicago Physicians.—A young man, possibly 25 years of age, giving various names and representing himself as a young medical graduate, has been calling on physicians and others, representing himself to be a Belgian refugee. He is very successful in gaining sympathy, and as a result has succeeded in getting money from many physicians, as well as from others. One of his stories is that he has an uncle, a surgeon, whose name is similar to that of the physician on whom he calls.

INDIANA

Isolation Hospital Secured.—The city health board of Indianapolis has purchased property owned by the Indianapolis Kindergarten Society, opposite the City Hospital, to be used as a ward for contagious disease.

State Eugenics Law.—Senator Neal's amended bill to provide a physical examination for bridegrooms was passed in the upper house by a vote of 32 to 12, January 21. The original bill required that the bride-to-be should also be required to present a health certificate before a license could be granted.

---

[1] This committee was composed of Dr. Edward Martin, chairman, Dr. Charles B. Penrose, Dr. George E. de Schweinitz, Dr. William Krusen and Dr. John D. McLean. Copies of the report may be obtained from the secretary, Mr. Richard Waterman, 207 South Twenty-Second Street, Philadelphia, 2 cents being enclosed for postage.

Tuberculosis Foes Meet.—At the annual meeting of the Indiana Society for the Prevention of Tuberculosis, held in Indianapolis, January 21, all the officers were reelected. Resolutions were unanimously adopted in both branches of the legislature, January 20, providing for the setting aside of the first Friday in October, as disease prevention day.

Personal.—Dr. Charles LeRoy of the staff of the Northern Hospital for the Insane, Long Cliff, has entered the United States Public Health Service, with station at Kansas City.——Dr. Sidney G. Cortner, Otisco, was severely burned on the face and hands by an explosion of acetylene gas in his garage, January 6.—Dr. Samuel Hollis, Hartford City, is reported to be critically ill.

Amendment to Advertising Law.—In the legislature a bill has been introduced as an amendment to the pure advertising law. The amendment provides a minimum fine of fifty dollars for any advertising which is false or fraudulent, or which has a tendency to deceive the public or to impose on credulous or ignorant persons and so to be harmful or injurious to public morals or safety. If this amendment be passed it will eradicate most of the patent medicine manufacturers and advertising physicians in Indiana.

Medical Legislative Problems.—A spirited fight has taken place during the last week in the state legislature on two medical problems. The first, as to whether the chiropractors shall be recognized to the extent of giving them a state board of chiropractors or not. The committee in charge of this work has made a divided report on the same and the matter will have to be fought out on the floor of the legislature.——Second, the bill originated and authorized by Dr. John N. Hurty, Indianapolis, secretary of the State Board of Health providing for health officers who devote their entire time to the work is being antagonized by another bill which makes it optional with the county as to whether the health officer devotes his entire time or only part of it to the work. A conclusion has not yet been reached.

MARYLAND

Personal.—Dr. N. E. Berry Oglehart, Baltimore, entertained the Medical Dinner Club at his home in Baltimore, January 16.——Dr. Samuel A. Nichols, Dayton, is reported to be seriously ill with pneumonia.

Scarlet Fever Prevalent.—St. Mary's parochial school, Ilchester, has been closed by order of Dr. W. H. Gassaway, health officer, owing to an outbreak of scarlet fever among the pupils. Nine cases of the disease have developed. An outbreak of the same disease in an institution for children in Baltimore has led Dr. Nathan R. Gorter, health commissioner, to issue a warning against the disease. The fever has entered the city from the counties and seemed to be spreading from East Baltimore to West Baltimore. Dr. Gorter was notified of the outbreak in the institution by Dr. John F. Hogan, superintendent of Sydenham Hospital, Baltimore, who was asked to care for the children who had developed scarlet fever. He, however, had to decline owing to the situation in other parts of the city.

Health Exhibit Arranged.—A special exhibit in connection with Public Health Week opens on February 6 in the Medical Library, Baltimore, showing the old and the new methods of caring for the insane, prepared by the Sheppard and Enoch Pratt Hospital; an exhibit on "Patent Medicines and Other Frauds," a Health Department exhibit; also the work of the Public Athletic League and the Maryland Workshop for the Blind, and finally an exhibit of lifesaving machines by the Life Saving Devices Company. The Medical and Chirurgical Faculty has offered a prize of $10 to any person, not a physician, for the best essay of not over 1,500 words on "What I Learned from the Health Exhibit." Another prize of $10 is offered to all pupils of the secondary schools of the city on the same subject.

MASSACHUSETTS

Cutter Lectures.—The Harvard Faculty of Medicine has announced that the Cutter series of lectures on preventive medicine will be delivered by Dr. Victor C. Vaughan of the University of Michigan and Surgeon Joseph Goldberger, U. S. Public Health Service.

Health Officials Die.—Charles E. Davis, Jr., for nearly forty years secretary of the Boston Board of Health, died January 5, in a hospital in Montreal.——Thomas J. Lally, director of public health of Salem, is said to have committed suicide in a hotel in Lynn, January 21.

Boston Board of Health.—The city council has given its approval of Mayor Curley's plan to reorganize the Board of Health as a single commissioner, as has been done in the State Board of Health. The mayor's candidate for this position is P. A. Surgeon Richard H. Creel, U. S. Public Health Service.

Organize Against Cancer.—A meeting was held in Boston, January 17, of physicians and laymen with the object of educating the public in the prevention of cancer. Dr. J. Collins Warren presided at the meeting. It is proposed to open an office, prepare literature for distribution, and provide lectures to address organizations throughout the city.

State Board of Health.—The new health commissioner of Massachusetts has appointed, with the approval of the Council, four of the former employees: X. H. Goodnough, chief engineer; H. W. Clark, chemist; William C. Hanson, Boston, records; and Herman C. Lythgoe, foods and drugs. Prof. Theobald Smith, Boston, being unable to remain as pathologist, Prof. Milton J. Rosenau, Boston, has been given that position, necessitating the appointment of another man to fill his place in the council. Dr. Eugene R. Kelley of Seattle, Wash., takes the division of communicable diseases.

Personal.—Dr. Theobald Smith has been invited to come to Illinois to study the foot-and-mouth disease and suggest means for saving the affected herds.——Dr. Wilson G. Smillie, Boston, has been appointed assistant in preventive medicine and hygiene at Harvard Medical School.——Dr. William J. Delahanty, Worcester, has been appointed trustee of the Worcester State Hospital in place of Dr. Samuel B. Woodward, resigned.——Dr. Wilfred E. Rounseville has been appointed city physician for Attleboro.——Dr. Thomas F. Joyce has been appointed resident physician at the Lawrence City Home.——Dr. N. Emmons Paine, West Newton, has been appointed trustee of the Westboro State Hospital.——Dr. Elizabeth A. Carleton, founder and president of the Home for Aged Couples, Boston, was reelected president of the institution at its annual meeting, January 12.——The Holyoke Association for the Prevention and Relief of Tuberculosis, at its annual meeting, January 11, reelected Dr. Carl A. Allen, president, and elected Drs. George L. Taylor and Julia Bauman, vice-presidents.——Dr. John J. Dowling has been elected superintendent of the Boston City Hospital, vice John H. McCollom, retired.——Dr John D. Adams has been elected president; Dr. Frederick C. Cobb, vice-president, and Dr. Elmer W. Barron, secretary-treasurer, of the medical staff of the Boston Dispensary.

NEW YORK

Antivaccinationists in Albany.—The Albany *Times* of January 27 contained a half-page article headed "Urgent Vaccination Warning," signed and paid for as an advertisement by Charles M. Higgins, treasurer of the Anti-Vaccination League of America, calling on the friends of the league to oppose legislation proposed in the state legislature, which it is asserted takes the authority to order vaccination from the the local school authorities and places it in the boards of health. The article contains the usual misinformation concerning the dangers and accidents of vaccination, and ignores all facts as to the efficacy of vaccination. It calls for an "amendment to the constitution for medical freedom," and demands specifically that all compulsory vaccination be prohibited and that all "vaccinating doctors and members of medical societies" be removed "from the head of our departments of health and vital statistics and place able laymen in their places with honest doctors and statisticians under them," etc. The "warning" is addressed to all "public, private and parochial schools in the state."

New York City

Harvey Society Lecture.—The eighth lecture of the Harvey Society series will be given at the New York Academy of Medicine, February 13, at 8:30 p. m., by Dr. John A. Fordyce on "Some Problems in the Pathology of Syphilis."

Personal.—Dr. Abraham Jacobi made the address before the People's Institute and the American League to Limit Armaments at Cooper Union, January 25. He was of the opinion that it would be well for this country to have a secretary of peace instead of a Secretary of War.——As the result of a competitive examination for the director of public health education, Dr. Ira S. Wile secured first position; Dr. Winthrop Talbot, Flushing, second; and Dr. Charles F. Bolduan, third.

OHIO

Honor Oldest Member.—In honor of Dr. Isaac Kay, Springfield, the oldest member of the Clark County Medical Society, a banquet was given in his honor, January 25, at Springfield. Dr. Kay was presented with a silver loving cup on behalf of the society by the president, Dr. John J. Moore, South Charleston.

Personal.—Drs. Joseph C. Placak and Archibald N. Dawson have succeeded Drs. John H. Lowman and Robert H. Bishop, Jr., as members of the visiting staff of the tuberculosis department of the Cleveland City Hospital.——Dr. Harry B. Blystone, Columbus, was operated on for appendicitis at Washington, Ia., recently, and is reported to be doing well.——Dr. Daniel L. Mohn, Ashland, fell on a slippery sidewalk, January 22, sustaining a severe contusion of the hip.——Dr. Addison D. Hobart, Toledo, was operated on in the Jewish Hospital, Cincinnati, January 15, for the removal of gall-stones, and is reported to be doing well.——Dr. Myron S. Clark, Mentor, was operated on in Johns Hopkins Hospital, Baltimore, recently.——Dr. James B. Ray, Scioto, is reported to be seriously ill with disease of the gall-bladder.——Dr. Harry B. Harris, Dayton, has been elected president, and Dr. George P. Dale, Dayton, secretary, of the staff of the Miami Valley Hospital, Dayton.——At the annual meeting of the People's Hospital Company, Akron, Dr. William S. Chase, Akron, was elected president and chief of staff and Dr. George M. Logan, Akron, secretary.——Dr. Ira J. Mizer has been appointed a member of the Municipal Civil Service Commission of Columbus.——Dr. Wilbert A. Hobbs, East Liverpool, fell on the ice in that city, December 23, fracturing his right clavicle.

Cincinnati

Personal.—Dr. Clifford C. Kennedy has resigned as assistant superintendent of the Cincinnati Tuberculosis Sanatorium and has opened an office in Cincinnati.——Dr. Ellis R. Bader, assistant receiving physician at the Cincinnati City Hospital, has been appointed receiving physician, vice Dr. Charles J. McDevitt, resigned to enter the U. S. Public Health Service.——Dr. William J. Manning has been elected state medical examiner of the Catholic Knights of Ohio.——Dr. Edwin M. Craig, Norwood, was injured January 2, in a collision between his automobile and an interurban car.——Dr. and Mrs. Edward S. McKee, who have been abroad for two years, have returned.

PENNSYLVANIA

Vistors to Pittsburgh.—Dr. Simon Baruch, New York City, was given a luncheon at the Fort Pitt Hotel, January 20, by the Civic Club of Allegheny County, at which he delivered an address on "The Economic Value of Public Baths." On January 21 Dr. Baruch was the guest of the medical profession of Pittsburgh and was entertained by the College of Physicians, and in the evening he delivered an address.——Dr. Abraham A. Brill, New York City, was the guest of the Montefiore Clinical Society, Pittsburgh, January 25, and read a paper on "Psycho-Analysis; Its Scope and Limitations."

Philadelphia

Portraits Presented.—At a stated meeting of the College of Physicians, February 3, a portrait of Dr. René La Roche was presented on behalf of the donor, Mr. J. Percy Keating, by Dr. William J. Taylor, and a portrait of the late Dr. Louis A. Duhring was presented by Dr. David Riesman.

Personal.—Dr. S. Lewis Ziegler has been appointed director of the Department of Public Health and Charities, vice Dr. Richard H. Harte, New York City.——Powell F. Fenton, son of Dr. Thomas H. Fenton, sailed, January 30, for France, where he will become attached to the engineer corps of the American Ambulance Hospital of Paris.

Demand New Hospital.—At the annual meeting of the Philadelphia County Medical Society, January 20, resolutions were adopted declaring that the present Philadelphia General Hospital is inadequate, and if permitted to continue without alterations will endanger the prestige not only of the state, but the medical profession, and demanding that councils make available $1,000,000 for the reconstruction of the building. A committee, consisting of Drs. William H. Walsh, Charles A. E. Codman, Herman B. Allyn, W. M. Late Coplin, and William L. Rodman presented the resolution to the councils.

SOUTH CAROLINA

Contracts to Care for Sick of Charleston.—A communication from the Medical Society of South Carolina to the city council of Charleston offering to renew the contract between the city and the society for the treatment of the pauper sick at the Roper Hospital, for a five year period for $40,000 a year, was approved by the city council, December 31. The present contract calls for an annual payment of $37,000.

Personal.—P. A. Surg. R. M. Grimm, U. S. P. H. S., has arrived in Spartanburg to take charge of the Federal Pellagra Hospital, succeeding P. A. Surg. R. A. Herring, transferred to New Orleans.——Dr. Joseph O. Wilhite, Anderson, has been reelected chairman and Dr. John B. Townsend, Anderson, secretary of the medical directors of the Anderson County Hospital.——Albert W. Todd, Charleston, has been appointed a member of the board of trustees of the Medical College of South Carolina, succeeding Dr. William A. Tripp, Easley, resigned. Dr. Robert S. Cathcart, Charleston, previously appointed, declined to accept.——Dr. Frank D. Mower, Newberry, has been appointed assistant physician to the State Hospital for the Insane, State Park, succeeding Dr. Angus B. Patterson, resigned.——Dr. Edgar A. Hines, Seneca, has been appointed superintendent of the Anderson City Hospital.

TENNESSEE

Small-Pox, Not Plague, at Chattanooga.—Public Health Reports, Jan. 29, 1915, contains a report of an investigation by government physicians of the conditions at Chattanooga, from which point plague was reported. Instead of plague, the investigators found that the trouble at Chattanooga was small-pox of a virulent form, undoubtedly brought from Mexico. It is said that virulent small-pox is being continually imported from Mexico into the states bordering on that country, and has also reached points in Oklahoma and Arkansas. The policy of denial of the presence of disease, which has been followed in some places, is deprecated in the report of the government investigators, who say that this course creates in the minds of people of neighboring communities fear and dread out of all proportion to the real danger, and results in unnecessary and injurious quarantine against communities having the infection. The virulent infection in Chattanooga started from a man who arrived from El Paso, Tex., Nov. 9, 1914, suffering from a severe case of small-pox, from which he died. Two other cases of confluent small-pox developed in the same house. The total number of cases from November to January 15 was 56, with 16 deaths, a fatality rate of 28.6 per cent. In December there were 38 cases, of which 13 patients died. From January 1 to 15 there were 15 cases with 2 deaths. Most of the fatal cases were of the hemorrhagic type. With the exception of the cases of varioloid, all of the cases have been of the hemorrhagic or confluent type.

WISCONSIN

Laboratory for Superior Physicians.—At the last meeting of the Douglas County Medical Association at Superior, it was decided to purchase or rent a building to be used by the physicians of the city for laboratory and research work.

Hospital Social Service Department.—A social service department has been established in the Children's Free Hospital in Milwaukee in charge of Gertrude Martin, who in addition to a nurses training has had three years' experience in the Boston Dispensary. Cooperation with the visiting nurses of Milwaukee is to be arranged. There are now more than 150 social service departments connected with hospitals and dispensaries in the United States.

Personal.—Dr. John G. Meachem, Racine, celebrated his fiftieth anniversary of his entrance into the practice of medicine, January 25, in that city, by a reception given at the Guild Hall, for physicians of the city and their wives. Dr. Walter S. Haven acted as toastmaster at the banquet which followed and presented Dr. Meachem with a gold watch as a token of affection.——Dr. George A. Pugh, Kenosha, has recovered $3,000 damages against the United States Express Company on account of the death of Mrs. Pugh, Aug. 27, 1912, which was due to a collision between the automobile in which she was riding and a delivery wagon owned by the express company.——Dr. George Keenan, Madison, is reported to be seriously ill with pneumonia.——Dr. Rudolf F. Teschan, has been elected president, Dr. Louis A. Fuerstenau, secretary, of the board of trustees of the Emergency Hospital, Milwaukee.

CANADA

University News.—The standard of the medical matriculation of the Manitoba Medical College has been raised. Beginning with the session of 1915-1916 all students must have standing equivalent to the first year in the science course in the University of Manitoba. The total number of students enrolled in the present session number 176, the freshmen class being forty, including four women. Owing to the war having called away several of the teaching staff, the following appointments have been necessitated: Lecturer in Róentgen rays and electrotherapeutics, Dr. Walter L. Watt; Dr. Boyd, professor of pathology; Dr. Robert D. Fletcher, lecturer in genito-urinary diseases; Dr. Hugh Mackay, lecturer in dermatology; Dr. T. Herbert Bell, lecturer in clinical ophthalmology; Dr. George W. Fletcher, lecturer in clinical otology and laryngology; Dr. Daniel S. MacKay, lecturer in clinical gynecology; Dr. John D. McQueen, lecturer in materia medica and pharmacy; Dr. Alvin T. Mathers, lecturer on contagious diseases; Dr. James A. Gorrell, demonstrator in anatomy. Dr. John O. Todd has been appointed lecturer in theoretical surgery in place of Dr. B. J. Brandson, resigned; Dr. Ernest S. Moorhead has been appointed lecturer in theoretical medicine in place of Dr. William Chestnut, resigned.

Hospital News.—Chilliwack Hospital (B. C.) has had its accommodation almost doubled by the addition of a new wing.——A new wing four stories high and each story provided with balconies, has just been added to the Regina (Sask.) General Hospital. This will provide amply for the overcrowded older portions of the hospital.——Although the financial stringency has been severely felt in connection with Notre Dame, the Western and the General hospitals, Montreal, it is announced that the Western and Notre Dame will be kept open for some time to come; whilst the General is fortunate in its governors having guaranteed sufficient funds for the work of the hospital for three years.——By the opening of the new wing in connection with St. Luke's Hospital, Ottawa, Ont., increased accommodation has been provided to the extent of twenty in each of two wards.——Two new cottages have been added to the Mowat Memorial Hospital for Tuberculosis, Kingston, Ont.——The St. John County Hospital for Tuberculosis at Little River, N. B., is nearly completed. It consists of a main building and two wings. ——The entire staff of the Vancouver (B. C.) General Hospital has agreed to a reduction of salaries of from 5 to 10 per cent., in order that the board of governors may liquidate the deficit of $11,811.75 reported at the end of October.

Personal.—Dr. James A. Crozier, Port Arthur, Ont., in response to a cable from England advising of his appointment as captain in an English regiment, has left for the front. Dr. Crozier saw service as a surgeon in the South African War.——The militia council of Canada has selected the following doctors to proceed at once to England for service in the Duchess of Connaught's Canadian Red Cross Hospital, established on the Waldorf-Astor Estate, Cliveden: Dr. George O. Taylor, Moncton, N. B.; Dr. R. F. Flegg, Ottawa; Dr. Samuel R. Harrison, Minnedosa, Man. Dr. Charles W. F. Gorrell, Ottawa, is commanding officer of this hospital. ——The following Canadian doctors have been selected in response to a request of the war office for immediate service in the Canadian Base Hospital in England: Captain John P. Walsh, Quebec; Lieut. Keith C. Dean, St. Boniface, Win.; Lieut. R. M. Linton, London, Ont.; Lieut. A. L. Jones, Victoria, B. C.; Lieut. M. V. Valliquette, Ottawa; Capt. Ernest R. Selby, Calgary; Captain Lozier, New Brunswick.——Dr. James A. Montgomery, Deloraine, Man., has joined the British Red Cross for active service.——Dr. William E. Home, Victoria, B. C., having offered his services to the British Admiralty, has left for England.——Dr. John A. McCollum, Toronto, is visiting friends in the Canadian Camp on Salisbury Plain, England.

GENERAL

Tri-State Physicians to Meet.—The annual meeting of the Tri-State Medical Society of the Carolinas and Virginia, will be held in Charleston, S. C., February 17 and 18, under the presidency of Dr. Edward C. Register, Charlotte, N. C.

New Supply Table for Navy.—A new supply table for the medical department of the Navy has recently been issued by the Bureau of Medicine and Surgery. This table is intended as a basis for all requisitions from hospital and store stations, as well as ships of the fleet.

International Health Commission to Move.—The International Health Commission, one of the three divisions of the Rockefeller Foundation, will remove in March from Washington to New York City. The object of the removal is the concentration of the work in one central field.

To Guard Health of Passengers.—The officials of the Pennsylvania Railway have instituted a system for the protection of the health of passengers of the lines. The employees in station restaurants and dining cars of the system, numbering 1,100, are examined by the company's physicians each month. Traveling medical inspectors also examine kitchens, cooking vessels and store rooms, and especial attention is paid to the ventilation of cars.

Eradication of Foot and Mouth Disease.—To January 1 over one hundred thousand animals have been slaughtered on account of foot-and-mouth disease. Of these over forty-six thousand were cattle, forty-seven thousand swine and the remainder sheep and goats. Under the urgent deficiency act passed by Congress and signed by President Wilson, January 25, the sum of $2,500,000 is now available to pay the national government's share of the cost of animals destroyed in eradicating the disease. To January 1 the outbreak had cost the government over two million dollars. One million eight hundred thousand dollars of this represents the government's share of the expense of slaughtering the infected herd and reimbursing owners for their loss, of which the government pays half and the states the remainder.

A Warning.—A subscriber writes that a certain Mr. J. H. Hanaford is soliciting subscribers to a bureau called "American Bureau (or institute) of Medical Research," at Indianapolis. The Journal published a warning concerning this man in September, 1914, after investigation showed that no such institute existed. The purpose of the bureau, the man states, is to receive all medical journals of the world and to make reprints of each individual article, which are kept in stock and sent to subscribers of the bureau on request. The cost of membership is $5 a year. All mail addressed to this bureau is returned. The editor of the *South Texas Medical Record* advises us that this individual has been operating in Texas, naming as sponsors for the bureau of information, Drs. Harvey A. Moore, J. Rilus Eastman and E. E. Wishard of Indianapolis. A letter of inquiry addressed to Dr. Moore brought the reply that he had no knowledge of any such information bureau, but that he had received many letters from different parts of the country asking for information regarding it. Physicians should be careful not to pay money in advance to such doubtful enterprises.

Bequests and Donations.—The following bequests and donations have recently been announced:

Mount Sinai Hospital, New York City, $100,000; St. Luke's Hospital, $25,000; German Hospital, $25,000; New York Eye and Ear Infirmary, $25,000; and Lincoln Hospital and Home, $25,000, by the will of Benjamin Altman.

Seaside Home for Children, New York City, $1,000 by the will of Alexander R. Brewer.

St. Rose Free Home for Incurable Cancer, New York City, $5,000 by the will of Agnes A. Connell.

Washington University, St. Louis, a contingent bequest estimated at more than $1,000,000 for the establishment of an Eye, Ear, Nose and Throat hospital in connection with the institution, by the will of Mrs. William McMillan.

Michael Reese Hospital, Chicago, $1,000 by the will of Simon Yondorf.

Northwestern University Medical School, Chicago, a donation of $27,000 to cover eight full courses, by Mr. James A. Patten, Evanston.

Louisville Anti-Tuberculosis Association, a bequest of $1,000 by the will of Mr. and Mrs. Thurston Ballard for the building, equipping and maintenance of one shack at the Hazelwood Sanatorium.

Hazelwood Sanatorium, $3,310, the net proceeds of the Christmas seal campaign in Louisville.

Philippine Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination, March 2, for bacteriologists and pathologists, for men only, to fill vacancies in this position in the Bureau of Science at Manila, at salaries ranging from $2,000 to $2,500 a year. Applicants must be citizens of the United States, must hold the degree of M.D. or Ph.D., must have had at least one years' training in bacteriological laboratory work and must have had training in immunity and serum-therapy.——An open competitive examination for specialists in nervous and mental diseases, March 2, for men only, to fill a vacancy of the Civil Service at a salary of $3,500 a year. The applicants must be thirty years of age, must be graduates of a medical college or school of recognized standing and must have had at least two years' experience in hospitals or institutions for the insane.——An open competitive examination is also announced for medical inspector and surgeon. March 2, for men only, to fill a vacancy in this position in the Philippine service at a salary of $3,000 a year. The duties are to take charge of the health station at Manila or in the provinces as the Philippine director of health may require and to attend to such surgical work as may be assigned in the Philippine General Hospital. Applicants must be graduates in medicine from a medical college or school of recognized standing and should have at least three years' experience in surgical hospital practice. Persons who meet the requirements and desire these examinations, should apply at once for forms B. I. A. 2, and 2095, to the United States Civil Service Commission, Washington, D. C., prior to March 2.

FOREIGN

Vital Statistics of Madrid.—From the figures just published for 1914, Madrid, with a population of 614,106, had 27.22 births and 26.48 deaths per 1,000 inhabitants. There has been little change in these proportional figures during the last ten years.

Importation of Meat in Italy Temporarily Suspended.—The *Policlinico* states that as cattle plague, swine plague and trichinosis are prevailing in certain countries, especially in the Orient, the importation of animals or meat from the specified countries has been prohibited by the Italian authorities.

Honors to Town Physician.—The town of Tiero in Italy recently commemorated with a banquet and souvenir volume the fortieth year of service of Dr. A. Cisternino as *medico condotto* of the township. A new public dispensary has been named for him and a set of resolutions on parchment was also presented to the "brave and modest man who," it says, "has exalted *la professione medica* to an *apostolato.*"

Deaths in the Profession Abroad.—J. W. R. Tilanus, professor of surgery at the University of Amsterdam until he retired in 1893, aged 92. He founded in 1851 a medical weekly in Holland and later was on the editorial staff of the *Nederlandsch Tijdschrift v. Geneesk.* until 1886. He was honorary member of a number of foreign scientific associations, including the French Académie de Médecine, whose list of foreign associate members is limited to twenty. His father was professor of surgery at Amsterdam before him and there is still a Tilanus, a surgeon, on the staff of the medical faculty there.——K. von Kraus, at Vienna, aged 78. ——A. Geyl of Delft, aged 61. Since he was compelled by a severe nervous affection to retire from practice in 1899 he has been collecting data for the history of medicine, especially in Holland, and the results of his research are in press.——K. Liebermann, professor of organic chemistry at the University of Berlin, aged 72.——G. Jochmann, in charge of the contagious disease ward of the Virchow Hospital at Berlin, had general supervision of the conditions in regard to hygiene and prophylaxis of epidemics in the camps of prisoners in the vicinity of Berlin. One of the camp physicians, Dr. Hirschfeld, had acquired fatal exanthematous typhus from the prisoners, and Jochmann contracted the disease in tending him. It proved fatal in two weeks. Jochmann's early death at 40 has put an end to a promising career. He had recently published a manual on infectious diseases in addition to other works.——At the death of Dr. C. del Toro of Cadiz, Spain, in December, the city council, in recognition of his services to the town and province, voted a public funeral with honors and monument as if he had been the chief executive, and ordered his portrait placed in the gallery of illustrious sons of Cadiz and his name given to one of the principal streets of the city.

WAR NOTES

Italian Daily Gives Issue to Red Cross.—The entire proceeds of a recent special illustrated number of the *Giornale d'Italia* in Italy were given to the Red Cross.

War Relief Funds.—Up to January 16, $439,646.01 has been subscribed to the American Red Cross; $171,752.87 to the German Relief Fund; $841,645.82 to the Belgian Relief Fund; $304,344.68 to the American Ambulance Hospital; $101,028.81 to the Committee of Mercy Fund, and $103,513.88 to the Prince of Wales Fund.

Medical Corps from McGill.—McGill University has decided to send a fully equipped field hospital as a part of its medical contribution to the aid of the allies in the European War. There will be 21 medical officers, 43 nurses and a total staff of 210 persons and the hospital will have accommodations for 520 patients.

Needs of War Sufferers.—An appeal has been received from Belgium for anesthetics, antityphoid serum and diphtheria antitoxin.——The committee for the relief of Belgian physicians announces that it has arranged to send a large supply of drugs and medicines at once to be distributed among physicians and pharmacists in Belgium.——Georgia and South Carolina have donated a shipload of food stuffs for the Belgians.

McGill Men on Active Service.—The following medical graduates of McGill University are on duty with the Canadian expeditionary force at camps of instruction, or on the staffs of general hospitals in England and on the continent: Lieut.-Col. Kenneth Cameron; Lieut.-Col. Frederick Gault Finley; Majors Charles Fenwick Wylde and Roland Playfair Campbell; Capts. Allan Coats Rankin, Alexander Mackenzie Forbes, George Shanks, George Graham Corbet, St. John, N. B.; James Caryle Fyshe, George A. Stuart Ramsay, Robert B. William, Charles Harold Robson, Theodore Adolph Lober, Arthur Livingstone Johnson and Louis Wellington MacNutt.

Personal.—Col. Henry R. Casgrain, Windsor, Ont., has been appointed head of the new Canadian Hospital now under construction in France. Colonel Casgrain will have under his command, 7 commissioned officers, 45 nurses and 98 non-commissioned officers and privates of the hospital corps.——Dr. Wesley Earle Drennen, Birmingham, Ala., has been placed in charge of the work of the American Ambulance, Paris, during the absence on leave of Dr. Joseph Blake. ——Dr. Samuel L. Ledbetter, Birmingham, Ala., is chief of staff of the Red Cross Base Hospital, near Paris.——Dr. Henry Matthey, Davenport, Ia., is reported to be one of the two surgeons in charge of the military hospital at Castle Holzen, Ebenhausen, near Munich.

The Work of the Red Cross.—From Aug. 1, 1914, to Jan. 8, 1915, the American Red Cross had sent to Europe 45 surgeons and 150 nurses. The English units are in charge of the American Woman's Hospital, Paignton, Devonshire; the French units are in charge of the hospital at Pau, the Russian units are in charge of a hospital at Kiev; the German units are in charge of hospitals at Gleichweitz and Kosel; the Austro-Hungarian units are in charge of hospitals in Vienna and Budapest, and the first unit sent to Servia is in charge of a hospital in Belgrade.——Funds have been transmitted to aid in the maintenance of the American Ambulance, Paris; the American Woman's Hospital at Paignton; the American Red Cross Hospital, Munich; for the hospitals under the charge of the units sent to Germany and Austria and for the work of the American Relief Clearing House, Paris; for the prisoners' bureau of the International Red Cross Committee at Geneva; for the relief of Belgian refugees in Holland; to aid the Netherlands Red Cross; for the British and French hospitals and the American Mission Hospital in Turkey; for the hospital and hospital work in Beirut, and for the American Red Cross Committee at Pekin, China, and for the aid of Austrian and German prisoners in Siberia.——The supplies forwarded include 772,900 pounds of absorbent cotton; 802,400 yards of gauze; 709,000 bandages; 3,168 rolls of adhesive plaster; 13,965 pounds of anesthetics; 77 cases of drugs and medicines; 35 cases of instruments and accessories; 20 United States Army field medical outfits; 7 sterilizers; 20 cases of disinfectants; 15,000 doses of antityphoid serum; 50,000 doses of tetanus antitoxin; 10,000 tubes of small-pox vaccine; 7,500 blankets; 2,211 shawls; 516 coats; 1,740 sweaters for women and children; 10 barrels of alcohol; 2,638 cases of miscellaneous supplies including hospital garments and dressings and clothing for women and children.

Aid for the Belgian Profession.—The committee of American physicians for the aid of the Belgian profession announces that it is constantly receiving heartrending reports regarding the distress of our Belgian colleagues and their families. In February great suffering from severe weather will be added to their other trials. Arrangements have been perfected by which contributions are being promptly converted [illegible] every assurance that they will reach our [illegible] Two hundred boxes of food have been purchased during the week ending January 30.

The treasurer, Dr. F. F. Simpson, announces the following contributions for the week ending January 30:

Drs. C. H. and W. J. Mayo, Rochester, Minn.	
Miss Margaret E. Reed, Chicago, Ill.	$100.00
Dr. E. L. Neff, Pittsburgh, Pa.	1.00
Dr. F. P. Sprague, Boston, Mass.	5.00
Dr. Caspar W. Miller, Wallingford, Pa.	50.00
Dr. John T. Bottomley, Boston, Mass.	50.00
Dr. Henry W. Frauenthal, New York, N. Y.	25.00
Dr. Edwin Sternberger, New York, N. Y.	25.00
Capt. W. A. Powell, M.C., U. S. A., Nogales, Ariz.	10.00
	5.00

Dr. Frederick Fraley, Philadelphia, Pa.		10.00
Dr. George W. Ely, Pittsburgh, Pa.		5.00
Dr. Samuel C. Plummer, Chicago, Ill.		5.00
Dr. R. W. Hodges, Baltic, Mich.		10.00
Dr. Ellen A. Stone, Providence R. I.		10.00
Dr. Charles A. Elsberg, New York, N. Y.		25.00
Dr. F. M. Hicks, San Antonio, Tex.		10.00
Dr. Marion Marsh, Worcester, Mass.		2.00
Ohio Valley Academy of Medicine, Bellevue, Pa.		25.00
Dr. M. P. Messinger, Oakfield, N. Y.		2.00
Total		$375.00
Previously reported receipts		$1,791.00
Grand total		$2,166.00
Previously reported disbursements	$1,650.00	
Disbursements week ending January 30	440.00	
Total disbursements		2,090.00
Balance		$76.00

F. F. Simpson, M.D., Treasurer,
Jenkins Arcade Bldg., Pittsburgh, Pa.

PARIS LETTER

Paris, Jan. 14, 1915.

The War

THE IMPROVEMENT OF THE MILITARY HEALTH SERVICE

The minister of war has just decided to create a special commission to investigate the service of military hygiene with a view to making all possible improvements. This commission is composed of eighteen members whose technical knowledge and previous experience are a guarantee of the results. The medical profession is represented by Professor Landouzy, dean of the Faculté de médecine de Paris, Dr. Léon Labbé, senator, Dr. Roux, director of the Pasteur Institute, Dr. Vaillard, medical inspector general of the military health service, Drs. Hartmann and Delbet, professors of clinical surgery at the Faculté de médecine de Paris, and Dr. Troussaint, director of the war department health service.

HEART AFFECTIONS IN THE ARMY

At one of the last sessions of the Académie de médecine, Dr. C. Fiessinger pointed out that men with heart affections (myocarditis, paroxysmal tachycardia, mitral insufficiency or stenosis or aortic insufficiency) can undergo considerable fatigue if sustained by a rational treatment with digitalis. Thus a soldier dismissed at the age of 21 for aortic insufficiency returned as an aviator in the middle of August and is still continuing to do aerial reconnoitering. A military surgeon affected with mitral stenosis, made prisoner in Lorraine, returned to the Aisne as soon as he came back to France and passed fatiguing days and nights which caused a dilatation of the heart. He refused the necessary rest and rejoined his post at the end of forty-eight hours. In a previous letter (The Journal, Jan. 9, 1915, p. 163) I mentioned a series of cases reported by Dr. Aubertin in which men aged from 20 to 30 years went through a campaign without bad results although they were affected with aortic insufficiency.

SECONDARY HEMORRHAGES FROM WOUNDS IN WAR

Dr. Hardouin, substitute professor of pathology and clinical and obstetric surgery at the Ecole de médecine de Rennes, read an interesting paper on this subject before the Société de chirurgie de Paris which completed the discussion recently reported in The Journal (Jan. 9, 1915, p. 163). To judge by about twenty cases of secondary hemorrhage which he had the opportunity to observe since the beginning of the war, such hemorrhages seem to take place in wounded men who arrive at the hospital deeply infected, from four to eight days after the wound and after a fatiguing journey of three or four days. Most frequently they are caused by lesions of important vessels. In other cases the hemorrhage may be an indefinitely recurring general oozing. No matter to which of these classes the secondary hemorrhage belongs, immediate operation is necessary. Tamponing ought not to be used in any case. The seat of the hemorrhage should be opened up and the two ends of the artery in the wound or in its immediate neighborhood should be tied. High ligature of the principal artery has the disadvantage of being sometimes insufficient and also of endangering the vitality of the limb more than lower ligature. Therefore it should be used only when it is impossible to find and to ligate the vessel near the wound. In the relatively rare cases of generalized hemorrhage, the best treatment is drainage from the lowest part of the wound preventing all stagnation of the septic liquid, reopening of the wound, abrasion of the bleeding tissues and tamponing.

PRIVATE PRACTICE AND THE MILITARY SERVICE OF CIVILIAN PHYSICIANS

The necessities of war have caused a great number of civilian physicians to be drafted into the medical reserve corps. The attention of the minister of war has been called to the fact that many young civilian physicians are stationed in hospitals or military camps in the same city where they live and practice their profession in times of peace. These physicians continue to carry on their private practice while their colleagues, often much older, are called on for service in the army or in distant parts of the country. Not only is this situation unjust; it also does not always permit the drafted physician, especially when his service is at one of the military camps, to detach himself from local demands, and to preserve the professional independence indispensable to military physicians. Consequently the minister of war has decided that in the future physicians of the reserve shall be, as a rule, stationed at some distance from their residence. Physicians who, though released by age from military obligation, are serving voluntarily, may, on the other hand, be stationed in the place where they ordinarily practice if their services are required by the population. In no case shall local physicians be employed in the army camps.

In response to a request expressed by several of those affected by the rule, physicians filling an elective civil office (members of parliament or of general councils) are not to be stationed in the department from which they are elected.

The Campaign Against Alcoholism

August 16 last, the minister of the interior instructed prefects to forbid the sale of absinthe and similar drinks in their respective departments (The Journal, Sept. 19, 1914, p. 1044). The president of the republic has just signed a decree making permanent this prohibition, which up to the present was limited to the duration of the war.

Another decree has just been signed forbidding the granting of any new license for the sale of intoxicating liquors except those having a basis of wine and titrating less than 23 degrees. Unfortunately this measure is not so radical as it should be, for it contains a clause stating that later decrees will define the exceptions to this rule. It is to be feared that after the war political influences will open the door to numerous abuses which will be labeled "exceptional cases."

It is to be noted that in our country there is a license for each thirty adults. This average is considerably exceeded in certain departments. Thus, the proportion rises to one license for each twenty-two adults in the Seine-Inférieure and to one for each fifteen adults in the department of the Nord and one for each eleven in the Eure. Several years ago the plans of the government comprised the limitation of the number of licenses to one for each 500 inhabitants. Even a ratio of one license to each 200 inhabitants would mean the existence of about 200,000 licenses. At present there are nearly 500,000. Refusal to grant any new licenses is consequently merely the minimum of what is required in the new campaign against alcoholism. No exceptions should be tolerated.

Death of Dr. Suchard

Dr. Eugène Suchard, former substitute professor at the Collège de France, has just died, aged 62. He was born at Mulhouse on the Upper Rhine and after a brilliant course at the Faculté de médecine de Paris, he passed many years attached to the laboratory of Professor Potain at the Charité Hospital. Then for more than twenty years he brilliantly filled the place of Professor Ranvier in the chair of general anatomy at the Collège de France.

BERLIN LETTER

Berlin, Jan. 5, 1915.

Personal

Prof. J. Rosenthal, formerly director of the physiologic institute at Erlangen, died January 2 at the age of 78. He was a pupil of DuBois-Reymond and became his assistant immediately after taking the state examination. In this position, he joined the faculty in 1862, was made professor extraordinary in 1867, and in 1872 received a call as regular professor to Erlangen, where he spent the rest of his life. His work lay chiefly in the field in which his teacher was a pioneer. He published a general physiology of the muscles and nerves and, together with Professor Bernhardt, a treatise on medical electricity for physicians. Other works treat of the respiratory movements and their relation to the vagus nerve, heat regulation in warm-blooded animals, public and private hygiene, etc.

The Number of Students in Berlin

In spite of the fact that 1,501 men and 27 women among the Berlin students are in the service of the army, either in the field or in subsidiary positions, such as nursing and the like, the number of students in the winter semester at the university is not particularly smaller than usual. Eight thousand and thirty-five students have matriculated, 7,037 men and 898 women. The number of the latter has relatively largely increased. In the previous winter semester there were only 859 women while the men students numbered 8,200. Of medical students there are 1,798 men and 199 women.

The War

ORTHOPEDIC INSTITUTIONS AND THE CARE OF THE WOUNDED

Attention to the after-treatment of the wounded has already begun with great zeal. All the German cripple hospitals, of which there are more than one hundred, have expressed their readiness to receive the wounded who are in need of orthopedic after-treatment or apparatus and artificial limbs. A large organization is being established for the treatment and future employment of crippled soldiers.

WAR OPERATIONS OF THE IMPERIAL INSURANCE

The president of the Imperial Insurance Office made an address recently giving in general an account of the work which the imperial insurance organization has so far devoted to the tasks of the war. All hospitals, convalescent homes, and lung sanatoriums have been prepared for the reception of the wounded. The insurance societies have offered to devote to the purposes of the war as much as 5 per cent. of their means. As this amounts to about $500,000,000 (2 billion marks), a sum of more than $25,000,000 is available. Of this, about $375,000 have been given to the Red Cross, and more than $250,000 to the committee for providing woolen underclothing for the troops. All those unmarried German sailors who are without work have been assured a home and care free of cost on a large steamship. The sums which have been appropriated for the survivors of those who have fallen have already reached $500,000. An appropriation of $375,000 has been made for the purpose of preventing the lapse of the right to insurance on account of the non-payment of dues by the insured who are in the field. An amount up to $50,000,000 will be loaned out on easy terms to needy communities, societies, etc. The insurance societies have subscribed $37,500,000 for the war loan—a slight evidence that the $1,125,000,000 subscribed to the war loan will be quickly forthcoming.

EXHIBITION SHOWING THE CARE OF THE WOUNDED AND SICK IN WAR

For the instruction of the public regarding the measures which are being taken for the care of the wounded and sick in the war, an exposition was opened in the parliament buildings, under the auspices of representatives of the civil and military medical authorities. All that is being done by the state and by voluntary effort for the care and restoration to health of the wounded and sick soldiers is on exhibition, beginning with the prevention of sickness and the first aid to the wounded on the battlefield, and extending to the convalescent soldier in his home country. The exposition is divided into groups: The first group illustrates the sanitary arrangements for the army in the field. Here one sees the first aid package, closed and open, of which every soldier carries two sewed into his coat, and which are intended for the first care of the wound by the wounded man himself or by a comrade; also the set of articles to be carried in the pocket, the set for the whole troop, the cavalry case and pocket case of bandage material, an instrument case for the hospital, a field Roentgen car, models of hospital tents and barracks. How the business of caring for the wounded is arranged is shown from a large relief map of a battlefield. One sees the medical forces lying on the abdomen under fire, bandaging the wounded and then, still in the field of battle, the sanitary squads, the transportation of the wounded, the work at the temporary dressing station, the gathering places, and the field and base hospitals. How the wounded are transported in motor buses, carts and hospital trains is illustrated by plain models.

The second group depicts the medical work in the navy. For the narrow, steep and crooked passages of a ship, other means of transportation are needed than on land. The best is a transport hammock, shown at the exposition, by which the steep, stairs may be avoided by use of rails. The chief attraction of this department is the hospital room of a battleship in its natural size. The bandage rooms are placed in a lower part of the ship, protected as much as possible from the fire of the enemy, and have modern surgical apparatus. The operation table has a special arrangement to keep it steady. Furthermore, the genuine hospital ship with movable beds adapted to the movements of the ship, the so-called swinging berth, is shown. To this the wounded are transferred after the battle. In addition to the space for the sick, there is also an operation room and a drug room, which serves, at the same time, as a clinical and bacteriologic laboratory.

A further group exhibits the means for combating infectious diseases in war, giving pictures and cultures of the various bacteria, showing the method of obtaining serum, tables with regard to the results of vaccination, arrangements for disinfection, a flying laboratory, as well as tables and charts illustrating the spread of and campaign against tuberculosis.

The other departments of the exposition are devoted to the application of the Roentgen rays in the care of the wounded, the work of the dentist in war, the technic of nursing in all its details, and the methods for occupying and amusing the sick, and the organization of nursing in war. In this last department is an exposition of the work of the order of the Knights of St. John and of Malta, and there is also a beautiful model of the Mount of Olives Foundation at Jerusalem which was established under the protection of the order of the knights of St. John (Johanniter).

The department showing the provisions for those crippled in the war illustrates by pictures and models how, with proper care and training, a relatively large number of those who have been maimed can be rendered more or less self-supporting. For example, it is shown that a man who has lost both feet and hands is yet capable of dressing and washing himself without help, eating, writing and working at a lathe in a turner shop. One fine specimen of mechanical work was exhibited done by a man whose right hand had been lost. Other models illustrate the instruction of a cripple in a trade. The historical department of the exhibition gives an interesting view of the historical development of medical military service.

Marriages

William Richard Janeway, M.D., New Brighton, Staten Island, N. Y., to Miss Carol Rodman of Ridgewood Road, N. J., January 20.

George Stanford Hensyl, M.D., to Miss Helen Bacon, both of Mahanoy City, Pa., at Mt. Carmel, Pa., January 19.

John Roy Westaby, M.D., Clark, S. Dak., to Miss Marcia Blanch Eldred of North Pownal, Vt., Dec. 17, 1914.

Charles August Riemcke, M.D., North Yakima, Wash., to Miss Lois Steen of Spokane, Wash., Dec. 30, 1914.

Maurice Jacob Greenstein, M.D., Bridgeport, Conn., to Miss Hattie Singer of New York City, January 17.

Isadore Emanuel Freed, M.D., Greensburg, Pa., to Miss Diana Zeldenrust of Allentown, Pa., January 19.

David Alfred Angus, M.D., to Miss Mabel Meuli, both of Rosalia, Wash., at Spokane, Wash., January 15.

Frederick William Manning, M.D., Windsor, Ont., to Miss Florence Pfeiffer of Detroit, January 11.

Arthur Augustus Rang, M.D., Washington, Ind., to Miss Gladys H. Halter of Garrett, Ind., January 12.

Thomas Madison Morgan, M.D., Wesson, Ark., to Miss Ella Combes of El Dorado, Ark., January 19.

Paul J. Landry, M.D., New Iberia, La., to Miss Willie Walters of Vicksburg, Miss., in April, 1914.

Henry Shillingford Miles, M.D., to Miss Edith Alicia Zink, both of Bridgeport, Conn., January 9.

Dudley Steele Conley, M.D., New York City, to Miss Sidney Ann Boales of St. Louis, January 2.

Henry B. Esmond, M.D., St. Albans, Vt., to Mrs. Martha J. Herrin of Upper Alton, Ill., January 22.

James Laurence Sullivan, M.D., to Miss Anna J. Sadler, both of Bridgeport, Conn., January 18.

Orril Le Grand Suggett, M.D., St. Louis, to Miss Virginia Parker of Lexington, Ky., January 21.

Hendery Allison, M.D., to Miss Clara Lucille McLoud, both of Kingsville, Tex., January 8.

Deaths

James Morrison Bodine, M.D., noted for his work in medical education in the South; died in the apartment of his nephew in the Atherton Building, Louisville, January 25, from senile debility, aged 83. He was born in Fairfield, Ky., Oct. 2, 1831. His early education was received at St. Joseph's College, Kentucky, and Hanover College, Indiana, and his medical course was taken in the Kentucky School of Medicine, Louisville, from which he graduated in 1854. Two years later he became demonstrator of anatomy and later professor of anatomy in his Alma Mater. He entered the faculty of the University of Louisville in 1866 as professor of anatomy, serving in that capacity for forty-five years. He was dean of the university from 1867 to 1907, and was made president of the faculty in 1907. He was a Fellow of the American Medical Association and for many years served as a member of the Louisville Board of Health. From 1881 to 1886 Dr. Bodine was president of the American Medical College Association. After his retirement from the presidency of the University of Louisville, in 1910, the alumni of the institution and medical friends from twenty states gave a testimonial banquet in his honor. The death of Dr. Bodine marks the passing of one of the old-time medical gentlemen of the South.

William Grant Moore, M.D. Jefferson Medical College, 1875; a Fellow of the American Medical Association, and third vice-president in 1910-1911; formerly president of the Missouri State Medical Association; one of the founders of and professor of theory and practice of medicine and clinical medicine in the Marion Sims-Beaumont College of Medicine, St. Louis; a member of the staff of the St. Louis Protestant and St. Ann's hospitals, and the Missouri Baptist Sanitarium and physician in charge of St. John's Hospital, St. Louis; died at his home in that city, January 28, from pneumonia, aged 61.

Samuel Augustus Fisk, M.D. Harvard Medical School, 1880; a Fellow of the American Medical Association; professor of practice of medicine in the University of Denver from 1884 to 1899; secretary of the faculty for many years and dean for four years; once president of the American Climatological Association; a member of the first board of the Home for Consumptives, Denver, and a member of the staff of St. Luke's and Deaconess hospitals; died at his home in Boston, January 18, aged 58.

Joseph Eve Allen, M.D. Medical College of Georgia, Augusta, 1877; a Fellow of the American Medical Association; dean and professor of obstetrics in his Alma Mater; president of the Augusta Academy of Medicine in 1894 and 1896; for several years a member of the Augusta Board of Health; consulting obstetrician to the Augusta City Hospital and the Lamar Hospital; one of the most prominent obstetricians and gynecologists of the South; died at his home in Augusta, January 19, aged 57.

Levi Francis Warner, M.D. College of Physicians and Surgeons in the City of New York, 1889; a Fellow of the American Medical Association; attending physician to St. Francis' Hospital and physician-in-chief to the New York Dispensary; medical examiner for the Municipal Civil Service Commission and a member of the Board of Police Surgeons of New York City for eight years; died in St. Luke's Hospital, January 20, after a surgical operation, aged 50.

Alonzo Byron Hughes, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1897; a member of the Iowa State Medical Society; for twelve years a member and since 1909 president of the Keokuk Board of Education; formerly professor of chemistry in his Alma Mater and prior to that time, school principal and professor of chemistry in Nebraska schools; one of the most prominent citizens of Keokuk; died at his home, January 16, from diabetes, aged 58.

Ira A. Cottingham, M.D. Eclectic Medical Institute, Cincinnati, 1885; St. Louis College of Physicians and Surgeons, 1890; of Carthage, Mo.; a member of the Missouri State Medical Association; for twenty-four years a practitioner of Aurora, Mo., and for three terms mayor of that city, and local surgeon for the railways centering in Aurora; died in the Carthage Hospital, January 19, from meningitis due to an infection of the middle ear, aged 55.

George Clayton Feigel, M.D. Syracuse University College of Medicine, Syracuse, N. Y., 1898; a member of the Medical Society of the State of New York; visiting physician to St. Joseph's Hospital, Syracuse; who disappeared from his home in Syracuse ten days before, despondent on account of ill health; was found dead in a hotel in Chicago, January 24, from the effects of poison self-administered, it is believed, with suicidal intent, aged 45.

Charles A. E. Lesage, M.D. Northwestern University Medical School, Chicago, 1897; a Fellow of the American Medical Association; once president of the Dixon Medical Association and secretary of the Lee County Medical Society, and a specialist on diseases of the eye, ear, nose and throat, of Dixon, Ill.; a member of the staff of the Dixon Public Hospital; died at his home in that city, January 22, aged 42.

Benjamin Sharp, M.D. University of Pennsylvania, Philadelphia, 1880; later professor of invertebrate zoology at the Academy of Natural Sciences, Philadelphia, and two years later professor of zoology in his Alma Mater; zoologist of Commander Peary's first Arctic expedition in 1901; a scientist of national repute; formerly of Brookline and Nantucket, Mass.; died in Beaufort, N. C., January 15, aged 56.

Adam Monroe Kalbach, M.D. Long Island College Hospital, Brooklyn, 1867; Bellevue Hospital Medical College, 1868; a member of the Medical Society of the State of Pennsylvania, who gave up practice thirty years ago to conduct extensive lumber enterprises in Maryland; died at his home in Lancaster, Pa., January 20, from heart disease, aged 69.

Dabney Minor Trice, M.D. Hospital College of Medicine, Louisville, Ky., 1890; assistant physician to Long Island State Hospital from 1903 to 1908; president and resident physician of Moore's Brook Sanitarium, near Charlottesville, Va.; a member of the Medical Society of Virginia and a prominent specialist on diseases of the nervous system; died January 17, from pneumonia, aged 54.

Ralph Walsh, M.D. University of Georgetown, Washington, D. C., 1863; a Fellow of the American Medical Association and for many years a practitioner of Washington, D. C.; for thirty-five years connected with the National Vaccine and Antitoxin Laboratory; died at his home in Jerusalem, Md., January 15, from paralysis, aged 73.

Albert James Browne, M.D. Berkshire Medical College, Pittsfield, Mass., 1865; a member of the Medical Society of the State of New York; for several terms supervisor of the town of Newton; in 1895 and 1896 health officer of Utica; died at his home in Utica, January 23, from pernicious anemia, aged 74.

James Boone Lincoln, M.D. Jefferson Medical College, 1883; a member of the Medical Association of the State of Pennsylvania; for twenty-three years physician for the relief department of the Pennsylvania Railroad; died at his home in Lancaster, Pa., January 17, from cerebral hemorrhage, aged 56.

John Wesley Gray, M.D. Jefferson Medical College, 1864; Bellevue Hospital Medical College, 1867; a member of the Indiana State Medical Association; surgeon in the United States Indian Service from 1885 to 1888; died at his home in Bloomfield, Ind., January 25, from heart disease, aged 75.

Charles T. Montgomery, M.D. Albany (N. Y.) Medical College, 1874; a member of the Medical Society of the State of New York and one of the best-known practitioners of Ulster County; died at his home in Saugerties, N. Y., January 15, from arteriosclerosis, aged 65.

Lloyd L. Edgell, M.D. Starling Medical College, Columbus, Ohio, 1885; a member of the West Virginia State Medical Association; for several years a practitioner of Keyser, W. Va.; died at his home in Cumberland, Md., January 18, from heart disease, aged 55.

Isaac Shelby Warren, M.D. Kentucky School of Medicine, Louisville, 1870; health officer of Somerset, Ky.; a member of the Kentucky State Medical Association; died in the Somerset Sanitarium, January 15, following an operation for malignant disease, aged 59.

John Adam Person, M.D. Jefferson Medical College, 1888; a Fellow of the American Medical Association and a member of the staff of Nesbitt West Side Hospital, Wilkes-Barre, Pa.; died at his home in Wilkes-Barre, January 19, from diabetes, aged 53.

William Waldo Knowlton, M.D. Hahnemann Medical College, Philadelphia, 1893; of Camden, N. J.; a member of the Medical Society of the State of New Jersey; a specialist in dermatology; died in Philadelphia, January 23, aged 43.

Montague J. Jones, M.D. Medical College of Ohio, Cincinnati, 1871; for several years a practitioner of Peoria; died at his home in Chicago, January 27, aged 74.

Davis Bruce Richards, M.D. Jefferson Medical College, 1896; also a graduate in pharmacy in 1891; a Fellow of the American Medical Association; died at his home in Philadelphia, January 21, from nephritis, aged 47.

Louis P. Pollmann, M.D. Missouri Medical College, St. Louis, 1870; a Fellow of the American Medical Association and for forty-four years a surgeon of St. Louis; died at his home in that city, January 23, aged 64.

Claude Dearborn Warren, M.D. Baylor University, Dallas, Tex., 1905; a member of the State Medical Association of Texas; died at his home in Houston, Nov. 9, 1914, from tuberculosis, aged 31.

John Buchanan Dewar, M.D. Bellevue Hospital Medical College, 1888; a member of the Michigan State Medical Society; died at his home in Cedar Springs, Mich., about January 20, aged 61.

Albert W. Squires, M.D. Columbus (Ohio) Medical College, 1883; a member of the Ohio State Medical Association; died at his home in White Cottage, Ohio, January 15, from pneumonia, aged 61.

John Adolphus McEachern, M.D. University of Louisville, Ky., 1889; a member of the Medical Association of the State of Alabama; died at his home in Brundidge, Ala., January 5, from heart disease.

David W. Beattie, M.D. University of Nebraska, Omaha, 1897; local surgeon at Neligh (Neb.) for the Northwestern System; died at his home in Neligh, January 8, from arteriosclerosis, aged 55.

John W. Cobb, M.D. Albany (N. Y.) Medical College, 1858; a surgeon of volunteers during the Civil War; died at his home in Binghamton, N. Y., January 14, from pneumonia, aged 76.

Henry Russell Lowe, M.D. Dartmouth Medical School, Hanover, N. H., 1883; a member of the Connecticut State Medical Society; died at his home in Putnam, Conn., Nov. 1, 1914, aged 65.

Wiley Thomas Simpson, M.D. Medical College of Georgia, Augusta, 1883; a member of the Medical Association of Georgia; died at his home in Smithville, Ga., January 8, aged 62.

John E. Barrette, M.D. State University of Iowa, College of Homeopathic Medicine, Iowa City, 1886; of Lawrence, Neb.; died in a sanatorium at Lincoln, Neb., about January 10.

James T. Hard, M.D. Albany (N. Y.) Medical College, 1877; resident physician of the Mary M. Packer Hospital, Sunbury, Pa.; died at his home January 12, from erysipelas, aged 65.

Charles Richard Dewey, M.D. University of Michigan, Ann Arbor, 1886; formerly of Olivet, Mich., but recently a practitioner of Lansing; died at his home in Olivet, January 13, aged 56.

P. C. Woodruff, M.D. Louisville (Ky.) Medical College, 1888; a member of the Oklahoma State Medical Association; died recently at his home in Stilwell, Okla., aged 49.

John Damascus Bambenek, M.D. Northwestern University Medical School, Chicago, 1908; died at his home in that city about January 7, from pneumonia, aged 33.

Adelbert Allen Bryson, M.D. Bellevue Hospital Medical College, 1892; died at his home in Dorchester, Boston, about January 15, from heart disease, aged 54.

Erazmus Z. F. Golden, Jr., M.D. Birmingham (Ala.) Medical College, 1912; died at his home in Langdale, Ala., December 24, from acute gastritis, aged 26.

John D. Baker, M.D. American University of Pennsylvania (Eclectic), Philadelphia, 1880; died suddenly at his home in Eshcol, Pa., January 12, aged 71.

William F. Cook, M.D. Hahnemann Medical College, Philadelphia, 1899; died at his home in Port Allegany, Pa., January 3, aged 44.

Charles Edward Anderson, M.D. Trinity Medical College, Toronto, 1908; died at his home in Brooks' Station, Alta., about January 10.

Vincenzo Delpiano (license, Connecticut, 1898) was shot and killed at his home in Norwalk, Conn., by his brother-in-law, January 6.

Henry Clark Bradford, M.D. Bellevue Hospital Medical College, 1893; died at his home in New York City, January 10, aged 50.

Association News

THE SAN FRANCISCO SESSION

Special Trains from Chicago and New York

Arrangements are being made for special trains from Chicago to San Francisco over three different routes. These trains will be designated, the American Medical Scenic Route Special, the American Medical Grand Canyon Route Special, and the American Medical Direct Route Special.

THE AMERICAN MEDICAL SCENIC ROUTE SPECIAL

This train will go over the Chicago, Burlington and Quincy Railroad from Chicago to Denver, and the Denver and Rio Grande, Denver to San Francisco. The party is to be personally conducted. The train will be made up of modern equipment, observation Pullman sleeper, drawing room standard sleepers, dining car and baggage car.

SCHEDULE

Lv. Chicago	9:45 a. m.	June 15
Ar. Denver	1:00 p. m.	June 16
Lv. Denver	Before 12 p. m.	June 16
Ar. Colorado Springs	4:00 a. m.	June 17
Lv. Colorado Springs	4:00 a. m.	June 18
Ar. Glenwood	3:30 p. m.	June 18
Lv. Glenwood	6:30 p. m.	June 18
Ar. Salt Lake	8:30 a. m.	June 19
Lv. Salt Lake	12:00 Noon	June 19
Ar. San Francisco	5:00 p. m.	June 20

Starting from Chicago at 9:45 a. m., June 15, this train traverses the prairie sections of Illinois, crosses the Mississippi at Burlington and during the afternoon goes through the corn belt of Iowa, crossing the Missouri River at Council Bluffs and Omaha. During the night it travels through Nebraska, reaching McCook in the early morning and arriving at Denver at 1 p. m., June 16. Here a stop will be made during the afternoon and evening which will provide an opportunity for sightseeing, and arrangements can be made with the "Seeing Denver Company" to take the party for a ride through the parks and avenues of the "Queen City of the Plains."

Leaving Denver before midnight, June 16, over the Denver and Rio Grande the train is due to arrive at Colorado Springs (75 miles south of Denver) at 4 a. m., June 17. The train is to be parked directly outside the grounds of the Antlers Hotel. Here a number of side trips may be made into the Pike's Peak region by carriage, automobile, etc., to the Garden of the Gods (time for the round trip about two hours; street car fare 20 cents); to Monument Park (about the same time; street car fare 20 cents); across the Mesa to Palmer Park and return, via the Boulevard (about three hours, $1); to Stratton Park (5 miles, street car fare 20 cents); North and South Cheyenne canyons and the Famous Seven Falls (about four hours, street car fare 20 cents, admission 50 cents); the "High Drive," thence down through Bear Creek Canyon and Colorado City, back to Colorado Springs (half a day's trip); to Crystal Park by automobile from either Colorado Springs or Manitou (about four hours, $3). From Manitou, trips can be made to the Cave of the Winds (admission $1); to the Cliff Dwellers ruins (car fare 10 cents, admission $1); incline up Mt. Manitou (street car fare to incline 10 cents, trip $1); Ute Pass and Temple Drive (may be made on foot, 3 miles; two hours' time should be allowed). A party may be made up to start early in the morning for Pike's Peak by way of the cog wheel road. (Pike's Peak, height 14,147 feet. The round trip requires four hours and the fare is $5). The party may return to Manitou and have time to go to the Cripple Creek gold mining district via the "Short Line"—"the one way trip that bankrupts the English language" (cost of trip, $3). For parties of 100 or more, a special train, special schedule, and in some instances, special rates, may be arranged for the trip up Pike's Peak, the Cripple Creek district and some others of the foregoing list. Special accommodations for some of the other trips may be arranged for smaller parties.

Leaving Colorado Springs at 4 a. m., June 18, the train enters the Royal Gorge about 7:30 a. m. The scenery is almost beyond conception in grandeur. Between sheer walls of granite half a mile high and but 30 feet apart, the train passes to the hanging bridge, and then for hours the road goes through mountain scenery, the grandeur of which is beyond description. The Continental Divide is crossed through Tennessee Pass (altitude 10,240 feet) where streams start both for the Pacific and the Atlantic.

The train is due to arrive at Glenwood Springs at 3:30 p. m., June 18. Here a stop is planned permitting a swim in the open air hot swimming pool (750 feet long, with a depth of from 4 to 6 feet), a unique attraction. Dinner may be obtained at the Hotel Colorado. Leaving at 6:30 p. m., the Palisades are passed at Grand Junction, and the Great Grand River Valley fruit section is entered before dark.

Salt Lake City is reached at 8:30 a. m., June 19. The many fine buildings erected by the Mormons are of interest not only because of the durability of their construction, but also on account of their unique style of architecture. "Sightseeing automobiles" permit travelers in a short time to see the most interesting points in the city. Salt Lake, 70 miles long by 30 wide, and with an average depth of 10 feet, is 4,000 feet above the sea level. On its shore is Saltair Beach, which is 13 miles due west from Salt Lake City and is reached by a thirty-minute railway ride.

Salt Lake City is left at 12 noon, June 19, by the Western Pacific Railway. During the night, the train will cross the salt beds of the Salt Lake desert basin. The salt, in places, is 12 feet thick and almost 98 per cent. pure. The following morning the train will be in the sage country, a region almost virgin in character. Soon the foothills of the Sierras appear in the distance. The beauty of the scenery increases as the summit of this range is approached at Beckwith. The train enters along the rock walls of the Feather River Canyon, a 90 mile long gorge, where the rails are laid on a shelf chiseled from the solid rock along the side of the canyon. Alternate views of the river, meadow, glen and valley present themselves until the train arrives at Oroville, at the western end of the canyon. This is said to be the center of the largest gold dredging district in the world. Then the road passes down the western slope of the Sierra Nevadas into the Sacramento Valley through the capital city of California and the center of the great fruit growing industry of that section, crosses the northern portion of the Rich San Joaquin Valley and spans the little valleys of Livermore, Pleasanton and Niles, and passing through Oakland, arrives at San Francisco at 5 p. m., Sunday, June 20.

It will be noted that the entire trip—through the mountains, the Royal Gorge, across the Continental Divide, through Glenwood Springs, past Grand Junction and through the Feather River Canyon—is made in daylight, and that the party arrives in San Francisco in the early evening.

NEW YORK AND NEW ENGLAND SPECIAL

This train will be under the management of McCann's Tours. The itinerary is planned to provide a fast schedule, over an interesting route for the outward trip, leaving eastern points as late as the afternoon and evening of June 16 and getting to San Francisco on Sunday evening, June 20. The return trip will be made in a leisurely manner over an interesting scenic route, including a trip from San Francisco to Portland by way of the Shasta line. Stops will be made at Portland, Seattle and Spokane, and a five day trip through the Glacier National Park is planned. The itinerary, as has been noted, contemplates leaving New York at 2 p. m., June 16, over the New York Central lines, thence by way of the Chicago, Milwaukee and St. Paul, the Union Pacific and the Southern Pacific to San Francisco, where the party will stop from Monday, June 21 to Friday, June 25, leaving San Francisco at 8 p. m. on the last-named day. From Wednesday, June 30, to Sunday, July 4, the party will be in Glacier National Park, returning to New York on Thursday, July 8.

Those who do not have time or are not disposed to return by the route indicated, may arrange to take the special train to San Francisco and to return within three months after the date of starting, by any authorized route selected.

A description of other special trains will appear in future numbers of The Journal.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

TRI-IODIDES, THREE CHLORIDES AND MAIZO-LITHIUM

Report of the Council on Pharmacy and Chemistry

As an illustration of unreliability of claims and unscientific character of proprietary mixtures, the Council has authorized publication of the following reports on Tri-Iodides, Three Chlorides and Maizo-Lithium, products of the Henry Pharmacal Co. (J. F. Ballard, proprietor).

W. A. Puckner, Secretary.

Tri-Iodides (Henry)

Tri-Iodides (Henry Pharmacal Co., St. Louis) is a nostrum whose ingredients apparently were selected at random. Since the effects of such a mixture cannot be predicted, no thoughtful physician would think of prescribing in any one condition all the drugs named in the formula of Tri-Iodides—if he had to write out the prescription. Yet because the misleading name of the preparation gives it the semblance of a therapeutic entity—and because it is advertised in medical journals—a certain number of physicians thoughtlessly prescribe this shotgun mixture.

LABORATORY REPORT

Regarding the composition of "Tri-Iodides" the Association's Chemical Laboratory makes the following report:

> A trade package of Henry's Tri-Iodides purchased in 1910 bore the following formula on the label:
>
> "Colchicin, 1-20 grain,
> "Phytolaccin, 1-10 grain,
> "Solanin, 1-3 grain,
> "Sodium Salicylate, C. P., 10 grains,
> "Iodic Acid, (equal to 7/32 gr. of Iodine) in two fluid drachms of Aromatic Cordial."
>
> In the circular which was wrapped with the bottle the wording of the formula differs somewhat from the foregoing, "iodic acid" of the label being replaced by "hydro-iodic acid." While the label on the bottle named "phytolaccin" as one of the constituents the label on the carton which contained the bottle gave "decandrin." The following formula appears on a trade package purchased June, 1914:
>
> "Colchicine, 1-200 Grain,
> "Phytolacca, 1 1-5 Grain,
> "Mydriatic Alkaloids, 1-500 Grain,
> "Sodium Salicylate, 3 1-2 Grain.
> "Iodic Acid (equal to 7-125 Grain of Iodine) in two fluid drachms."
>
> The differences between the formulas are striking. Colchicin has been reduced from $^1/_{20}$ grain to $^1/_{200}$ grain; sodium salicylate from 10 grains to 3½ grains; iodin (claimed to be present as iodic acid) from 7/32 grain to 7/125 grain. "Phytolaccin" ("Decandrin") has been replaced by "Phytolocca" and "Solanin" by "Mydriatic Alkaloids." While the formula for the preparation has been changed, the circular accompanying the package still refers to "solanin" (in some parts of the circular wrongly spelled "salonin") and "phytolaccin." As no principle having the characteristic effects of poke-root is known to have been isolated the terms "decandrin" and "phytolaccin" are meaningless.
>
> The circular states that solanin is an alkaloid obtained from the sprouts of *Solanum tuberosum*, but wrongly calls this plant "bittersweet" instead of potato. At the market price the amount of solanin claimed, according to the old formula, to be present in a bottle of Tri-Iodides, would cost $1.60, although a bottle of the preparation sold at wholesale for 67 cents.

Tri-Iodides is a dark brown, mobile liquid having a faint clove-like odor and a mawkish, sweet taste. Salicylate was found in considerable amounts. Traces of alkaloids were found, a portion of which appeared to be colchicin. Iodic acid and its salts were absent, although claimed by the formula to be present. Potassium iodid was present. Determinations of the iodin by distillation with ferric ammonium sulphate solution and sulphuric acid indicated the presence of about 1.68 gm. of iodin (equivalent to 2.18 gm. of potassium iodid) in each 100 c.c. of the preparation. This is equivalent to about 7.65 grains of iodin per fluidounce, or more than thirty-four times the amount claimed by the formula on the bottle. An approximate determination of the salicylic acid by extraction of the acidified preparation with ether and evaporation of the solvent indicated about 2.67 gm. in 100 c.c., equivalent to 3.09 gm. of sodium salicylate, or about 14.11 grains per fluidounce. Since the amount of sodium salicylate claimed is 3.5 grains in 2 fluidrams or 14 grains in each fluidounce, the amount found agrees essentially with the claims.

ABSURD CLAIMS

It should be unnecessary, after pointing out the conflict between the name and the published formula, between the formula and the actual composition, and between the composition and all established therapy, to discuss this heterogeneous and unscientific mixture further. A few specimen absurdities, however may be quoted from the advertising "literature:"

". . . Free of the Disagreeable Effects of the Alkaline Iodides."

[Tri-Iodides, according to the laboratory report, depends for its iodin action on potassium iodid.]

". . . we have an assimilable form of vegetable hydriodates.

"The hydriodates of these valuable vegetable alkaloids afford the specific alterative action of iodine without such disagreeable results as the iodism produced by the ordinary iodides."

["The hydriodates" is an obsolete term formerly applied to iodids of vegetable alkaloids. Iodids of vegetable alkaloids, if present at all in Tri-Iodides, are present in negligible amounts.]

"Containing Iodine in an available form, it is obvious that the formula must be beneficial in the majority of syphilitic skin lesions."

The falsity of the first two of these claims and the mischievousness of the last are self-evident.

It would be possible, but is unnecessary, to produce an almost unlimited amount of evidence to show the transparent character of the deception by which this preparation is exploited.

The referee feels that the nostrum will have been sufficiently characterized when he has mentioned further that the name "Henry's Tri-Iodides" is blown in the glass of the bottle, that the label contains the recommendation "For Gout, Rheumatism and other Diathetic Diseases," and that the circular accompanying the bottle recommends the use not only of Tri-Iodides, but also of Three Chlorides, Maizo-Lithium, Campho-Phenique and Satyria in the treatment of many diseases.

Three Chlorides (Henry)

Three Chlorides (Henry) is advertised as:

"An oxygen-carrying ferruginous preparation, suitable for prolonged treatment of children, adults and the aged. Indicated in anemia and convalescence from acute diseases and surgical operations."

The following report on the composition of Three Chlorides is submitted by the Association's Chemical Laboratory:

LABORATORY REPORT

It is claimed that each fluidram of Henry's Three Chlorides contains:

"Mercuric Bichlorid	1-72 Gr.
"Arsenic Chloride	1-40 Gr.
"Proto-Chloride Iron	2-25 Gr.

". . . in a cordial of Calisaya Alkaloids."

The preparation is a pale yellow, clear solution having an odor of alcohol. The addition of potassium ferricyanid solution does not produce any blue coloration, thus demonstrating the absence of ferrous chlorid (iron protochlorid). Instead potassium ferrocyanid solution produces at once an intense blue precipitate and potassium sulphocyanate solution an intense red coloration, thus proving the presence of iron in the ferric condition. It is obvious that the claimed superiority of Three Chlorides over preparations containing ferric iron is absurd. Since it contains iron in the ferric condition, Three Chlorides decomposes soluble iodids with the liberation of free iodin. The assertion that it is a suitable "vehicle" for the administration of iodids is likely to lead the physician unwittingly to administer free iodin.

As the laboratory report shows, the "formula" of Three Chlorides (Henry) is incorrect for proto-chlorid of iron (ferrous chlorid) was absent from the preparation. There is, however, a more serious objection to the formula than the misstatement of fact. When the physician is dealing with conditions that call for mercury, arsenic or iron, it is irrational and unscientific to prescribe a preparation containing these three drugs in fixed proportions.

OBJECTIONABLE ADVERTISING

Three Chlorides is marketed in bottles having the name "Three Chlorides" blown in the glass, in a carton containing a circular extolling the curative powers of this and other proprietaries of the same concern. Thus a physician who prescribes Three Chlorides is likely to place in the hands of his patient the advice that

"Three Chlorides . . . is suitable for the prolonged treatment of children . . ."

"In tertiary syphilis, with or without potassium iodide, it holds first rank among remedies directed against the specific taint . . ."

Further, that "Maizo-Lithium" is:

"A Genito-Urinary Sedative" and a "remarkable uric-acid solvent."

Also that "Satyria" is:

"An Ideal Genito Tonic and Nerve Reconstituent."

"Indicated in Prostatic trouble, Cystitis, Urethritis, Gonorrhea, Gleet, Leucorrhea, Sexual Debility and Impotence."

We are told that

"As a hematinic, the protochloride of iron justifies the confidence of the medical profession."

"The protochloride, more than any other salt of iron, stimulates the paptic [*sic*] and hydrochloric glandular system of the stomach, increasing the flow of acid gastric juice."

It is unnecessary to discuss the truth or falsity of these assertions, since Three Chlorides does not contain the protochlorid of iron. For the same reason, it is obvious that the small amount of iron which it contains is the only possible justification for the claim that the preparation is

". . . Non-Productive of . . . Constipation or Teeth Discoloration."

It is hardly necessary to point out that it is a therapeutic exaggeration to claim that Three Chlorides is of particular value in the treatment of tertiary syphilis, that in eczema it is "the most effective remedy," that in any form of constipation it is "the remedy par excellence," or that

"After arresting malarial attacks with quinine, the combination of iron, arsenic and mercury with calisaya is an essential requisite."

"Whenever gastric troubles and digestive disturbances furnish a contra-indication to iron, this contra-indication disappears when the iron is combined with arsenic."

"The simultaneous exhibition of small doses of arsenic and bichloride of mercury, besides augmenting the effect of iron upon the red blood-cells, completely obviates the tendency to vascular congestion and hemorrhage."

Finally, the suggestion that by the use of Three Chlorides iodids may be prevented from causing iodism is absurd.

In short, whatever may be the advisability of prescribing iron, arsenic or mercury in any given case, it is irrational to prescribe them in fixed proportions. A physician who is induced by the exaggerated advertising claims to prescribe these drugs in a proprietary mixture, under a non-informative name, does grave injustice to his patients.

Maizo-Lithium

Maizo-Lithium (Henry Pharmacal Co., St. Louis) is one of the many proprietary lithium preparations based on the disproved theory that lithium dissolves uric acid deposits in the body. The label on a trade package states that:

> "Maizo-Lithium promptly facilitates the elimination of the uric and phosphatic deposits from the system."

As might be expected, the promoter of Maizo-Lithium ascribes a long list of ills to "uric and phosphatic deposits," and argues that, therefore, Maizo-Lithium is the proper treatment:

> "In lithemia, hematuria, incipient diabetes, cystitis, urethritis, pyelitis and ALL inflamed conditions requiring a non-irritating diuretic."

"Inflamed conditions" naturally, include almost all of the real or imaginary ills of kidney, bladder, etc.

Maizo-Lithium is distinguished from its congeners chiefly by the claim that it contains a mythical or problematical compound, maizenate of lithium.

LABORATORY REPORT

The following report on the composition of Maizo-Lithium has been submitted by the Chemical Laboratory of the American Medical Association:

> The promoter of Maizo-Lithium makes the following statement upon the label concerning the composition of the preparation:
>
> "Each fluid drachm contains two grains maizenate of lithium."
>
> The following is also found in a circular which is enclosed with the trade package of Maizo-Lithium:
>
> "Maizo-Lithium, the remarkable uric acid solvent, is a nascent chemic union of maizenic acid, obtained from green corn silk, with the alkaline base lithium forming maizenate lithium, of which the mother liquid carries two grains to each drachm."
>
> Standard works on organic chemistry and pharmacology, such as Beilstein's Organische Chemie and Cushny's Pharmacology and Therapeutics, do not mention maizenic acid. Neither is it mentioned in comprehensive bibliographies of phyto-chemical investigations such as Huseman-Hilger's Die Pflanzenstoffe or Wehmer's Die Pflanzenstoffe. The first to use the term appears to have been a Dr. Vautier (*Arch. méd. belg.*), but his publication is not available to the laboratory. Rademacher and Fischer (*Amer. Jour. Pharm.*, 1886, lviii, 369) claim to have isolated the substance from green corn-silk, but the record of their work is unsatisfactory and indefinite and therefore their results could not be verified; it seems unlikely, however, that they isolated a pure proximate principle.
>
> Examination of Maizo-Lithium demonstrated the absence of bromids, chlorids, phosphates, sulphates, acetates, benzoates, salicylates and tartrates—combinations in which lithium might be expected to be present. The presence of a citrate, however, was shown by the usual tests. Lithium and sodium were present. Free acid was absent. Determination of lithium citrate and of sodium citrate indicated the presence of a total of about 3.7 gm. of these two salts in each 100 c.c. of the preparation, or about 2.1 grains in each fluidram. About 25 per cent. of the total salts appeared to be lithium citrate. The examination, therefore, does not demonstrate the presence of "maizenate of lithium," but does show that Maizo-Lithium contains a mixture of lithium citrate and sodium citrate. Tests for citric acid and citrates were made on a commercial specimen of fluidextract of corn-silk. The results were negative, although the preparation had an acid reaction to litmus. The presence of maizenate of lithium in Maizo-Lithium—in fact, its actual existence—thus failed of demonstration. In view of this fact, it was felt that the burden of proof rested on the promoter of Maizo-Lithium to supply some satisfactory evidence with regard to this substance. The following letter was, therefore, sent to James F. Ballard:
>
> "According to the label on a recently purchased bottle of Maizo-Lithium, each fluidram of this preparation contains 2 grains of 'maizenate of lithium.' From an examination made in this laboratory we are inclined to conclude that this statement is not in accordance with the facts. A search of chemical and pharmaceutical publications does not reveal that such a compound as 'maizenate of lithium' has ever been isolated and described and we are very much inclined to question its existence. We should be pleased to receive from you any evidence which you may care to send in substantiation of your claim in regard to the content of 'maizenate of lithium' in Maizo-Lithium—particularly a specimen of 'maizenate of lithium' or the method by which it is produced."
>
> While this letter was sent Oct. 13, 1914, no evidence has been submitted up to date (January, 1915) to substantiate the asserted presence of maizenate of lithium in Maizo-Lithium.

The report just given shows that the manufacturer has found it expedient to surround his worthless nostrum with a cloak of mystery. A discussion of the jumble of uncritical claims, baseless assertions and evident falsehoods presented in favor of Maizo-Lithium would seem a waste of time when the secrecy of this nostrum is all-sufficient for its condemnation.

[Editorial Note.—When the Council on Pharmacy and Chemistry was started we announced that we did not see any clear line of demarcation between "patent medicines" and many so-called "ethical proprietaries." Time has not caused us to change our opinion. As we have already shown, and as we shall have occasion to show in the future, not a few of the "ethical proprietaries" offered to physicians are being advertised by those who are pushing the rankest of "patent medicines." The three preparations mentioned above are sold—and presumably manufactured—by Mr. Ballard, of St. Louis. Mr. Ballard is the promoter of Ballard's Snow Liniment, Brown's Iron Bitters, Herbine, Dr. Herrick's Vegetable Liver Pills, Swaim's Panacea, Renne's Pain Killing Oil, etc. He is also the promoter of Campho-Phenique, exposed in The Journal some eight years ago.[1] The spectacle is not an edifying one. A manufacturer with one hand offers the public a profusion of cure-alls, while with the other he endeavors to foist on the medical profession preparations which are just as fraudulent. Some day our profession will awake to the disgrace of it all. It will also awake to the fact, which should have been evident ere this, that the nostrum business would cease if physicians would refuse to accept into their offices, even as a gift, the nostrum-promoting medical journals that live off this trade. Fraudulent "patent medicines" will continue to thrive just so long as newspapers will publish "patent medicine" advertisements; fraudulent "ethical proprietaries" will continue to exist just so long as medical journals will advertise such proprietaries. As the better class of newspapers are rejecting "patent medicine" advertising on their own volition, so are the better class of medical journals rejecting advertisements of fraudulent proprietaries. Some newspapers will continue to carry nostrum advertising until their subscribers raise a protest that will cause the business department to take notice; so, too, some medical journals will continue to share the profits with the nostrum exploiters until an outraged medical profession repudiates such publications.]

---

[1] The Journal A. M. A., April 20, 1907, reprinted in "Propaganda for Reform," 8th Edition.

Milk Sugar and Charcoal in a Case of Mercurial Poisoning.—A young woman with chronic nephritis took mercuric chlorid with suicidal intent, but recovered. The treatment was with 100 gm. of lactose a day, supplemented by vegetable charcoal, which was given by the tablespoonful every two hours and by an enema twice a day. No food was allowed but milk, and water was given freely. The tendency to anuria was transiently relieved by wet-cupping, but when the anuria became complete, A. Lamas, who reports the case in *Medicina Contemporanea*, 1914, xxxii, 406, made an intravenous injection of 700 c.c. of a 25 per cent. solution of sugar. He injected the whole amount in fifteen minutes, regarding haste as a factor in the result. Urine was voided at once and repeatedly during the following hour, to a total of 1.1 liter.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DOAN'S KIDNEY PILLS AND SOME SHOTGUN PRESCRIPTIONS

To the Editor:—1. Please state the formula of Doan's Kidney Pills. 2. Please comment on the following prescriptions:

℞ STOMACH AND NERVE TONIC TABLETS

Carica papaya (papain)	1 gr.
Strychnin phosphate	1/64 gr.
Willow charcoal	2 gr.
Ext. eucalyptus	1/4 gr.
Ext. hydrastis	1/8 gr.
Celery seed	1/4 gr.
Ipecac po	1/8 gr.

Sig.: For an adult, 1 or 2 tablets before or after meals as directed.

℞ LIVER AND BOWEL REGULATORS

Ext. chionanthus	1/2 gr.
Podophyllin	1/6 gr.
Po. ipecac	1/4 gr.
Cascarin	1/4 gr.
Aloin	1/4 gr.
Ext. hyoscyamus	1/8 gr.
Ext. nux vomica	1/8 gr.

Sig.: For an adult, 1 or 2 on retiring as directed.

J. H. LOWE, M.D., Mentor, Ohio.

ANSWER.—1. According to "Secret Remedies" (first edition), published by the British Medical Association, analysis of Doan's Backache Kidney Pills "showed them to contain oil of juniper and (in spite of their 'purely vegetable' nature) potassium nitrate, together with a considerable proportion of a resinous substance, and of powdered fenugreek seeds and wheat and maize starches." According to the same authority, the following formula gave a similar pill:

Oil of juniper	1 drop
Hemlock pitch	10 gr.
Potassium nitrate	5 gr.
Powdered fenugreek	17 gr.
Wheat flour	4 gr.
Corn starch	2 gr.

In twenty pills.

In "Nostrums and Quackery" (second edition) a comparison is made of the British and American labels of Doan's Pills. Attention also is directed to one of the Doan's Kidney Pills' newspaper advertisements of the testimonial type. It is shown that the individual whose name appeared in the testimonial died of nephritis two months before the testimonial was published! An article reprinted in the "Propaganda for Reform Department" of THE JOURNAL, Nov. 7, 1914, gives the reply of a weekly magazine to the arguments made by the representative of the Doan's Kidney Pills concern.

2. The most striking characteristic of the prescriptions given is their polypharmacy, the collection of a large number of ingredients in one pill. Some of these may be adapted to a certain condition, but it is quite doubtful if a condition can be found in which all of them would be of service. The question of chemical incompatibility does not apply in such a mixture, so that we are chiefly concerned with the therapeutic value of the ingredients. Papain, obtained from carica papaya (papain), is a vegetable product having some of the properties of pepsin, but of a very uncertain and feeble digestive power. Willow charcoal is a remedy often prescribed on the theory that it will absorb a large quantity of gas from the stomach. This assumption is not well founded, as the charcoal, when wet, has a very slight power of absorbing gases. Extract of eucalyptus is given as an antiseptic, but the value of antiseptics in the stomach is very problematic. In the first place, in most conditions, there is no fermentation in the stomach. The gas which is found in many cases is not the result of fermentation, but consists of swallowed air. Second, antiseptics can seldom be given in sufficient doses to arrest fermentation in the stomach when it actually occurs, as in cases of stasis. In these cases the only efficient remedy is to restore the motor power of the stomach so that it can empty itself.

Extract of hydrastis is a remedy which was formerly recommended for a supposed effect on the mucous membranes. Excepting the possible value of hydrastis as a bitter, there is little reason to believe that it is of any service in gastro-intestinal diseases. To secure its effect as a bitter, if it has any, it is necessary to give it in solution. Given as here, in the form of a pill or tablet, it is worthless.

Celery seed is a substance reputed to have value as a nerve tonic. The action of this substance is practically unknown. If it has any value it must be very small. We are unable to suggest the condition for which the powdered ipecac of this prescription is intended.

In the second prescription, like the first, the number of ingredients is excessive. Chemical incompatibilities may be disregarded, as the preparation is in the form of tablets or pills. Of the ingredients, the extract of chionanthus is a little used medicine of very indefinite properties, believed to be an alterative, a convenient but indefinite term, and also believed to have what is equally indefinite, a favorable effect on the liver. The other ingredients of this pill may be said to be synergistic, given for their effect on the intestines, especially for the relief of constipation. It may be said that this pill compares favorably with some of the venerable combinations, such as the compound cathartic pill and other polypharmacal combinations of the Pharmacopeia.

With reference to the first prescription, it is difficult to say what purpose it is intended for, and it would be equally difficult for the physician who should administer it, to determine which of its ingredients was the effective agent.

MARRIAGE OF THE TUBERCULOUS

To the Editor:—I should like to inquire as to the chances of the development of tuberculosis in patients, especially women, who have been discharged as "cured" after a course of sanatorium treatment and who afterward marry. By cured I mean patients that have been free from moisture for some time and who only show a certain amount of dulness and increased vocal fremitus over the site of the old lesion. Would you ever consider marriage advisable in such cases and would the occurrence of pregnancy mean very great risk in lighting up an old focus? I am compelled to deal with these things and would like an opinion on them. If this is published, kindly do not mention my name.

C. C. M.

ANSWER.—Patients who have recovered to the extent indicated by the correspondent should be advised that they take a considerable risk in marrying. In general it is not held that women strongly predisposed to tuberculosis should marry. The actual risk of marriage without pregnancy is not very great. If pregnancy occurs, there is danger of the lighting up of an old focus. Some authors, however, report experiences with pregnancy in tuberculosis which indicate no very great influence of the tuberculosis on the pregnancy, or vice versa. These, however, should be regarded as exceptional.

THE TEACHING OF REFRACTION BY CORRESPONDENCE

To the Editor:—I wish to take a course in refraction, and am unable to get away from my practice to do so. Is there not an institution where this is competently taught by correspondence? It seems to me I have seen such an advertisement somewhere, and I am writing to inquire if you can advise me of the address, if there is such a place.

H. L. G.

ANSWER.—The theoretical studies that underlie practical refraction work, such as physiologic optics, can be carried on by correspondence, and a knowledge of the elements of refraction can be acquired from books, just as one may, in theory, study other kinds of physical diagnosis. The practical application of these elements cannot, however, be learned except in a properly equipped "refraction room" with living patients and under the supervision of an expert. Effective refraction work involves the intelligent use of the skiascope, ophthalmoscope, phorometer, ophthalmometer, trial case and other devices that cannot be taught by mail, any more than can the use of the stethoscope or the laryngoscope. Prescribing for asthenopic and ametropic patients (apart from jewelry-store efforts) is not that simple procedure one is sometimes led to believe, while six months or a year in a hospital or a medical school is none too long a period to study this important form of therapeutics.

DOSAGE OF EMETIN IN PYORRHEA

To the Editor:—Will you kindly state the dosage and intervals between injections in the emetin treatment of pyorrhea alveolaris?

E. J. S.

ANSWER.—Emetin hydrochlorid is given in pyorrhea alveolaris in doses of from 1/2 grain to 1 grain at intervals of from one to two days. It is claimed that from three to six doses are necessary, and in some cases it may be necessary to repeat this course at the end of ten days.

Miscellany

Requirements of the Harrison Law

As previously stated,[1] the Harrison bill, which has been before Congress for the last two years, became a law, Dec. 17, 1914. Official copies of the law and the regulations for its enforcement have been issued by the Commissioner of Internal Revenue. While the provisions of the bill were discussed at length during its consideration in Congress, so many modifications took place that a general summary of the law as finally enacted seems advisable.

THE SECTIONS

Section 1 provides that on and after the first day of March, 1915, every person who produces, imports, manufactures, compounds, deals in, dispenses, sells, distributes or gives away opium or coca leaves or any compound, manufacture, salt, derivative or preparation thereof shall register, with the collector of internal revenue of the district, his name and place of business, the office of a physician, or residence in the absence of an office, being considered the place of business. At the time of registration and on the first day of July annually thereafter, each person who performs any of the acts covered by the bill must pay to the district collector of internal revenue a special tax of one dollar per annum. Officers of the United States government lawfully engaged in purchasing such drugs, or officers of any state, county or municipality purchasing drugs for public hospitals, are exempt.

Section 2 provides that it shall be unlawful for any person to sell, barter, exchange or give away any of the specified drugs except in pursuance of a written order from the person to whom the drugs are sold or given, which order must be on a form issued in blank by the Commissioner of Internal Revenue. These orders must be made out in duplicate, one copy to be written by the person ordering the drugs and the other by the person filling the order, and both copies must be accessible to the revenue officer for a period of two years. The following acts are exempt: The dispensing or distribution of any of these drugs to a patient by a physician, dentist or veterinary surgeon, registered under this act, in the course of his professional practice only, provided the person dispensing shall keep a record of all such drugs for a period of two years. The filling of a prescription written by a physician, dentist or veterinary surgeon, registered under the act, is also exempt. Such prescriptions must be dated and signed by the physician and must be preserved by the druggist for a period of two years. The various forms and blanks required shall be furnished by the Commissioner of Internal Revenue at a price not to exceed one dollar per hundred.

Section 3 provides that any registered person shall on request of the collector of the district render a sworn statement of the quantity of the prescribed drugs received by him during the past three months and the names of the persons from whom they were received.

Section 4 forbids interstate commerce in these drugs, except by a registered person, common carriers being exempt.

Section 5 provides that all records shall be open to the inspection of the officers of the Treasury Department or officers of any state or territory or municipality charged with regulating the traffic in the specified drugs. Certified copies of returns can be secured from the collector of internal revenue by state or municipal officers. The disclosing of information except for the enforcement of the act is forbidden.

Section 6 provides that the act shall not apply to the sale, distribution, giving away, dispensing or possession of preparations which do not contain more than 2 grains of opium or more than ¼ grain of morphin or more than ⅛ grain of heroin or more than 1 grain of codein or any salt or derivative of them in 1 fluidounce, or if a solid or semisolid preparation, in 1 avoirdupois ounce, or to liniments, ointments or other preparations prepared for external use only, except those which contain cocain or any of its salts or alpha or beta eucain. Decocainized coca leaves or other preparations of coca leaves which do not contain cocain are also exempt.

Section 7 provides for the extension of all internal revenue laws so as to make them applicable to this act.

Section 8 provides that no person not registered under the provisions of this act shall have in his possession or under his control any of the specified drugs, such possession or control to be presumptive evidence of the violation of this act. Employees of registered persons, nurses under the supervision of physicians, dentists or veterinary surgeons registered under this act or the possession of drugs in accordance with a prescription of a physician registered under the act are exempt.

Section 9 provides a penalty of a maximum fine of $2,000, imprisonment of not more than five years or both for violations of the law. Section 10 authorizes the Commissioner of Internal Revenue to appoint necessary persons to enforce the law. Section 11 appropriates $150,000 for carrying it out, and Sections 12 provides that this act shall not amend or repeal the previous laws on this subject.

THE REGULATIONS

The regulations are somewhat more illuminating, as they form the application of the law to specific conditions. The registration fee for the period remaining from March 1, 1915, to July 1, 1915, is prorated at 34 cents, remittance to be made in currency, money order or certified check. Application for registration blanks should be made to the collector of the district. Each application will be given a registry number which will be permanent and which will be entered on all blank orders issued to the applicant. All applications will be recorded alphabetically by classes, and coupon stamps to the amount of the special tax required will be furnished by the collector. Orders for any of the specified drugs must be made on the prescribed form, supplied by the collector of internal revenue bearing the registry number and signature of the person ordering the drugs. All orders must be in duplicate, the duplicate retained by the maker and the original by the person filling the order, and both copies must be kept on file for two years in such a way as to be readily accessible to the inspecting officers. A written order is not required for the dispensing or distribution of any of the specified drugs to a patient by a physician registered under this act in the course of his professional practice, but a record of drugs so dispensed must be kept by each physician in a suitable blank book to be provided by the physician, the records showing the date, the kind and quantity of drugs dispended and name and residence of the patient to whom the drugs were given. Prescriptions must be dated and signed on the day issued, and must contain the name of the physician and the name of the person for whom the prescription is filled. Druggists are required to file such prescriptions separately or else to keep a separate record of such prescriptions, showing the file number in each case. In addition to the signature of the physician, the prescription must state the registry number, the location of the office of the physician and the name and address of the person for whom such prescriptions are written. Druggists are required to refuse to fill prescriptions that are not so signed, or any prescriptions that they have reason to suspect were fraudulently issued. The dispensing of such drugs by druggists, except in accordance with the physician's original prescription, is forbidden. Refilling of prescriptions containing habit-forming drugs is therefore prohibited under this law. Each person dispensing these drugs directly to consumers is required on the first day of March, 1915, to prepare and keep on file an inventory of all such drugs on hand at that time.

Copies of the law, and the regulations with an appendix giving the collection districts and the address of the collectors of internal revenue for each district, can be obtained from the Commissioner of Internal Revenue at Washington or from the collectors of the various districts. The pamphlet is Internal Revenue Regulations, No. 35, dated Jan. 15, 1915.

COMING EXAMINATIONS

CONNECTICUT: New Haven, March 8-9. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic; New Haven, March 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic: New Haven, March 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

KANSAS: Topeka, Feb. 9-11, 1915. Sec., Dr. H. A. Dykes, Lebanon.

MAINE: Portland, March 9-10. Sec., Dr. F. W. Searle, 776 Congress Street.

MASSACHUSETTS: Boston, March 9-11. Sec., Dr. Walter P. Bowers, Room 501, No. 1 Beacon St., Boston.

California July Report

Dr. Charles B. Pinkham, secretary of the Board of Medical Examiners of the State of California, reports the written examination held at San Francisco, July 14-17, 1914. The total number of subjects examined in was 9; total number of questions asked, 90; percentage required to pass, 75. The total number of candidates examined was 56, including 7 osteopaths, of whom 33 passed, including 1 osteopath and 1 drugless practitioner; 23 failed, including 6 osteopaths. Sixty-seven candidates were licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.

Book Notices

The Nervous System and Its Conservation. By Percy Goldthwait Stiles, Instructor in Physiology in Harvard University. Cloth. Price, $1.25 net. Pp. 229, with illustrations. Philadelphia: W. B. Saunders Company, 1914.

This book consists of twenty-three brief chapters, as follows: Introduction. The minute structure of the nervous tissues. The elements of nerve physiology. Reflexes. The general anatomy of the nervous system. The afferent part of the nervous system. The neuromuscular mechanism. The neuromuscular system: neuromuscular fatigue. The autonomic nervous system. The cerebrum. The cerebrum and human development. The cerebrum and the life of the individual. Emotion. Sleep. Dreams. Causes of nervous impairment. Neurasthenia. Some matters of general hygiene. The author states that "if this volume is not to be an impertinence it must be justified by the attempt made to combine some elements of the anatomy, physiology and hygiene of the nervous system." He has succeeded in giving a clear and interesting account of the main facts and principles involved, and while in his modesty he does not address himself to the medical profession, we can assure our colleagues that unless they have kept unusually well abreast of the advances in the physiology of the nervous system, they may spend a few profitable and pleasant hours with this little book and then turn it over to educated lay friends who wish a readable account of the workings of the nervous system and the principles which govern our efforts at maintaining its efficiency.

Abdominal Surgery. Clinical Lectures for Students and Physicians. By Thorkild Rovsing, Professor of Clinical Surgery at the University of Copenhagen. Edited by Paul Monroe Pilcher, A.M., M.D. Cloth. Price, $5. Pp. 477, with 136 illustrations. Philadelphia: J. B. Lippincott Company, 1914.

The title of this work is broader than the subject matter. Of the twenty-five chapters, five are on general subjects, such as the history of antiseptics and on the use of anesthetics, general and local, etc., seventeen are on surgery of the stomach, and the remaining three on echinococcus and abscess of the liver, and chronic jaundice. Each chapter is a clinical lecture, and the author says, "The clinical lecture unquestionably offers certain advantages and affords a point of view which cannot be found in the systematic compact text-book." It is true that the clinical lecture and demonstration offer great advantages, but these advantages rest largely in the demonstration, that is, in what one sees done, and the manner of doing it. All this is lost when the clinical lecture is put into print. In the clinic, what is said is exemplified by what is done; but when the clinical lecture is put into print minus the objective part, it has usually lost most of its value, as one seldom talks in the clinic in the concise manner in which one writes. Under the subject of "Local Anesthesia," the author says, "Amputations and resections cannot therefore be performed with this method, but even if they could be they should in my opinion never be done under local anesthesia, but under ether narcosis, because it is really inhuman to allow a fully conscious patient to undergo such dangerous and physically overwhelming operations when we are in possession of such a safe general anesthetic." He condemns Bier's method of local anesthesia, because "in the first place it is quite superfluous and as I said before inhuman, and secondly because one can safely foretell that it will prove very dangerous." From these statements it is very evident that the author has had little experience with modern local anesthesia, as none of the direful things which he predicts about it have come true; on the contrary, its use is rapidly gaining ground. Spinal anesthesia, on account of its high mortality, is justly discarded. The author's method of treating gastroptosis is specially interesting and the rather high percentage, namely, from 71 to 75 per cent., of complete relief from all symptoms after operation is encouraging, considering the complicated nature of the lesions found in these cases. The author's experience in gastric surgery has been quite large, and his lectures on this subject contain many valuable suggestions.

Acute General Miliary Tuberculosis. By Prof. Dr. G. Cornet. Translated by F. S. Tinker, B.A., M.B., B.C. Cloth. Price, $1.50 net. Pp. 103. New York: Paul B. Hoeber, 1914.

This monograph is devoted chiefly to the etiology and pathology of acute miliary tuberculosis. The etiology is chiefly concerned with the way in which tubercle bacilli can reach the blood from lesions already existing in the body. This may occur in three principal ways: by the transmission of a large number of bacilli from the thoracic duct into the veins, by rupture of a cheesy tuberculous gland or other collection into a blood vessel, or by the gradual invasion of several of the smaller blood vessels by tuberculous lesions from which the bacilli escape into the blood stream. The symptoms are sketched with some detail, and a brief discussion of diagnosis and prognosis is given. Strange to say, notwithstanding the exact methods of determining the presence of bacilli in the blood, the correct diagnosis of this condition has not been made clinically in the majority of cases. The author quotes Silbergleit to the effect that "in almost all of thirty-one cases of acute miliary tuberculosis reported by Lubarsch, the diagnosis was not clinically proved and, as a rule, the suspicion of it was not found once expressed." Prophylaxis and treatment occupy scarcely two pages. The author suggests, however, that "as healing is not absolutely impossible, we must not put our hands in our pockets but must strive to attain our aim, even though this is rarely accomplished." It is the hope and possibility of attaining this aim that gives value to a discussion of this subject, which is unfortunately too little known.

The Evolution of the Study of Anatomy and Its Important Relation to the Development of Surgical Knowledge. By J. Ewing Mears, M.D., LL.D. Cloth. Price, 75 cents. Pp. 26, with 6 illustrations. Philadelphia: William J. Dornan, 1914.

This little book gives an interesting account of the development of the science of anatomy from the early Greeks to the present time. Investigators from the beginning have had to combat the antipathy of the people to the desecration of the human body. Later, when the need of such study was more universally recognized, the difficulty of obtaining sufficient material is dwelt on, with its consequent grave robbing and "burking," and the outburst of indignation against the anatomists incident thereto. With the present reasonable laws for supplying the needs of medical schools, and the question of preservation of available material quite satisfactorily solved, the author pleads for an exhaustive study of the whole subject as a basis for surgical practice in general, or in any specialized line. It is an interesting essay.

Medicolegal

Practice of Medicine by Clairvoyants

(Commonwealth vs. Delon (Mass.), 106 N. E. R. 816)

The Supreme Judicial Court of Massachusetts overrules exceptions to a conviction of the defendant of practicing medicine in violation of Section 8 of Chapter 76 of the Revised Laws of Massachusetts. The court says that her defense was that what she did was done by her as a clairvoyant within the last clause of Section 9, which provides that the penalty of Section 8 shall not apply to a clairvoyant who violates none of the provisions of that section. Evidence was introduced that two men called on her for treatment; while asleep, holding the patient's hands, she gave advice to the first and told the second the nature of his sickness; and that in both cases she furnished the patients with medicine for which she was paid. The defendant took the stand in her own behalf and testified that she was not learned in diseases or in medicine; that when consulted by a patient she went into a trance and that while in the trance she was told by "occult force" what the matter with the patient was and what remedy to prescribe; that on coming out of the trance she prescribed what had been revealed to her while she was in it. The judge instructed the jury that if the defendant was a clairvoyant, in her line of practice, she was not within the exception specified in the statute if, for the cure, prevention or alleviation of any pain, disease or sickness of those seeking treatment from her, she prescribed or directed any drug or medicine, with the expectation of receiving compensation therefor. To this an exception was taken. Possibly the word "clairvoyant" might be interpreted to include one who hears communications made by "occult force" while in a trance. But in the accurate and indeed in the ordinary meaning of the word it is confined to a person who sees, while in a trance, things which by reason of distance or for other reasons are not ordinarily visible. The court is of the opinion that Section 9 above referred to, in creating exceptions to the general rule established by Section 8 of that act, is to be construed strictly. It follows that the word clairvoyant must be construed accurately. So construed, it does not authorize a defendant to prescribe medicines revealed to him by "occult force" while in a trance. The instruction given was right.

Roentgen-Ray Examination Required—Photographs of Body as Evidence

(Cincinnati, N. O. & T. P. Ry. Co. vs. Nolan (Ky.), 170 S. W. R. 650)

The Court of Appeals of Kentucky reverses a judgment recovered by plaintiff Nolan in this personal injury case, remanding the case for a new trial. The court says that he was a brakeman and was thrown to the ground by the giving way of a handhold at the top of a car. A little while after this he appeared at the station, apparently suffering great pain, and was taken to a hospital. The physicians in charge could find no evidence of a broken bone, but he declined to allow them to put him under an anesthetic. After staying at the hospital about a month, he was taken home, and later brought this suit against the company, charging, in substance that in his fall his hip-joint bones were broken. Thereafter the court entered an order that, on a certain date, he should go to the office of a named physician and submit himself to a Roentgen-ray examination, to be made by the physician for the purpose of ascertaining whether or not one of his hip bones was broken and what his injuries were, the physician to report in writing the result of the examination, an attorney of each of the parties being allowed to be present at the examination. It was also provided in the order that Nolan should not submit himself to the examination if in the opinion of the physician danger was to be reasonably apprehended thereform. On the appointed day he went to the physician's office with his attorney, who stated to the physician that Nolan had been exposed to the Roentgen rays four times within the past three weeks, and that they refused to allow him to make a roentgenogram unless he would be responsible for any trouble that might come from the use of the Roentgen ray, which responsibility the physician was not willing to assume, and no examination was made. The Court of Appeals holds that, when the case was called for trial a few days later, the defendant's motion that the trial be postponed that a Roentgen-ray examination might be made should have prevailed, on the facts stated, and that the defendant should not be forced to trial until the examination had been made, unless it was shown that it could not be made with safety to Nolan.

On the trial of the case the plaintiff introduced in evidence certain photographs taken of his legs and hips, and proved by his physician, who had examined him, that the photographs were a fair representation of their condition. The defendant objected to the introduction of the photographs in evidence, insisting that the plaintiff's person itself was the best evidence. There is some conflict in the authorities on the subject, but this court approves the rule adopted in some jurisdictions that the nude body of the plaintiff should not be exhibited in court, and that photographs of it may be given in evidence; but in order that the photographs may be introduced, it must be shown that they were fairly and correctly taken. Here there was no proof as to how the photographs were taken, and no proof that they were fairly taken; without this they should not have been introduced in evidence.

If the condition of any private part of the body of a male or female is material on any trial, and cannot be examined in court without an improper exposure of the person, it should, under an order of the court, be examined out of court by experts appointed for that purpose.

Society Proceedings

PHILADELPHIA COUNTY MEDICAL SOCIETY

Meeting held Dec. 23, 1914

The President, Dr. William Duffield Robinson, in the Chair

Surgical Treatment of Chronic Indolent Ulcer of Stomach

Dr. Charles H. Frazier: There is no doubt that the incidence of organic lesions such as gastric and duodenal ulcer, compared with gastritis and other functional disorders, is greater than one would gather from the hospital reports. In my last fifteen cases, partial gastrectomy was performed in twelve instances for chronic ulcer alone, and in three for ulcer with carcinoma implanted. Of this number one patient, the fourth of the series, died. In diagnosis I have come to place reliance chiefly on the history and the roentgenogram. Operation is imperative in perforative ulcer, but surgery should not be thought of in cases of severe hemorrhage. I should ardently advocate surgical measures in chronic ulcer of the stomach and duodenum. In a series of 120 cases of gastric ulcer treated by medical measures, Parila (*Arch. f. Verdauungskr.*, 1912, xviii) showed that at the time of discharge from the hospital, 86 per cent. were completely cured or very much improved; only sixteen, or 13 per cent., were improved but not cured. Mostly within two years after this series of 120 patients left the hospital, 30 per cent. had died; 5 per cent. were unimproved; 35 per cent. improved (that is, they had either to live on a very restricted diet or were unable to resume their occupation without return of symptoms), and 30 per cent. were entirely well. In reporting 1,000 operations for gastric and duodenal ulcer, W. J. Mayo advises that the treatment of all duodenal and obstructing ulcers of the pyloric end of the stomach by gastrojejunostomy and excision, or infolding the ulcer, is satisfactory, and gives 98 per cent. of cures or great improvement. Secondly, 85 per cent. of ulcers of the body of the stomach will be either cured or greatly relieved by excision or suture compression with gastrojejunostomy. The remaining 15 per cent. will be more or less benefited, and so far as we have observed, none has been made worse by operation. The mortality of the surgical treatment of chronic gastric and duodenal ulcer is well under 2 per cent. My mortality for simple gastrojejunostomy in gastric and duodenal ulcer, excluding perforation, is under 2 per cent.

In the chronic callous ulcer of the stomach, the transverse resection, or partial gastrectomy as proposed by Rodman, is the operation of choice. In considering whether these ulcers shall be treated by gastrojejunostomy with or without pyloric exclusion, by excision or by partial gastrectomy, three essential and equally important factors are: the risk at operation or the immediate outcome; the incidence of cancer or the intermediate outcome, and the eventual condition of the patient or the end result. Greater care in the selection of cases and early recognition of symptoms will greatly reduce the mortality statistics. Furthermore, in starved cases of gastric ulcer, the treatment may be begun by a jejunostomy under local anesthesia, and the final operation may be delayed until, by feeding, a safe margin of vitality has been attained. In none of the results following partial gastrectomy in my own series has there been a suggestion either of recurrence of symptoms or of unpleasant consequences. In von Eiselsberg's series of 334 gastro-enterostomies for ulcer of the stomach and duodenum, there were seventeen deaths, a mortality of 5 per cent. The majority of these were, however, recent ulcers, and death was due in seven instances to recurring hemorrhage which the operation did not stop. Of the surviving patients, a little over half were recorded as cured, about one-seventh as improved, and thirty-one as unrelieved, of which eight were cases of duodenal ulcer. Of forty-one out of 334 patients who were known to have died at various times after gastro-enterostomy, twenty-three were traced, and of these thirteen, or more than half, died of cancer of the stomach, and six, or a quarter, of extension of the disease. I advocate operation in cases in which (1) because of recurrent hemorrhage the patient despite medical treatment, becomes progressively more anemic; (2) there is obstruction with retention; (3) the patients are disabled through pain or starvation, and (4) the diagnosis is uncertain as between chronic appendicitis, gall-bladder disease, or ulcer. The nearer to middle life the patient is, the more urgently do I emphasize the need of operation for fear of cancer. Transverse resection offers the greatest assurance of a complete and enduring "cure."

Simulation of Gastric and Duodenal Ulcer by Adhesions, Duodenal Dilatation, Visceroptosis, Etc.

Dr. George P. Muller: The most important feature of the history in duodenal and pyloric ulcers is the periodicity of attack. The most constant single symptom is pain. A right-sided tender point, occult blood, hyperchlorhydria and hypersecretion are also of affirmative importance, but their absence must never negative the diagnosis. The Roentgen-ray finding, next to the history, is the one important means of diagnosis, and the finding of hyperperistalsis and a residue in the stomach at the end of six hours make the diagnosis of duodenal ulcer probable. There are certain cases in which it is difficult to make an exact diagnosis. Ulcer of the pylorus and duodenum without complication, however, are usually clear-cut in symptomatology. In ulcer of the stomach proper, the attacks are not so clear-cut, and the symptoms are apt to be continuous for long periods, are not often eased by food and are more often affected by the taking of food. In the later stages of pyloric and duodenal ulcer, stenosis produces the symptoms of gastric dilatation. In all of these cases the Roentgen rays are of the greatest help. Any patient over 40 who has chronic gastritis or dyspepsia, or a so-called acute gastritis which does not disappear promptly, must be suspected; if he loses weight, strength and appetite, and has a continuance of his dyspepsia, he must be labeled cancer until it can be proved that the condition is due to another cause.

We should be cautious in making a diagnosis of ulcer in a patient previously operated on, unless we have eliminated the possibility of an omental adhesion dragging on the stomach and producing similar symptoms. It should be remembered that duodenal ulcer and appendicitis are often associated. Just as appendicitis may reflexly produce stomach symptoms, so will the mobile cecum and the Lane kink produce symptoms of "dyspepsia," although never quite simulating ulcer. Duodenal dilatation may simulate duodenal ulcer. In considering appendicular gastralgia or appendiceal dyspepsia, as it is variously called, we must distinguish between appendicitis with ulcer and appendicitis with symptoms simulating ulcer. There is no such lesion as chronic appendicitis. Inflammation is an acute process, and what we really mean when we speak of chronic appendicitis is that as a result of acute lesions, obliteration of more or less of the lumen, stricture of the lumen, peritoneal adhesions of fecal concretions exist. It should be remembered that chronic appendicitis with gastric symptoms may be simulated by the action of congenital bands and membranes persisting in the right iliac fossa. Chronic tuberculous diaphragmatic pleurisy may resemble gastric ulcer. Hematemesis is an uncertain indication for operation, and usually suggests some toxic erosion rather than surgical ulcer. The differential diagnosis of gastric ulcer or gallstone colic, and the gastric crises of tabes dorsalis, is well nigh impossible, unless the other characteristic symptoms of locomotor ataxia are detected. There are other conditions and lesions simulating gastric ulcer. The history is the keynote in diagnosis.

DISCUSSION

Dr. Edward H. Goodman: Internists and surgeons, it is evident, are practically in accord in the treatment of gastric and duodenal ulcer. Some cases of gastric ulcer are seen late by the surgeon because it is very hard for the internist to impress on the patient the need of operation. The indications given for surgical interference are agreed to by the majority of internists. I am not entirely in accord with Dr. Muller in believing that the symptoms of duodenal and gastric ulcer are essentially the same. I think they can be differentiated. I agree with him that the roentgenogram is the most important diagnostic help. I would emphasize the importance of observation of the patient for six months after operation, with examination of the stools for bleeding and to know that the ulcer has healed.

Dr. William L. Rodman: I agree with Dr. Muller that in the diagnosis of gastric ulcer we should rely first on the clinical history, and next on the roentgenogram. I do think however, that there will be cases in which diagnosis is impossible without an exploratory laparotomy. While I recognize the value of the Roentgen ray, I do not place the percentage of positive diagnosis by its use at so high a figure as 85. The impaired motility that comes with cancer is of great value in diagnosis. Roentgenograms frequently indicate the presence of hour-glass contraction when such is not the condition. I would emphasize the point made by both Drs. Muller and Frazier as to the inadvisability of operation in acute hemorrhage; chronic hemorrhage which is sapping the vitality of the patient calls for operation in nearly all cases. In addition to the ordinary means, I have found the injection of very hot water into the stomach valuable in the arrest of hemorrhage from either gastric or duodenal ulcer. I agree with Dr. Frazier that if the ulcer be a duodenal one or a pyloric one near the outlet, producing a constriction of the pylorus, gastro-enterostomy is always a satisfactory operation so far as the relief of symptoms is concerned; but that it is not the operation of choice even in these cases, because of the cancer incidence in this region. We should keep before us the fact that there are 75,000 deaths from cancer in the United States annually, and 26,000 from cancer of the stomach. According to Leopold, 35 per cent. of all cancers are in the stomach. More operations should be done in the precancerous stage, because very few cases of cancer that can be diagnosed clinically can be cured by operation. The most unsatisfactory thing about gastro-enterostomy is that many of the patients will rapidly convalesce, but that they die in eighteen months, and you feel sure that cancer was present at the time of operation. I would emphasize the point made by Dr. Frazier that it is not only impossible clinically to differentiate between cancer and ulcer, but that the diagnosis cannot be made at the operating table. In three cases out of four, when we remove suspicious ulcer it proves to be carcinoma.

Dr. Francis J. Dever: The actual diagnosis of gastric or duodenal ulcer is not so easy as it would appear to be. A large number of patients have no pain, and no bleeding from the stomach and rectum, and have a normal or subnormal quantity of hydrochloric acid in the stomach contents. We are, therefore, apt to be led astray by our insistence on the presence of certain symptoms. The occult blood test is valuable if all the antecedent conditions are proper. Blood may show in the feces, but it is well to remember that many patients have hemorrhoids. The use of the stomach tube in diagnosis should be restricted because of the danger of perforation and hemorrhage. It use is not justified except in the most obscure cases. It must be remembered also that gastric ulcer may be associated with gall-stones, appendicitis, etc. The differential diagnosis between gastric or duodenal ulcer and carcinoma is unimportant, because if we are not sure whether the patient has carcinoma, it is time to refer him to the surgeon.

Dr. David Riesman: The subject of gastro-intestinal disease was quite sterile and unprofitable until the surgeon attacked it. Of course, the surgeon has many advantages; he sees the patients generally in the hospitals; the medical man sees them in the office, in their homes, in the dispensary and in hospital practice. He cannot, therefore, obtain accurate data from all patients, and he cannot follow them as well as the surgeon who has operated on them. I believe there is no one symptom that diagnoses ulcer of the stomach or duodenum. If the history were so absolutely reliable as has been indicated, the Roentgen ray would be unnecessary; yet the surgeons depend on it to confirm the diagnosis, which many say can be made without seeing the patient. The atypical case is the one in which one needs the Roentgen ray and all clinical and laboratory help possible. The most important feature is the periodicity of the attacks. I agree with Dr. Frazier on the indications for operation. I believe we must accept the surgical experience on the frequency of cancer developing on ulcer.

Dr. James M. Anders: Cholelithiasis and duodenal ulcer are often confused with one another. The pain in cholelithiasis is almost periodical, at times coming on in a couple of hours after meals. In such cases the pain may be controlled by a change from a solid to a liquid diet. The pain in cholelithiasis is the more severe. When sufficiently intense to demand morphin, the condition may be ascribed to gall-stones, as a rule, rather than to duodenal or gastric ulcer. This point of difference is worthy of being emphasized. I have collected all of the cases of duodenal ulcer to be found in the literature, 262 cases, and in more than one-half, the cause was of intraduodenal origin. The obstruction in most cases was only partial, due to a healing or healed duodenal ulcer, and the symptoms were indefinite, but they were those of dilatation of the stomach indistinguishable from ordinary pyloric or partial pyloric obstruction when the seat of obstruction was above the ampulla of Vater. These cases have for the most part been diagnosticated duodenal ulcer in the active stage because there was a previous history—sometimes, however, years before—of the symptoms of duodenal ulcer. I think it is important to remember the frequency with which duodenal stenosis occurs, and that the symptoms when the stenosis is above the ampulla of Vater cannot always be differentiated from those of pyloric obstruction, although in many cases the history would include the symptoms of duodenal ulcer preceding, often by many years, the indications of partial stenosis.

Dr. Ernest LaPlace: Although Dr. Muller says there is no such condition as chronic appendicitis, there are cases in which the appendix shows signs of having been inflamed and in which it is bound down by adhesions. This does not necessarily mean that the disease existed continuously for a long time, but that at one time the appendix has been inflamed, causing changes which will produce the set of symptoms that are interpreted as chronic appendicitis.

Dr. S. Solis-Cohen: I am not impressed by the absence of definite symptoms of ulcer in a history in cases in which the other indications point to a serious lesion, for there are many classes of patients—some who exaggerate, some who describe symptoms perfectly; some, not at all. Until the cause of gastric ulcer is entirely settled, I doubt whether we shall be able to discriminate as closely as we might desire between operative and non-operative cases in which the diagnosis of gastric ulcer is positive.

NEW YORK NEUROLOGICAL SOCIETY

Meeting held Dec. 1, 1914

(Concluded from page 464)

Pain and Tenderness in Spinal Disease, and Its Surgical Treatment

Dr. Charles A. Elsberg: In 100 spinal operations I noted that there was a marked difference between the cervical and the dorsal spinal roots in structure as well as in course: the cervical roots originated from the cord over an area from 1 to 2 cm. wide, and ran as separate bundles to the dura, while in the dorsal region the bundles soon united to form one nerve root. Therefore, in the cervical region, a tumor could press on a few of the root bundles and give rise to symptoms from those bundles only, so that one should differentiate between root bundle symptoms and root symptoms. In several cases, pressure on the lower root bundles of the seventh cervical posterior root produced pain limited to the index finger. In the dorsal region, the roots first run downward, bending upward again at a very acute angle. Further investigation has shown that the outer surface of the dura of the spinal cord is very sensitive, while the cord itself is insensitive excepting near the origin of the posterior roots; the posterior roots themselves are very sensitive. Taking these facts into account, it is easy to understand how a small focus of malignant disease in the posterior and lateral surface of the body of a vertebra can cause very acute root pains. Extramedullary tumors which do not press on nerve roots might cause pain in the back from pressure on the inner surface of the dura, especially if they lie in front of the slip of the dentate ligament.

In several cases of extradural tumor I observed a peculiar set of symptoms. There was a sort of reverse Brown-Séquard, the motor symptoms being on the opposite side and the sensory symptoms on the same side as the tumor. In these cases there was a collection of fluid under the dura on the side of the tumor, which pressed the spinal cord to the opposite side against the walls of the spinal canal, so that the motor symptoms were due to the pressure of the contralateral pyramidal tract against the bony wall of the canal. This could be called *contre-coup*, and was similar to what occurs in the posterior cranial fossa when a cerebellar tumor of one side pushes the cerebellum to the other side and causes the facial nerve of the contralateral side to be pressed against the petrous portion of the temporal bone, with resulting facial paralysis on the side opposite to the lesion. I also noted peculiar anomalies of the spinal vessels which gave rise to irregular symptoms and which have not heretofore been described.

DISCUSSION

Dr. J. Ramsay: The vertebral pain associated with spinal tumors, I have always explained on the basis of a localized meningeal irritation. This pain is usually bilateral, and has not the unilateral distribution of the root pains. Dr. Elsberg did well to emphasize the importance of cutting the posterior root where it has been subjected to pressure for a considerable length of time. I should like to ask him as to the advisability of cutting these roots for the relief of a long-standing unilateral spasticity, when the site of operation exposes the necessary root distributions. The possibility of contralateral pressure symptoms occurring in connection with lesions of the cord is of extreme interest. The mechanism of contralateral pressure is recognized as a rare occurrence in the hemispheres of the brain and also in the brain stem, in which event its recognition would be of great importance from the operative point of view.

Dr. I. Abrahamson: I have seen two cases in which marked changes of the vessels of the cord were present. One specimen did not show any dilatation of the vein—only a moderate hyaline degeneration of its walls. These cases were quite typical in their symptoms, and were in sharp contrast to those common to extramedullary tumors of the cord. In the latter, the motor symptoms were markedly predominant, with root symptoms at the level, while the cases with varicose vessels showed a marked preponderance of the sensory symptoms, the motor symptoms never equaling the sensory in their intensity. The finding of this dilated blood vessel at the exact level and position that was indicated by the signs and symptoms left but little doubt as to its etiologic importance. When one has to deal with a rather atypical level cord picture suggesting an intramedullary lesion, and yet not characteristically so, associated with slight motor symptoms and marked sensory symptoms, one should be on the lookout for this condition of varix or a type of angioma of the cord.

Dr. Foster Kennedy: Apropos of angioma of the cord producing symptoms referable to the interior of the cord rather than to pressure on the outside of the cord—that is, intramedullary rather than extramedullary, it is well to bear in mind that a chronic syphilitic pachymeningitis of long duration very frequently produces such circulatory conditions, usually by nipping of the blood vessels, so as to cause a breaking down of the interior of the cord, a syphilitic syringomyelia. Does Dr. Elsberg regard these symptoms as being due to the direct pressure of the varix or to the circulatory disturbance produced thereby; in other words, are the symptoms mechanical or circulatory?

Dr. Alfred S. Taylor: One must be careful not to attribute too much importance to the presence of these varices. There is a considerable space between the cord and the dura, and I recall several cases in which I observed large veins in this location, and a simple decompression had given perfectly satisfactory relief, the condition probably being one of inflammation in the cord, and the enlarged vessels being an expression of such inflammation.

Dr. C. A. Elsberg: As to the advisability of cutting the posterior nerve roots for the relief of spasticity, I should advise such a step only in cases in which the cord had been subjected to pressure for a long time, perhaps four, five or six years, and had been injured beyond the hope of recovery. As to the significance of these enlarged vessels, I am convinced that they were not the ordinary congested vessels accompanying an inflammatory process. The veins were from six to eight times their normal size, larger than the radial artery. In 114 spinal operations, I have observed this peculiar enlargement six times; ordinary slight inflammatory enlargement I have seen many times.

The Response of the Organism to Environment.—One of the most remarkable features of organic evolution is that it results in the adaptation of the organism to its environment, and for this adaptation mutation and hybridization utterly fail to account. Of course, the argument of natural selection is called in to get over this difficulty. Those organisms which happen to exhibit favorable mutations will survive and hand on their advantages to the next generation, and so on. It has frequently been pointed out that this is not sufficient. Mutations occur in all directions, and the chances of a favorable one arising are extremely remote. Something more is wanted, and this something, it appears to me, is to be found in the direct response of the organism to environmental stimuli at all stages of development, whereby individual adaptation is secured, and this individual adaptation must rise again and again in each succeeding generation. Moreover, the adaptation must . . . tend to be progressive, for each successive generation builds on a foundation of accumulated experience and has a better start than its predecessors.—Arthur Dendy, *Medical Journal of Australia.*

3. **Ventilatory Function of Lung in Emphysema and Asthma.**—The real difficulty of ventilation in emphysema and asthma, according to Hoover and Taylor, lies in the distention of the infundibula, and this fails to allow an equal diffusion of carbon dioxid throughout the alveolar air.

4. **Intravenous and Intraspinal Treatment in Cerebrospinal Syphilis.**—Twenty-five cases are analyzed by Draper. Symptomatically they have been arranged so that pain predominates at one end of the series and psychic disturbance at the other. These twenty-five patients were all treated intensively for active syphilis. All but one received combined intravenous and intraspinal injections. Mercury and potassium iodid were also used, but the chief reliance and interest were centered on the action of salvarsan, neosalvarsan and salvarsanated serum. Intravenously most of the patients were treated at weekly intervals with doses of salvarsan varying from 0.3 to 0.6 gm., or neosalvarsan in full doses. Salvarsan was the drug of choice and was changed for neosalvarsan only when the patient had an anaphylactic reaction. Intraspinally most of the cases received 30 c.c. of 50 per cent., or from 20 to 25 c.c. of full-strength serum, separated by centrifugalization from blood withdrawn forty minutes after the intravenous dose of salvarsan. The serum was heated to 56 C. and was introduced intraspinally the same day. Several patients have been bled before the intravenous dose, and then salvarsan up to a milligram added in vitro to the serum. This mixture was heated to 37.5 C. for forty minutes, and then 56 C. for half an hour. No serious symptoms followed any of the injections. Clinically very marked improvement occurs in all groups of cases. In the spinal types pain is usually relieved; ataxia helped in most instances, and not very markedly in a few. The bulbar types and those with fairly pronounced psychic disturbances, depending perhaps on meningeal irritation, show marked improvement in symptoms as well as in spinal fluid. The more definite psychic disturbances also may clear up completely, but their spinal fluids cannot in every case be brought to normal. The cell-count has almost always been reduced in them but the Wassermann test rarely disappears below 0.3 c.c.

In some cases, especially those treated with serum salvarsanized in vitro, transient numbness in the feet has appeared;

in other cases a slight failing in general robustness which may be an arsenic effect; and in several instances rather severe pains following the intraspinal injection have been seen. In two cases there has been a sudden increase in ataxia following a period of definite improvement. It is unsafe to give more than two, or at most three, consecutive injections of serum to which salvarsan has been added directly. In no case should more than 0.0005 gm. be added. On the other hand, apparently any number of intraspinal injections may be given with impunity when serum salvarsanized in vivo is used.

6. **Pancreatic Organotherapy and Ketogenesis.**—Kirk summarizes the results of his studies as follows: In the severe or total pancreatic diabetes of dogs, ketonuria of sufficient intensity to be demonstrable by the qualitative tests always develops provided the animal survives several days, and is on a diet covering its calorific requirements. The "total acetone" figures for adult normal dogs of from 5 to 15 kg. weight run about 0.005 to 0.1 gm. per diem. After total or near total pancreatectomy and on complete starvation (except for water), there is a slight gradual increase to about 0.01 gm. up to 0.09 gm. per diem. By judicious administration of a low calorie mixed diet after pancreatectomy the total acetone figures may be kept down to about the latter limits. Heavy protein diets of any sort exert a ketogenetic influence on the diabetic organism. Thus the feeding of an exclusive protein diet of lean beef for several days invariably precipitates a ketonuria appreciable by ordinary qualitative tests, the total acetone going up to 0.1 to even 0.4 gm.

On dynamogenetically equivalent amounts of raw pancreas the total acetone always increases greatly to 0.5 to 0.7 or even over 0.1 gm. per diem, which represents tremendous amounts for dogs; the color reactions have a maximum intensity. Such increases occur on a single feeding of pancreas. The feeding of raw liver is responded to by a greater ketonuria (0.3 to 0.4 gm.) than that following muscle feeding, but not nearly so marked as the reaction after pancreas. These differences were proved to be not due to variations in protein content or in glycogen content. Kirk doubts whether this ketogenetic influence of pancreatic opotherapy is altogether specific. Yet, in view of the consideration that it is so much greater for pancreas than for other representative protein foods we cannot deny the possibility of its being specific. As to the mechanism of its action, Kirk holds that it is not referable to increased absorption of protein or of fats, although both these are factors in additional increase of ketogenesis. It may be associated with increased intermediate metabolism of body-fat; he has not attempted to prove this. It is probably a toxic action, comparable to the increased glycosuria demonstrated by Reach on pancreas feeding. Doubtless such toxic influences are largely directed toward the hepatic functions. If views as the nature of diabetic acidosis be classified into two groups, namely, (*a*) those maintaining that this is a condition *sui generis* and (*b*) those holding it to be due solely to carbohydrate deficiency, then Kirk believes his experiments tend strongly to show that "acidosis" in dogs may vary independently of the status of carbohydrate ingestion and metabolism.

7. **Pathologic Physiology of Heart.**—The details of the pressure changes in the auricles, ventricles and aorta during auricular fibrillation were studied by Wiggers by means of optically recording manometers of high vibration frequency. The results obtained were as follows: Intra-Auricular Curve.—In experimental animals the fibrillating contractions in the auricle in themselves produce no intra-auricular pressure waves. The strong ventricular contractions cause a sharp oscillation in the auricle during early systole, while weaker contractions often cause a single rounded wave or a double oscillation similar to *c* and *v* waves of the normal pulse. When, as often happens, two or three weak contractions which produce no pulse in the arterial system follow each other, a series of small waves are created in the auricle (two to each ventricular systole) which gives the erroneous impression that they occur during ventricular diastole. Intraventricular Pressure Curve.—The intraventricular pressure curves show that the ventricle contracts at a very irregular rate. The height of the pressure and the gradient of the isometric rise before the semilunar valves open is determined largely by the interval between contractions. Hence, whenever the pace is set too rapidly a series of inefficient systoles results which may cause the arterial pressure to fall and the ventricle to dilate. As these weaker contractions often begin before the *a-v* valves are open and are not strong enough to open the semilunar valves, it follows that such contractions may be accompanied by no audible sound. It is important to realize this clinically in estimating the ventricular rate by auscultation in such cases. Central Arterial Pulse.—Since the aortic pressure is affected only by those systoles which elevate intraventricular pressure above the arterial diastolic pressure, it follows that the contour and amplitude of the arterial waves depends not only on the strength of ventricular contraction, but on the diastolic pressure as well. Since the venous pulse tracings taken from the supraclavicular region are always complicated by arterial impacts from the central arteries, the failure to recognize this may lead to misinterpretation of the systolic wave groups. The failure to recognize that the arterial pulse amplitude is not a criterion of the strength of the heart-beat in such cases has given rise to the erroneous impression that the strength of the ventricular systoles follows no law, whereas the intraventricular pressure curves show that the vigor of ventricular systole is largely governed by the time relations between contractions.

8. **Iodin in Cell Following Administration of Organic Iodin Preparations.**—McLean found that the iodin derivatives of fats and fatty acids are absorbed in a lipoid-soluble form after administration by the gastro-intestinal tract or subcutaneously, and are taken up and held in part by the lipoids of the cells. Iodalbin loses its identity during the process of absorption, and its iodin appears in the tissues entirely in water- or alcohol-soluble combination.

10. **Mental and Nervous Disorders Associated with Pellagra.**—Singer says that mental disturbance occurs in about 40 per cent. of all cases of pellagra. Such disturbances are more frequently with repeated attacks. Children are practically exempt. They are most common in men between 21 and 40, and women about 41 to 60. About 95 per cent. of the mental disorders are the direct result of the pellagrous intoxication, and although the mortality in such cases is much higher than in cases without such disorder, yet the mental disturbance will fully recover if the patient survives. They correspond to similar disturbances in other somatic diseases and in such case are often described as not "insanity." The remaining 5 per cent. are examples of mental disorder primarily dependent on the individual's make-up, or else are merely concomitant. Faulty nervous organization, including inadequate mental adaptability, seems to be associated with a predisposition to pellagra. This seems to afford the most satisfactory, even if only partial, explanation of the extraordinary frequency of pellagra arising among the insane, the increased frequency of functional psychoses and psychoneuroses and of nervous disease of the congenital anomaly type among pellagrins as compared with more normal individuals. Chronic "insanity" due strictly to pellagrous intoxication, if it occurs, is rare. Chronic nervous disease as the result of pellagra, if it occurs, is exceptional.

12. **Streptococcus Viridans and Infections of Upper Respiratory Tract.**—In a bacteriologic study made by Cecil of eighty-nine infections of the upper respiratory tract, the *Streptococcus viridans* has been the predominant organism in fifty cases, or 56.2 per cent. If the cases in which the pneumococcus or *Streptococcus hemolyticus* were predominant be added to this group, it can be said that in 85 per cent. of the cases studied, one or the other of these closely allied species was apparently concerned in the infection. *Streptococcus viridans* infections of the upper respiratory tract are characterized by their mild course and a tendency to chronicity and frequent recurrences, owing in great measure to the short duration of the acquired immunity. *Streptococcus viridans* infections of the upper respiratory tract, especially those of the tonsils, sinuses and alveolar sockets, are frequently asso-

ciated with endocarditis and arthritis. In these cases there is much evidence in favor of the theory that the infections of the serous membranes are secondary to the infections of the upper air passages. Autogenous *Streptococcus viridans* vaccines are of considerable value in cases in which structural changes are not too far advanced. Their administration may also be useful in the prevention of recurrences.

13. **Independent Ventricular Activity.**—A case of independent ventricular activity is described by Neuhof. The lowest ventricular rate is 56 per minute, the usual rate is 60 and remains so whether ventricular automatism is present or not. The electrocardiographic complexes of all beats are identical. At one time atropin injection is followed by ventricular escape. The occurrence of the automatic activity during the course of acute articular rheumatism and its disappearance later and a study of the physical signs make it possible that a small transient myocardial inflammatory focus at or near the auriculoventricular connections is the irritative cause of the abnormal mechanism.

21. **Diabetes and Surgery.**—The following rules are laid down by Risley in regard to operations on diabetics: (a) A thorough examination of the urine must be made in every case, especially for the detection of acetone and diacetic acid. (b) The total amount of ammonia must always be estimated. No operation except of the extremest emergency should be performed if there is 1 gm. of ammonia excreted in twenty-four hours, until this has been reduced to the normal amount, 75.9 gm. (c) An operation should be postponed should there be acetone or diacetic acid, even if the amount of ammonia is normal. (d) Much albumin in the urine is a contra-indication to operation and even in small amounts is of bad prognostic import. Most of the major operations of surgery have been and can be performed with success on diabetics. In Phillip's extensive series gathered from the literature the percentage of recoveries was 72.28, or a mortality of 27.72 per cent. The use of an anesthetic other than ether and chloroform, careful dietary treatment before operation, the prevention of sepsis and rapid technic will still further reduce the mortality.

33 *Studies on Action of Various Drugs on Vasomotor Center. J. D. Pilcher and T. Sollmann, Cleveland.

31. **Action of Strophanthin on Suprarenal Secretion.**—Experiments are described by Richards and Wood which show that the intravenous injection of strophanthin into dogs and cats is regularly followed by the development in the blood of capacity to cause decrease of tonus and inhibition of contractions in an isolated strip of intestinal muscle in a manner indistinguishable from that possessed by epinephrin. This result is not obtained after section of the splanchnic nerves or of the spinal cord between the fourth and fifth cervical nerves. This is evidence that strophanthin is capable of stimulating the central nervous mechanism controlling the secretion of the suprarenal glands. Experiments are also described which indicate that digitoxin has the same capacity in a high degree; but that strychnin and camphor are decidedly less active.

32. **Action of Conessin and Holarrhenin.**—The alkaloids of holarrhena congolensis, namely, conessin and holarrhenin. Burn states, have a very similar physiologic action, the former being more powerful than the latter. They both exert a considerable narcotic action on frogs, but in mammalia this effect is inappreciable. They also possess a local anesthetic action particularly marked when tested on the rabbit's eye. This property is of no practical value, as both alkaloids produce local necrosis when injected subcutaneously. Both conessin and holarrhenin are cardiac poisons, causing the isolated perfused heart to come to a standstill half way between systole and diastole. They possess a particularly destructive action on the tissue of A-V bundle, and even when injected intravenously produce incoordination, or heart-block. In small doses both alkaloids produce a rise in blood-pressure when injected intravenously. This rise is still seen after paralysis of the vacoconstrictor nerve endings with ergotoxin, and must therefore be due to a direct action on the blood vessel walls. Oxyconessin, an artificial oxidation product of conessin, has somewhat different properties. It possesses a curare action on the frog, but appears to have no general or local anesthetic action. When injected intravenously it produces marked cardiac acceleration and consequent rise of blood pressure. It has no true vasoconstrictor action.

33. **Action of Drugs on Vasomotor Center.**—According to Pilcher and Sollmann nitrites (sodium and amyl nitrite, nitroglycerin) usually stimulate the vasomotor center moderately; they never depress it directly. The nitrite fall in pressure is, therefore, purely peripheral. The stimulation of the center is probably secondary to the anemia from the lowered pressure. Nitrites and various pressor agents are mutually antagonistic. It is, therefore, suggested that the point of attack of nitrites differs essentially from that of pressor agents. Very large therapeutic doses of strychnin (0.05 mgm. per kilogram)—large enough to be dangerous under certain conditions are usually without action on the vasomotor center, but may stimulate the center moderately. Epinephrin has no direct effect on the central vasomotor apparatus. Frequently there may be slight central stimulation referable to increased pressure. Exceptionally dilatation may result, namely, when the increased blood supply relieves a preexisting asphyxial stimulation result.

In therapeutic doses, camphor is probably without action on the vasomotor center. Doses approaching the convulsive may cause moderate stimulation, which is greatly exaggerated when convulsions occur. Chloroform directly depresses the vasomotor center, but under certain conditions the center may be stimulated indirectly; when the blood pressure falls rapidly from cardiac depression or from cardiac arrest, or when asphyxia is induced either by direct respiratory depression or by depression of the oxygenating functions. Under such conditions there may be intense stimulation of the vasomotor center, with or without preceding depression of the center. Chloroform abolishes the effect of pressor reflexes (faradization of the sciatic nerves) at a higher level of blood pressure than such reflexes are ordinarily lost. The "vasomotor reversal" of Bayliss was also witnessed in one experiment.

Cyanids cause intense stimulation of the vasomotor center. This stimulation is probably asphyxial, as cyanids prevent the utilization of the oxygen in the blood independent of normal respiration. The rise of blood pressure caused by cyanids is proportional to the vasomotor stimulation. Nontoxic doses of aconite are without effect on the vasomotor center. Toxic doses of aconite produce maximal stimulation of the center, more intense than that from strong stimulation of sensory nerves. This is probably the main factor in the rise of blood pressure. Nicotin causes intense stimulation of the vasomotor center. There is no evidence of paralysis of the center; in fatal cases death results from other causes, while the tone of the center is still greatly above normal. Spartein is without direct action on the vasomotor center; but the depression of the respiration tends to produce asphyxial stimulation of the center.

Phenol usually depresses the vasomotor center, probably from its direct toxic action. Actual paralysis was not produced by the doses used. The action may be modified by the convulsant effects and by the anemic stimulation of the center, so that the center may be stimulated, or a period of stimulation may precede or follow the period of depression. Cholin tends to produce a marked direct depression of the vasomotor center, which seems to play a large part in the fall of blood pressure, and which seem to be abolished by atropin. However, other causes contribute to the fall of pressure. When these predominate, they may overcome the central depression, and even produce stimulation, by the anemia. Ergot and ergotoxin have practically no effect on the vasomotor center. Histamin also has no direct action, but the fall of blood pressure and respiratory disturbance usually produce a moderate stimulation. Hydrastis and its alkaloids, hydrastin and berberin, and the derivatives hydrastinin and cotarnin, have no direct action on the vasomotor center. The center may be excited from respiratory depression, convulsive phenomena or cardiac arrest.

Strophanthus stimulates the vasomotor center moderately; digitalis not at all, or to a much less extent. In neither case is the central action sufficient to influence the total action of the drug. Fatal doses, resulting in sudden cardiac arrest, stimulate the center greatly from the resulting asphyxia. Ether does not produce any direct effect on the vasomotor center, or stimulates it moderately. Occasionally there is evidence of depression of the center, but in this work the ether was not pushed to the point of vasomotor paralysis. The stimulation of the center is probably largely the result of asphyxia from respiratory depression. The active principle of the infundibular portion of the pituitary gland has but slight effect on the vasomotor center. Occasionally there may be depression and somewhat more frequently moderate stimulation, but these changes are so inconstant that they are probably secondary to the rise of blood pressure (depression of the vasomotor center, as in McCord's experiments), or to respiratory embarrassment (stimulation of the vasomotor center, as in the non-curarized dog). The response to sciatic stimulation is not materially diminished during the pituitary rise. This indicates that the pituitary principles act peripherally on the arterial muscle. The intravenous injection of lactic acid, in doses 1 to 7 c.c. of the N/7 solution per kilogram of body weight, produces moderate and temporary stimulation of the vasomotor center, independent of the behavior of the blood pressure. This is presumably a manifestation of the general excitatory effect of the increased H ion concentration of the blood.

52. **New Method of Examining for Movable or Floating Kidney.**—Pope's method is described as follows: With the abdomen bared (in women a sheet is thrown around the shoulders, covering the abdomen like a large shawl or a special kimona) the patient stands directly in front of the physician, who is seated in a chair. The right hand, or fist (if the right kidney), is placed on the right rectus and sufficient pressure made to overcome any rigidity. The patient is then instructed to lean forward over the right shoulder of the examiner (for the right kidney) and the tissues between the abdominal wall and the back are grasped between the thumb and fingers of the left hand (for the right kidney). By assuming the standing and forward bending position, the kidney moves or descends downward and forward toward the abdominal wall. In this position it is more easily accessible to the examining fingers. The thumb and fingers gently grasp the kidney between them and are thus enabled to detect whether the kidney is movable or not, and the extent or degree of movability. In examining the left kidney the process is reversed.

Microscopic and cultural examination of the centrifugalized morning urine, as well as the washings from the irrigation of the anterior urethra. 2. Microscopic and cultural examination of the urethral discharge—whether spontaneous or artificial. 3. Microscopic and cultural examination of the massaged secretion of the prostate and seminal vesicles. 4. Urethroscopic examination of the anterior and posterior urethra. 5. Complement fixation test. 6. Skin reaction and hypodermic injection with gonococcus vaccine (still *sub judice*). Should all of these tests prove negative repeatedly, the patient may be declared cured; but the physician cannot assume the full responsibility and guarantee the cure. The patient himself must assume that responsibility.

113. **Health—National Asset.**—Florence summarizes his paper as follows: Educate the people, beginning in the school and in the homes. Agitate health matters in season and out of season. Rely on the press for aid. Get in close touch with your law-makers that they may act with foresight and intelligence. Organized medicine must, as never before, be up and doing. There should be medical men to lecture at each farmers' institute or congress, also at the meeting of civic leagues, woman's clubs and commercial bodies; in fact, on every occasion possible let education and publicity be the keynote. There is no reason why the gospel of health should not be preached from every pulpit in the United States. Inform corporations of the money value of preserving health and life. Instruct each individual what sickness means in dollars and cents to each and every household. Be alive to the issues; extend your endeavors to the end that the citizenship of our great commonwealth may be a happy, healthful, home-loving and God-fearing people.

116. **Defective Metabolism and Its Results.**—Palmer feels himself justified in considering auto-intoxication as being the primary cause of all cases of rheumatism, Bright's disease, arteriosclerosis, apoplexy, cholangitis, pancreatitis, cardiac disease, many exanthemata, gastric ulcer and even cancer of the stomach as well as many other troubles with which we have to deal, to defective metabolism and the resulting auto-intoxication. The physical and mental degeneracy resulting from toxemia, he says, can and does bring about a physical degeneracy that is transmissible and many children are the victims of hereditary, degeneracy, the sins of the parent being handed down even unto the third and fourth generation. There is no work of the physician demanding more earnest thought, or no labor that we can perform for the public that will bring greater returns than to teach the individual the importance of how to eat and what to eat, what to drink, and how to live so as to protect himself against organic failures.

118. **Sugar-Cane Products as Cause of Pellagra.**—The following facts in Blosser's opinion seem to support his claim that sugar-cane products are causing at least a large majority of the cases of pellagra in the South. All but three of the 133 pellagrins whom he has questioned admit having eaten sugar-cane products very freely. Exclusion of all partially refined sugars and sugar-cane syrups from the diet of pellagrins has enabled him to cure 121 out of 133 patients treated; of the remaining 12, 8 were improved and 4 died, a mortality of 3 per cent. Recurrences have not occurred in any cases in which the diet was carried out as directed; slight recurrences developed in five cases, but in each of these it was found that the patients had previously relapsed into their former diet.

The presence in sugar-cane products of an actively poisonous substance is shown by a feeding experiment reported by Blosser a short time ago. A moderate amount of sugar-cane syrup was administered to a dog, together with a diet which was in other respects varied and well balanced; at the end of six months the dog was found to have developed pronounced organic changes of the liver, intestines and kidneys. These conditions could not have been due to an unbalanced diet or to the absence of "vitamines." The organs affected in this feeding experiment are the ones mainly affected in pellagra.

122. **Splenectomy.**—There are many points of interest in Perry's case. First, following a child-birth, in December, 1913, and the patient's admission to the hospital, in January, 1914, suffering from acute empyema of the gall-bladder, associated with stone, her uneventful recovery from this condition, followed by a period of apparent good health; her readmission to the hospital in August, 1914, with chills and fever, and a mass in the abdomen. Repeated blood examinations failed to reveal the presence of malarial parasites in the peripheral circulation, but by cystoscopic examination it was determined that she had a dead kidney on the left side. A nephrectomy was done, but the condition failing to improve under careful medical treatment, with a persistence of chills and a rise of temperature at irregular intervals, which could not be explained, finally led to a splenectomy, with fatal results.

127. **Tonsillectomy During Acute Endocarditis.**—Harrison believes that it is often wiser to perform tonsillectomy during an acute attack of endocarditis and remove the source of infection than delay with the hope of operating after the acute attack has subsided. One can sometimes cleanse the tonsil crypts by local applications and syringing with anti-

septic solutions, but in spite of the most assiduous care it will sometimes be impossible to find every focus. As to vaccines, Harrison believes that cultures should be made from the tonsil in all cases of joint or heart involvement and properly preserved, from which vaccines could be made and the patient properly treated with these in cases in which the fever and other signs of infection do not disappear within a reasonable time after the operation.

149. **Anaphylaxis Following Administration of Tetanus Antitoxin.**—The unusual features of Smith's case were: 1. The length of time elapsing between the injection of the antitoxin and the onset of anaphylactic symptoms, which was nine days. 2. The eruption, which was of a dual type, lasting four days. 3. The edema of the face, lasting six days. The edema put in its appearance promptly after the eruption had vanished. Although in the morning it was hardly discernible, in the afternoon the face was so puffed as to be startling in appearance; the eyelids being so edematous that they were opened with difficulty. 4. The joint infection, accompanied by fever, pain, swelling, prostration and delirium, lasting a week, making a total of twenty-seven days after injection. The series of symptoms started in nine days after the time of injection and lasted until the twenty-seventh. The treatment employed was eliminative and symptomatic. The bowels and kidneys were kept active and the patient kept in bed when necessary, and the pain, pruritus and fever met by appropriate measures. The patient is now in good health.

6. **Treatment of Infantile Paralysis.**—The treatment for any paralyzed muscle is immediate and anatomic rest. A muscle is rested only when it is placed in a position in which its work is zero and its origin and insertion are as nearly as possible on the same horizontal plane, for the resumption of function, which should be gradual, is always easiest along a straight line. The zero position is the position of anatomic rest in which the individual muscle itself is relaxed and both its own action and that of its opponent prevented.

MacKenzie's practice when reeducating a muscle is to begin each day at zero and gradually work up to and beyond the highest point achieved the day before. If, for example, the knee be contracted owing to a paralyzed quadriceps and overacting flexors, it is obvious that the former being at a disadvantage for functionating, equilibrium has been destroyed. Hence place the quadriceps in a position of relaxation (knee extension), prevent the overaction of its opponent when resting by means of a splint, or when exercising by means of position, then daily work at it to restore the lost equilibrium, by recognizing that it is incorrect to flex th knee beyond the point from which extension is possible—tha is, at which effort becomes manifest—thus recognizing the cessation of its opposition to its opponent flexor. Reeducation of the "paralyzed" muscle. No definite time can be stated when reeducation should begin, but the two guides would be the temperature and pain; until the cessation of these, the limbs are best rested as advised, and rested only. The difficult question then arises, to find some work the muscles can actually do; and although such work may be the minimum for a healthy muscle, it may be the maximum for the affected muscle. It is not a question of paralysis of muscle, but the loss of certain functions of the muscle, and it is to obtaining the resumption of these that our energies are directed. MacKenzie also discusses fully the surgical treatment of this condition.

9. **Appendicitis Treated with Anticolon Bacillus Serum and Vaccine.**—The possibility of appendicitis being due in some measure to infection of *B. coli communis* suggested to Guthrie that the serum and vaccine of the colon bacillus might be of service in this affection. He has tried it with success in no fewer than twenty-two cases. Most of the cases were in the acute stage; a few showed symptoms of chronic appendicitis, and in one the symptoms were of a postoperative character—that is, there was pain in the region of the cecum simulating appendicitis two years after the appendix had been removed. In only one case has there been a recurrence; here, too, little serum was used and no vaccine. What struck Guthrie most was the wonderful effect of the serum in causing complete relief from pain, also the feeling of well-being and hopefulness of recovery—a feeling entirely absent before treatment. It is therefore believed the serum should be used in the first stage, when the pain is general.

The most suitable dose is 20 c.c. anticolon bacillus serum; 10 c.c. should be injected subcutaneously first in the right and then in the left hypochondriac region. A few days later 100 million colon bacillus vaccine should be injected in a similar way into the deltoid region. This is to prevent recurrence. As organisms other than the *B. coli communis* may be the determining cause of this disease, the "fixation of complete test" should be tried, using the patient's serum and the most probable organism (*B. coli communis, Pneumococcus*, streptococcus), a corresponding serum or vaccine being used. The anticolon bacillus serum probably acts chiefly as an antitoxin, also as a counterirritant, causing local leukocytosis. It has also probably a physical effect, changing the equilibrium in the surrounding fluids and thereby producing increased osmotic pressure and favoring phagocytosis of the bacilli.

13. **Local Incidence of Cancer in Relation to Fuel.**—A very careful inquiry was made by Green as to the relation to cancer of coal, charcoal and wood in France. In nearly all the town districts of France coal is largely used. Wherever coal is exclusively burned the death rate is invariably very high, as is the case also in which charcoal is burned. The fact that charcoal seems to be as dangerous as coal is not surprising, when it is borne in mind that in the Kangri basket, which undoubtedly causes malignant tumors in the natives of Kashmir, the fuel used is charcoal. On the other hand, in cases in which wood is burned exclusively, the death rate is very low. The country death rate is even more striking. In the north the death rate in the country districts almost approximates that of the town. In certain of these districts the country death rate is actually higher than the town. The explanation of this is, to Green's mind, the simple one that cases in which coal is burned, as it often is in country districts, on hearths and in grates which were originally built to burn wood, the elimination of the products of combustion of the fuel is much less effective, and the results are correspondingly deleterious. In cases in which coal and wood are burned the death rate is about the average. In cases in which wood alone is burned the death rate is much below the average in some cases.

Green is convinced that the character of the fuel used in any particular district has a profound effect on the incidence of cancer. Cancer seems to be practically non-existent in some purely peat-burning districts in Scotland, whereas the death rate is almost invariably high wherever coal is burned. It is very prevalent in certain districts in Orkney in cases in which nothing but peat was burned, but this peat contains nearly 1 per cent. of sulphur, and is coal-like in character. Some other element than the strictly sulphur content may be involved in the relationship of certain fuels to the cancer death rates of the districts in which they are used; some chemical condition of the fuel, its ash or its other products of combustion may be responsible, but the results of such inquiries as Green has made into the fuel conditions of those districts in which cancer is rife seem to point conclusively to the fact that etiology of malignant disease has some subtle connection with fuel and its products of combustion, a connection which lies somewhere about the difference between wood and charcoal.

19. **Communication Between Ventricles of Heart.**—The communication in Griffith's case was between the conus arteriosus or infundibular part of the right ventricle on the one hand and the aortic vestibule on the other. The heart was enlarged and weighed 19½ ounces.

21. **Pneumoperitoneum Following Resection of Carcinomatous Rectum.**—An ulcerated tumor in the posterior wall of the rectum was removed by a combined abdominal and peritoneal method. The bowel was divided above the new growth, and both ends were closed. The rectum, with as much pelvic fat as possible, was separated and everted through the anus. The projected mass was then cut off between the growth and the internal sphincter. The remaining part of the rectum was held in its everted position by forceps, and through it the lower end of the mobilized sigmoid flexure was brought down. This was opened, and the bowel ends were united by interrupted sutures and replaced in the pelvis. The union was considered so accurate that Mayo's recommendation to drain the pelvis through an incision behind the anus was not followed. After the operation the highest temperature was 100 F., the bowels acted, and no unfavorable sign was noticed until the sixth morning, when the abdomen was distended. The bowels never failed to move when laxative medicine was given, and there was no vomiting, but the distention rapidly increased, and on the ninth day it was very great, the abdomen being tense and tympanitic all over and the pelvic floor being pushed down. The temperature was 99.2, the pulse rate was increasing, but only 118 and of fair volume. Respiration was not greatly distressed, and the general condition was alarming only because of the increasing distention.

The abdomen was reopened and its anterior wall immediately fell with a flop on the intestines, which occupied a small space. A large quantity of gas escaped, and an absence of odor was observed. The exposed part of the peritoneal sac contained no fluid, and its serous surface was very pale and showed no sign of inflammation. The intestines were not adherent except in the pelvis, in which all the parts were matted together. On separating these many ounces of offensive pus were released. The abscess cavity, which contained no free gas, was drained through the lower end of the incision, the remaining part of which healed by first intention, and no further accumulation of gas took place. After drainage of a secondary collection of pus through an incision in the right groin the abscess healed slowly and otherwise recovery was uninterrupted.

25. **Tuberculin in Treatment of Tuberculosis.**—From October, 1911, to May, 1913, tuberculin was given to 154 patients at King Edward VII sanatorium by Bardswell. One hundred and thirty had tubercle bacilli in their sputum; the remaining twenty-four patients had not. The results among the patients showing bacilli were as follows: Much improved, 64.6 per cent.; improved, 17.7 per cent.; stationary or worse, 17.7 per cent.; lost bacilli, 32.3 per cent. While the use of tuberculin has had no appreciable effect on the general results, as regards the loss of bacilli Bardswell says there has been an appreciable difference, 5 per cent. more patients having been discharged free from bacilli than in former years. The greatest improvement is seen in the group of moderately advanced cases, the figures for loss of bacilli having risen from 17.8 to 25.6 per cent. a significant increase, since this group includes the majority of the patients.

36 *Abortive Treatment of Typhoid and Paratyphoid. S. Ichikawa.

36. **Abortive Treatment of Typhoid and Paratyphoid.**—Ichikawa obtained remarkably good results with the intravenous injection of typhoid vaccine in eighty-seven cases of typhoid and paratyphoid. The vaccine was manufactured as follows: Ten platinum wire loops of a young culture of typhoid bacillus is mixed with 10 c.c. of serum from a few typhoid patients who are in the convalescent stage. It is kept in the incubator for five to six hours. Then it is centrifugalized and the bacilli are dissolved after washing three times in 100 c.c. of physiologic salt solution which contains 0.3 per cent. of phenol shaken thoroughly for one hour. Heating is to be avoided. The vaccine is well shaken before it is used, and then about 0.5 c.c., diluted with warm physiologic salt solution, is slowly injected into the median basilic vein, taking about two minutes.

Intestinal hemorrhage as an irritative symptom was noted in a few cases one to three days after the injection. However, the frequency of the intestinal hemorrhage was less than in those patients who did not receive the injection, and the hemorrhage was in most cases less in quantity. In two patients who had had intestinal hemorrhage previously, further hemorrhage was not observed. Beside the intestinal hemorrhage, Ichikawa observed two cases of hemoptysis, one case of epistaxis and two cases of cutaneous hemorrhage; all the hemorrhages were quite slight and never recurred. He claims that typhoid and paratyphoid can be abortively cured by intravenous injection of vaccine made by sensitizing the living typhoid bacillus with the serum of typhoid patients in the convalescent stage.

46 *Antityphoid Vaccination of the Public. (Vaccinations publiques contre la fièvre typhoide.) G. Maurange.

38. **Typhoid and Paratyphoid Fever Among the Troops.**—Landouzy remarks that the dread of the appearance of typhoid among the French troops proved only too well founded as a whole series of *endémies typhisantes*, as he calls them, developed along the eastern and northern line before the decree rendering vaccination against typhoid compulsory in the French army went into effect October 1. But the paratyphoid bacilli B. were found in the blood instead of typhoid bacilli in about a sixth or eighth of the cases or even oftener. In certain corps the infections numbered about the same for each, and in one corps out of twenty-five specimens of blood all but three developed cultures of the paratyphoid B. bacillus. He describes the clinical pictures of this infection and of "trench diarrhea" in general. It may induce a syndrome deceptively like true typhoid and very serious, or a subacute jaundice, or a syndrome suggesting dysentery or cholera or acute poisoning—all these may be induced by the paratyphoid bacillus. Treatment of both typhoid and paratyphoid can be only symptomatic, with special care to keep the heart working well. He reiterates that keeping the mouth and skin clean, changing the linen in a typhoid ward, etc., require more constant attention and devoted expert service than a ward full of wounded, while all entering the ward are exposed to greater dangers. After recovery, the heart, the liver, the kidney, the spine or the brain may be left irreparably damaged, so that persons contracting typhoid, paratyphoid or other infection in war may be left internally crippled as much as the lame, the halt and the blind cripples from external wounds.

Landouzy adds that when persons inoculated against typhoid develop what seems to be typhoid later, it will almost inevitably be found to be of paratyphoid origin. He encountered recently a case of this kind in a nurse who had been vaccinated against typhoid. Paratyphoid bacilli were cultivated from her blood when she was taken sick later with what seemed to be true typhoid. Landouzy urges therefore parallel vaccination against paratyphoid infection as the only means to stamp out the endemo-epidemic that has swooped down on the army at the front. The troops in the trenches are peculiarly exposed to these infections on account of the proximity of dejecta and the frequently polluted drinking water, to say nothing of the exhaustion from privations of all kinds.

39. **Morphin in Obstetrics.**—See editorial in The Journal, Dec. 19, 1914, p. 2233.

42. **Preventive Treatment of Tetanus.**—Chaput concludes from what he has observed in the numerous cases of tetanus he has encountered that the tetanus germ develops most readily in compact connective tissue and aponeurosis tissue, especially when gangrene is setting in; also in regions with numerous nerves as the nerve sheath is likewise a compact connective tissue. These conditions are realized most perfectly in the hand and the foot, and hence in the hands and feet, and in other regions with numerous nerves, the wounds require more thorough sterilization to ward off tetanus than injuries elsewhere. As gangrenous tissues offer a peculiarly favorable soil for tetanus germs, all such tissues should be carefully removed and all crushed tissues liable to become gangrenous. Most disinfectants have but a briefly transient action, but iodoform keeps generating iodin through days and weeks, and this is the main reliance in treating wounds liable to generate tetanus. The wound can be dusted thick with it and iodoformed wicks carried down in the depths. After forty-eight hours the mischief is done, as a rule. If iodoform is not tolerated, zinc peroxid or bismuth can be used instead.

43. **Paroxysmal Tachycardia.**—Godlewski emphasizes that when an attack of tachycardia can be arrested at once it does little harm, but if the heart is left to pound away its strength uselessly, it becomes exhausted and permanent damage may result. He has had two such cases in the last five weeks among the two hundred men in his company. After a fatiguing march on a hot day the men suddenly developed palpitations, the face red but not cyanotic, with distress in the precordial region and furious beating of the heart but no dyspnea. The beat was 140 and the pulse small. The men were given at once a chunk of bread, the size of a large nut, which they were told to swallow whole with a little water. The pulse dropped immediately to 78 and 70 and all disturbance was at an end. The cases were alike in every particular, as also the benefit from swallowing the chunk of bread a

few minutes after the onset of the attack. His explanation of the benefit from this simple measure is that the terminals of the pneumogastric nerve in the esophagus are irritated by the stretching of the esophagus as the large chunk of bread is swallowed whole, and this irritation seems to act on the whole pneumogastric system and modify its functioning so that it forgets to keep up the tachycardia phenomena, and conditions right themselves.

45. **Epinephrin in Cholera.**—Naamé shows by analysis of the symptoms of cholera that most if not all of them can be explained by an elective action on the suprarenals from the cholera toxins. There is a striking analogy between the cholera syndrome and the symptoms from defective functioning of the suprarenals. In short, he declares, cholera must be regarded as a *hypoépinéphric toxinique* and the logical conclusion is to treat it with the suprarenal extract which the suprarenals are no longer able to produce for themselves. The first stage of cholera, the bacillary invasion, runs its course in the intestines and is comparatively harmless. As the toxins generated act on the suprarenals and paralyze them, the dangerous second phase develops. The remarkable tolerance of cholera patients for epinephrin proves, he says, that it supplies a much needed active principle. He injects it subcutaneously in doses of 4 or 6 mg. in the twenty-four hours, keeping it up for several days, supplemented by saline infusion. Owing to the injury from the much-damaged condition of the suprarenals, the body is unusually sensitive to poisonous substances and hence, he declares, cocain, morphin and similar drugs should never be given in cholera and the patient should not be taken away from the spot. Epinephrin has not only a symptomatic action, combating the vomiting, diarrhea, cramps, abnormally low blood-pressure and chilliness, but it acts directly on the primary cause, having a manifest action both on functioning and on the germs.

46. **Vaccination Against Typhoid at Paris.**—Maurange has been urging the people of Paris not to wait for an epidemic of typhoid but to allow prophylactic vaccination, the same as is now compulsory in the French army. The newly organized service of gratuitous vaccination has been visited now by 5,100 persons and 13,800 injections have been made. The office is open every day for registering, and eight questions are asked each applicant, present health, typhoid, scarlet fever, pleurisy at any time, recurring bronchitis or bowel trouble, and whether there is albuminuria at present. In case of doubt, the urine is examined and the lungs ausculted, and all suspects are advised to abstain from the antityphoid vaccination. The vaccinating office is open four times a week for two hours, and the applicant's numbered card is compared with the register and the record of the previous reactions. The reaction is slight and transient; only very rarely are there still traces of it next day.

Archiv für Verdauungs-Krankheiten, Berlin

47 *Tetany from Thickening of the Blood. (Zur Aetiologie der Tetanie.) G. Rosenfeld.
48 *Concrements in the Pancreas. (Zur Kenntnis der Lithiasis pancreatica.) M. Rosenthal.
49 *Esophagoscopy. (Neue Gesichtspunkte für die moderne ösophagoskopische Technik.) W. Sternberg.
50 *Causes of Chronic Constipation. (Zur Pathogenese der chronischen Obstipation.) F. W. Hopmann.
51 *Harmlessness of Putrefaction Processes in the Intestines. (Darmfäulnis.) A. Rodella.

47. **Etiology of Tetany.**—Rosenfeld reports a case in which tetany developed with the exactness of a laboratory experiment when the blood became much concentrated, and then subsided as fluids were supplied to dilute the blood. The patient was a man of 34 with cicatricial stenosis of the pylorus and all disturbances ceased after a gastro-enterostomy, but in the meanwhile the man had lost so much fluids from excessive vomiting that the intake of water by proctoclysis was not sufficient to dilute the blood, and the tetany came on. More fluid was then allowed to run into the rectum and the tetany subsided. The next day it was the intention to give intravenously 1.5 liter of 0.6 per cent. salt solution and by proctoclysis 50 gm. of sugar in the water in the irrigator. By mistake the sugar was dissolved in the salt solution and the whole infused into the vein. The tetany came on again as the infusion was in progress, but yielded anew to more copious intake of fluids. In this case there was no question of auto-intoxication from the stomach trouble and nothing to indicate deranged internal secretion. The loss of fluids in the excessive vomiting caused such inspissation of the blood that tetany resulted. The tetany subsided each time as the deficit in fluids was made up.

48. **Pancreas Lithiasis.**—Rosenthal comments on the rarity of concrements in the pancreas, only about seventy cases being known. At necropsy of a man of 21 who had succumbed to pulmonary tuberculosis, he found the pancreas packed with stones, five of them as large as a hazelnut. There had been no symptoms of diabetes in this case, which fact Rosenthal explains by the finding that most of the islands of Langerhans were apparently normal, enough having been left uninjured by the presence of the concrements to attend to their task in regard to carbohydrate metabolism. This explains why in nearly all the cases of pancreas lithiasis on record the discovery of the stones was an operative or necropsy surprise. In the thirty-two cases in the literature in which the age and sex were mentioned, twenty-six were males; the youngest patient was a boy under 10 and the oldest two men nearly 75. Obstruction of the outlet alone cannot be the cause of this form of lithiasis as otherwise it would occur more frequently in the many cases of obstruction, and it would be possible to reproduce the lithiasis in animals, which has never yet been accomplished.

49. **Improved Technic for Esophagoscopy.**—Sternberg gives an illustrated description of the instruments he uses for esophagoscopy, commenting on the advantages of a tube not longer than 18 to 25 cm. with an inner tube which can be pushed farther in.

50. **Various Causes of Chronic Constipation.**—Hopmann, in a series of twenty cases, investigated the mode of life, the diet, the drugs previously taken, the state of mind, preceding diseases, studying further the heart, the liver and stomach, and examining the rectum and sigmoid flexure by palpation and direct visual inspection, and classifying the cases according to the Roentgen-ray findings. In fourteen of the twenty cases the feces were found accumulated in the cecum and ascending colon after eighteen and twenty-four hours. They were finally voided in two or three days; first came a hard lump and then soft stool, all containing mucus. In four other cases the feces were not voided for from four to seven days and then they came as small hard lumps, without mucus admixture, but when a loosening diet and a mild purgative were given, the stools contained microscopic mucus. He cites these details as evidence that in every case there was some catarrhal trouble in the cecum or ascending colon and possibly also in the small intestine. The mucus admixture in the cecum and ascending colon may interfere with the normal process of absorption of fluids from the feces in this region. The symptoms with this type of "ascending constipation" are the same as with the syndrome ascribed to spastic contraction of the bowel, the so-called "spastic obstipation." It thus seems evident that this syndrome is in reality merely the result of catarrhal conditions in the cecum or small intestine or both.

In conclusion Hopmann reiterates that nothing in all the experiences related confirms the assumption of nervous influences as directly responsible for chronic constipation.

51. **Pathogenic Stools.**—Rodella's further experimental and clinical experience at his private sanatorium at Venice for derangement in the digestive system and metabolism has apparently confirmed anew his previous assertions in regard to the comparatively harmless nature of the products of intestinal putrefaction. Animals were injected with extracts of stool from young and old, the sick and the healthy. Stool from the febrile with intestinal affections always killed the animals inoculated with an extract of it, while other animals bore without the least apparent harm

injection of extracts from dyspeptic and diarrheic stool if it came from the afebrile. In all his experiments there was no correspondence between the extent of the putrefaction processes and the toxicity of the stool extract. Everything seemed to indicate that the putrefaction products are very little if at all pathogenic. Even 10 c.c. of putrid albumin could be injected subcutaneously in a rabbit with scarcely any disturbance, while the same amount of stool proved always toxic, and if 10 gm. of an extract of diarrheic stool was injected, the animal inevitably succumbed.

This method of injecting the animal directly with an extract of the fresh stool is much simpler and more instructive, he declares, than first isolating the bacteria and then injecting the animal with the bacteria. This direct-extract method has revealed that the stools of infants are far more toxic for laboratory animals than the stools of adults. Even in healthy children the extracts of their stools manifestly contain pathogenic bacteria in larger numbers and of greater virulence than in extracts of adults' stools. This throws light on the more serious consequences of intestinal derangement in children, as compared with adults, especially in acute infectious disease. As adults eat food that is generally cooked and thus sterilized, and as they practice hygiene of the mouth, very few micro-organisms, comparatively speaking, are swallowed, and these are mostly destroyed by the powerful digestive juices. Most of the bacteria which get into the bowel are of the putrefaction-producing group, and these have been found to be only slightly, if at all, pathogenic. In infants the digestive juices are weak and the infant intestine is more sensitive and develops catarrhal conditions more readily than the adult. The products of the catarrhal condition are liable to ferment and generate toxic substances that promote in turn the growth of pathogenic micro-organisms which under other conditions are crowded out by the saprophytes. By inoculation of animals with extract of the stools it is possible to discriminate between the pathologic and the non-pathologic cases and institute treatment accordingly. The inoculation of animals is liable further to reveal the presence of tubercle bacilli in the stools, which is a matter of great import for both treatment and for prevention of the spread of tuberculosis. He mixes 1 gm. of the stool with 5 c.c. of sterile water and injects the whole subcutaneously in a rabbit.

52. **Transplanted Single Kidney.**—Zaaijer does not know of any other instance of six years of adequate kidney functioning by a transplanted single kidney. After the left kidney had been transplanted into the inguinal region, the renal vein sutured to the femoral and the renal artery to the femoral artery, the ureter implanted in the bladder, the urine for a time was blood stained. The plaster dressing was removed the eighteenth day as the wound had healed. Eighty-three days after the transplanting had been done the right kidney was removed through the back. This was in 1908, and the illustrations show the healthy dog six years later and the outlines of the kidney evident in its flank. It does not seem to have altered in size or consistency. The dog ran away once, but turned up again later, always in good health and spirits.

Zaaijer calls special attention to the technic with which he implanted the ureter in the bladder, as the six years of successful function confirm its value. The ligated ureter stump is fastened loosely to the bladder with three stitches which do not include the mucosa. The threads are left loose and the stump of the ureter is carried into the bladder, held in small artery forceps, through a minute incision in the bladder wall. The forceps are pushed in until they cause the opposite wall to protrude. A minute incision is made here and the stump of the ureter is pulled through by the ends of the thread with which it had been ligated. Then the threads fastening the ureter to the first bladder wall are tied. The outer stump of the ureter where it projects from the opposite wall is cut off just inside of the ligature, and the purse-string suture, previously taken around the incision, is drawn up as the outer stump, no longer held by the ligature threads, slides back inside the bladder. Zaaijer has applied this technic in sixteen rabbits also, confirming the advantages of this method. The ureter thus is not opened until the last moment.

53. **Polypous Proliferation of Stomach Mucosa.**—Heinz' patient is a man of 35, healthy until 1909 when he began to experience sensations of oppression in the stomach region, and nausea. The symptoms came on four or six hours after meals and subsided after eating. The Roentgen rays showed polyposis confirmed by an operation, at which several of the polyps were excised. In 53 cases of polyposis of the intestines on record, as compiled by Versé, the stomach was involved likewise in 5 but in none of the cases was the stomach the exclusive seat of the polyposis. Heinz has found a very few cases of this in the literature. The pylorus region is the one generally involved, and the patients are nearly always comparatively young. In the elderly the polyposis is usually accompanied with cancer. Heinz' patient was at first freed from disturbances and gained in weight, but the anemia is still so pronounced that the assumption of polyposis in the intestines or malignant disease seems justified at present.

54. **Prolapse of the Rectum.**—Ach discusses the various factors involved in production of prolapse of the rectum, especially the tendency to paresis of the rectal walls common in lean men subject to obstinate constipation or who have passed through typhoid or dysentery. Women also are particularly liable to prolapse of the rectum during repeated pregnancies or the menopause when there is a general tendency to hernia. In children, chronic catarrhal bowel trouble induces a predisposition by weakening the rectal walls, as also by the excessive straining at stool. Prolapse of the rectum is in reality first a hernia of the floor of the pelvis into the rectum. Treatment should be based on this pathogenesis. The simpler methods might be tried first, especially for children, massage, paraffin, or Thiersch's silver wire method. The various operative technics are described and compared, and Ach then illustrates a method he has applied in two cases with excellent outcome. The rectum is brought into normal shape by a strip taken from the fascia lata. The strip is 25 cm. long and 8 cm. wide and one end is slit about a third of the length of the strip. One of the slit ends is brought nearly around the rectum, to which it is sutured. The other end is sutured to the other side of the rectum and to the upper half of the vagina. The broad end of the strip is then drawn up as high as possible and fastened to Cooper's ligament.

59. ***Decompression Slitting of the Sternum.***—Friedrich not only divided the sternum its entire length, but cut out the bone each side of the slit. The first patient thus treated

had an aneurysm of the innominate artery and the relief from the lengthwise opening made in the sternum was astonishing, but the patient, a man of 47, succumbed to preexisting pneumonia. In a boy of 12 and a girl of 16 with a large tumor in the mediastinum, slitting the sternum in this way relieved the severe symptoms and permitted partial removal of the tumor. A gap of 3 cm. was left in each case, and there was no further cyanosis or dyspnea, not even as the tumor in one case continued to grow. Both patients have been treated since with Roentgen exposures and the tumors have materially retrogressed and the general health improved. In another case the thorax wall had lost so much of its elasticity in the man of 57 that merely slitting the sternum failed to relieve, and the bone on each side had to be cut away to leave a gap wide enough to be of any benefit. The tumor was a sarcoma.

60. **Damage to the Pleura with Operations and Artificial Pneumothorax.**—Boit emphasizes the importance of the phagocytosis and the bacteria-destroying properties of the endothelium of the pleura. When this is damaged in operations or by injection of a gas, the organism thus loses an important means of defense.

61. **Blocking the Brachial Plexus.**—Boit has applied Kulenkampff's technic over 200 times on patients ranging from 6 to 77 years of age. There is no doubt the injection of 10 or 20 c.c. of the 2 per cent. solution of the anesthetic for the purpose causes toxic or traumatic injury of the plexus, although it may be minimal. If the nerve is already pathologic, the effect is naturally felt more than by a healthy nerve. In his own 110 cases there were two failures requiring general anesthesia. He applied this method for all operations on the arms and found it particularly advantageous for reducing fractures and dislocations. The muscles of the arms become relaxed under it, as is observed otherwise only under deep general anesthesia. The phrenic nerve on the same side is temporarily paralyzed by the procedure, as can be seen by roentgenoscopy, but he never observed any tendency to dyspnea except in three instances. The conditions in these cases seemed to indicate that the phrenic nerve had been directly injured by the needle in seeking the plexus. The needle should never be introduced nearer to the median line than the first rib.

64. **Acute Dilatation of the Stomach.**—Linke analyzes 173 cases he has found in the literature, out of 200 on record. Only 78 of the 173 patients recovered, including 57 of the 105 postoperative cases and only 21 of the 68 non-operative, in which emaciation, mental disease or cachexia was evidently a factor. The atony and dilatation are functional, paresis of the gastric musculature being the cause of the acute dilatation. He describes 3 cases personally observed. The sudden explosive vomiting, collapse and enormous dilatation of the stomach proved fatal in 2 of the 3 cases, notwithstanding free use of the stomach tube. One patient had advanced heart disease, and conditions found at necropsy in the other suggest that placing the patient prone or in the knee-elbow position might have brought relief, as it did in the third case, in which it evidently helped to save the patient. This makes the twenty-eighth case on record, he says, in which turning the patient face down seemed to correct conditions at once. Prophylaxis is the main thing, Linke remarks, in conclusion, and the bearing in mind of the possibility of this contingency so that the diagnosis may not come too late.

79 Combination of Multiple Sclerosis with Poliomyelitis? E. Loewy.
80 *Diagnosis of Appendicitis. C. ten Horn.

76. **Intoxication After Antitetanus Serum.**—Boenheim injected in prophylaxis subcutaneously 3⅓ c.c. of the serum, representing 20 units. There was considerable itching at the spot, and this increased until at the end of the week the pruritus over the entire body became so intolerable that the man had to be given morphin. There was also urticaria; the pulse was small, the temperature subfebrile, and there was at one time a brief syncope and attack of weakness. The morning after the morphin had been given (0.04 gm. in the course of the day) the pruritus disappeared entirely, but severe pains developed then in the bones and muscles and there was great weakness. The symptoms improved in the next four days till nothing was left but weakness in the muscles of the calves. A marked but not durable subsidence of the pruritus was noticed after the bowels had moved freely, a hint to be utilized in treatment of toxic pruritus.

78. **Sepsis Following Gonorrhea.**—The man developed multiple joint trouble soon after acquiring gonorrhea, and then staphylococcus sepsis developed, fatal in less than three months after the venereal infection. Necropsy revealed acute nephritis, an abscess in the right lung, the marrow in the long bones yellow and containing staphylococcus. The blood was of the severest aplastic type.

80. **Early Diagnosis of Appendicitis.**—Ten Horn reiterates his former assertions in regard to the diagnostic importance of pain in the region of the diseased appendix when the right spermatic cord is pulled. If the appendix is much diseased, traction on the left cord also may elicit pain. (See abstract in The Journal, Nov. 21, 1914, p. 1887.)

150 *The Clinical Value of Vital Staining of the Granules of the Red Blood Corpuscles. B. Melkich.

144. **Myoclonia.**—Popoff describes a peculiar form of myoclonia which he proposes to call myotonoclonia, as in his case there was a combination of both tonic and clonic muscular contractions. The patient was 19 years old and the trouble began six years before with clonic contractions of the left wrist during voluntary movements. Later on the muscular contractions affected the fingers. Three years afterward tonic muscular contractions developed in the forearm muscles, followed by clonic and tonic contractions in the muscles of the neck, and finally in the flexor muscles of the trunk. The contractures would last for two months and then disappear and return later. The mind was not affected, and no signs of an organic lesion of the central nervous system could be discovered. The patient was drawn over far forward and also showed a tremor, which increased on attempts to straighten up the body. During sleep, lying or sitting, the rigidity and tremor disappeared. The father and a younger brother also showed similar myoclonic disturbances, though without the involvement of the abdominal muscles.

146. **Pernicious Anemia.**—Chosroeff has had thirty-five cases of pernicious anemia without known cause under his care during the last three years. Ten of the cases were studied for many months, with necropsy in three. He differentiates three clinical forms: the chronic intermittent or recurrent form of Türk, the acute form and the aplastic type, with numerous transitional forms. He tried almost every possible method proposed for the treatment of this disease, including drugs, arsenic, iron, hydrochloric acid, etc., dietetic-vegetable diet, then gastric juice, pancreas extract, blood transfusion, splenectomy, etc. His conclusion is that there is no specific remedy for pernicious anemia, but that spontaneous *remissions* are quite common and frequent, *especially* when the patient is no longer young. A method of treatment begun at the time of a beginning remission or when a relapse has reached its end, will give good results, but when used *in* the *beginning* of a relapse there is no *measure* that will prove effectual. These relapses and intermissions have thus nothing to do with the method of treatment. The older the patients, the better they bear the relapses, the younger ones usually *succumbing* during the first or second relapse.

147. **The Blood Pressure in Nephritis.**—In 100 cases of various forms of nephritis, Schwarzman found that the pressure during both systole and diastole was increased in uremic and in acute parenchymatous, interstitial and combined forms of nephritis, the increased blood pressure being not the result, but the cause of the cardiac hypertrophy. The systolic and diastolic pressure may be increased long before any other signs of nephritis, such as urinary changes, etc. The *high* pressure thus *forms* a reliable and early sign of nephritis. The increased blood pressure with nephritis differs from that with cardiac neuroses by being continuous, and by the diastolic pressure being higher than in cardiac or vascular neuroses, with which he never found the pressure over 120 or 130 cm. water (Recklinghaus). With the aggravation of the nephritic process, the systolic pressure sinks because of diminished heart activity and of the increased *diastolic pressure*. The fall of both pressures, occasionally observed in nephritis, is caused by paresis of the vasoconstrictors and failing cardiac power.

150. **Vital Staining of Blood Corpuscles.**—Melkich claims that the granules in the red blood-cells are not due to fixation of the specimen, but indicate merely young normal erythrocytes. Increased numbers of granular erythrocytes indicate an exaggerated but a normal activity of the bone marrow. This is found in all those processes that are connected with increased destruction of red blood cells which decrease in number. The granular erythrocytes greatly decrease in amount, or *even entirely disappear*, in diseases of the bone marrow, and probably also with malignant tumors.

151 *Rupture of the Rectum. (Ett fall av ruptura recti jämte några ord om de s. k. spontana rektalrupturerna.) N. Hellström.

151. **Spontaneous Rupture of the Rectum.**—Analysis of the cases of so-called spontaneous rupture of the rectum has convinced Hellström that the rectal wall was not normal at the point of the rupture. He reviews and compares a number of cases from the literature, only one of the patients recovering; the others succumbed to the consecutive peritonitis. The patient who recovered was a youth of 17, previously healthy until he experienced severe pain at defecation one day, with some bleeding. The operation half a day later revealed a protrusion suggesting a diverticulum, and a rupture above, with diffuse peritonitis. An artificial anus was made to allow the sutured rectal wall to heal, and there was no further trouble. Hellström then relates a fatal case from his own experience; a man of 63 was roused from sleep at night by intense pain in the rectum. The operation ten hours later showed a rupture with smooth edges and no blood in or around it. There was no history of trauma.

PYORRHEA DENTALIS AND ALVEOLARIS

SPECIFIC CAUSE AND TREATMENT [*]

C. C. BASS, M.D., AND F. M. JOHNS, M.D.
NEW ORLEANS

Pyorrhea dentalis and alveolaris is one of the most prevalent diseases of man. In our studies we have found it present to some extent in more than 95 per cent. of all adults examined. Something of its importance may be suggested by the fact that more than half of all the permanent teeth lost are lost from this disease. Each tooth lost represents a suppurative process in the mouth of at least a few or usually many years. It can hardly be possible that the harmful effect of such a disease is local only. Loss of the teeth alone is an important thing in the life of any individual. We feel quite certain that the great prevalence and importance of pyorrhea alveolaris is not now generally appreciated, even among the medical profession.

The specific cause of pyorrhea dentalis and alveolaris is endamebas.[1] These protozoa have been known for more than fifty years to inhabit the mouth, but the first published expression of opinion that they played an important part in the production of pyorrhea alveolaris was made by M. F. Barrett in collaboration with Allen J. Smith[2] during 1914. We recognized this parasite as the specific cause of the disease and began experimental treatment with emetin without knowing of the work of Smith and Barrett, but at a later date.[3] Recently Smith, Middleton and Barrett[4] have also found *Endameba buccalis* in five out of seventeen cases of diseased tonsils, and they believe this parasite may be pathogenic in these organs.

Our studies now include more than three hundred cases of pyorrhea dentalis and alveolaris. They have been directed to (1) determining the relation of endamebas as the cause of the disease; (2) the nature of the disease process; (3) the influence of emetin and ipecac as a specific remedy against the parasite—especially proper doses, best mode of administration, duration of treatment necessary, and prevention of relapse or reinfection.

ENDAMEBAS AS THE CAUSE OF PYORRHEA DENTALIS AND ALVEOLARIS

Endamebas, chiefly, if not altogether, of the species *E. buccalis,* are demonstrable by proper technic in material obtained from all pyorrhea lesions of sufficient extent to be diagnosed. They are not present in the absence of pyorrhea. They can, however, be demonstrated in material from small lesions that do not extend to the alveolar process, in which one may be unable to recognize the pus without the aid of the microscope. This is the early stage of the disease, more correctly called at that time pyorrhea dentalis, which finally involves the alveolar periosteum and then becomes pyorrhea alveolaris. The endamebas develop and live in the dead or dying tissue at the very bottom of the lesion or pocket. This should be kept in mind in examining for them (Figs. 1, 2, 3, 4, 5, 6, 7).

Material for examination is best obtained by scraping it from the bottom of the pocket with a suitable instrument. A narrow pointed toothpick will do, but a No. 22 Younger dental scaler is the best instrument we have found for general use. The material, which is chiefly pus, and which should not contain very much blood, may be diluted with five or ten times as much normal salt solution on a microscope slide, covered with a cover glass, and examined at once for motile endamebas. The usual high dry lens is suitable. They vary considerably in size and shape (Fig. 8) but with very little experience they are easily recognized. The clear ectosarc may project one or more pseudopodia, draw them back, project others in another direction, or the whole parasite may flow slowly in one direction or another. A pseudopod of ectosarc seems to always precede endosarc when it moves. Granules resembling portions of red blood cells in the endosarc help to give to the parasite an appearance similar to that of *E. histolytica.* The largest of the buccalis are about the size of the histolytica. Stained specimens are perhaps more easily diagnosed, especially by those not very familiar with endamebas. They may be stained by any one of several different methods, but the following is good enough for all ordinary purposes: (1) Spread pus on slide; (2) fix with heat; (3) pour on carbol fuchsin; (4) wash off at once; (5) stain with Loeffler's methylene blue ¼ to ½ minute; (6) wash, dry and examine with oil-immersion lens. With this stain the endo- and ectoplasm are well differentiated and the parasite can be differentiated from the much more numerous pus, epithelial, and other cells present. Their size varies from about three times the diameter of a pus cell down to smaller than pus cells. The large parasites contain in their endoplasm one or more large, dense staining bodies or granules which appear to be the nuclei of pus cells. There is usually a clear zone around each of these, and also around the entire parasite. This is apparently due to shrinkage in drying or fixing the preparation. When stained with this stain the endamebas are darker stained than the pus and other cells in the preparation. In a preparation containing many parasites they can be seen with the low power lens studding the field as blue dots. The constant presence of endamebas in the presence of the disease, and their absence in the absence of the disease, coupled with their situation in the lesions, and finally the coincident rapid recovery of the disease with the disappearance of the endamebas following treatment with a specific endamebacide, serve to establish the parasite as the specific cause beyond reasonable doubt. No more proof of the well-known specific pathogenicity of malaria plasmodia could be obtained until very recently, when we[5] were able to grow the parasite in pure cultures, with which experimental inoculations could be made and Koch's postulates satisfied.

[*] From the Tulane College of Medicine.

[*] The expense for the large amount of emetin employed in our experiments was defrayed out of a grant from the Committee on Scientific Research of the American Medical Association.

[1] The term endameba is used in place of entameba, proposed by Barbagallo and Casagrandi in 1897, because of clear historical priority first pointed out to us by Dr. Allen J. Smith (personal communication). Endameba was proposed for a parasitic ameba of the cockroach in 1879 by Jos. Leidy (Proc. Phila. Acad. Nat. Sciences, 1879, xxxi, 204) eighteen years before the term entameba was first proposed for parasitic amebas (Ann. d'ig. sper., 1897, vii, 103).

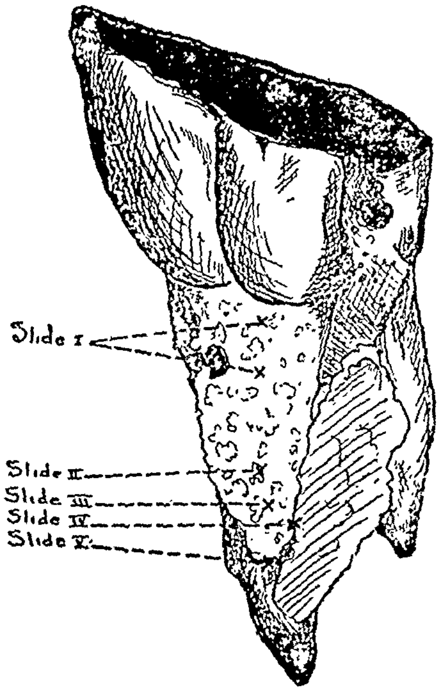

Fig. 1.—An extracted decayed root with site of amebic lesion showing location of the material obtained for photomicrographs.

DESCRIPTION OF THE DISEASE AND THE MANNER IN WHICH IT IS PRODUCED

A tooth consists of the crown (*a* Fig. 9), neck (*b*), and root (*c*). The root is deeply set in its socket in the alveolar process of the jaw bone (*g*). It is held in place by a tough peridental membrane (*d*) which serves as periosteum, covering the root and also lining the socket in the alveolar process. This periosteum is continuous with that (*f*) of the surface of the jaw bone, but it also continues up (*e*) and covers the neck of the tooth.

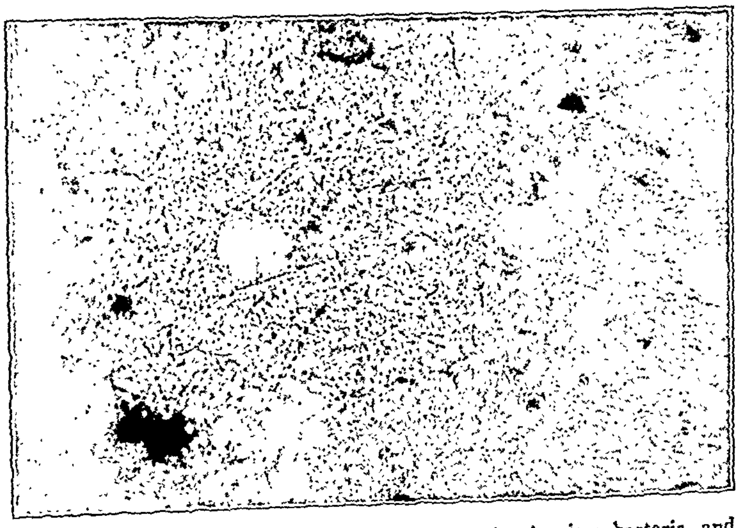

Fig. 2.—Photomicrograph, slide I a, Fig. 1, showing bacteria and débris.

Pyorrhea dentalis and alveolaris affects primarily the dental and alveolar periosteum. Whenever the periosteum is destroyed, of course, ulceration of the soft tissue attached to it occurs. Such ulceration includes granulation, pus formation and the usual tendency to bleed easily. It is not at all probable that endamebas can attack the normal tissue. Damaged tissue is necessary, very likely, and it is highly probable that the injury should furnish a kind of pocket or closed ulcer. These endamebas are not known to live on open surfaces. Any trauma such as wounding the edge of the gum with a toothpick, hard particles of food, etc., or the condition that would result from hard particles being forced between the teeth and making long-continued pressure on the soft tissue, or the pressure of ill-fitting crowns, would offer favorable conditions for establishing the endamebas. Once planted into dead or dying dental periosteum, their natural habitat, they are capable of multiplying and continuing the destructive process with the aid, no doubt, of important secondary factors. Once the infection is established the endamebas thrown off with the pus from the focus serve as a constant source of endamebas in the mouth to infect other suitable lesions whenever produced.

The infection usually begins around the back teeth and exists for months or years before the patient suspects its nature. The interdental soft tissue is most likely to be injured and to be the seat of the closed ulcers favorable for infection; therefore the disease begins there first in most instances. On superficial examination the gum may appear a little swollen or reddened, and extend a little high up between the teeth, but more often nothing abnormal is recognized. The patient may have noticed for months or even years that the gums between certain teeth bleed easily from picking, sucking or brushing them, but this came on so insidiously that nothing is thought of it. By examination with a suitable instrument we find the gum loosened from the tooth to a greater or less extent, and a

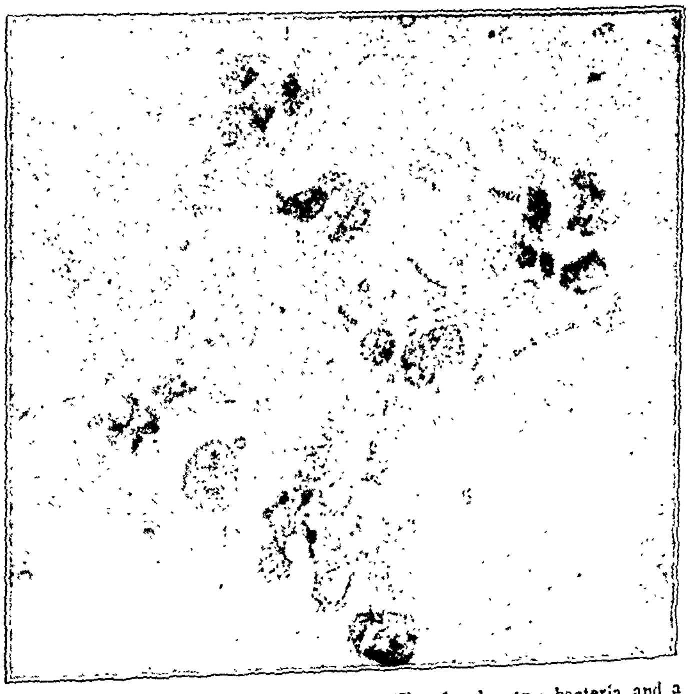

Fig. 3.—Photomicrograph, slide I b, Fig. 1, showing bacteria and a few pus cells.

---

[5] Bass, C. C., and Johns, F. M.: Jour. Exper. Med., 1912, xvi, 567.

certain amount of periosteum is already destroyed. Macroscopic or microscopic pus containing many endamebas can be obtained by scraping out the contents of the pocket. Blood usually flows freely, in contrast to what happens if we do an equal amount of trauma to a normal uninfected gum. This is the early stage. Perhaps the destruction of periosteum has not reached the alveolar level.

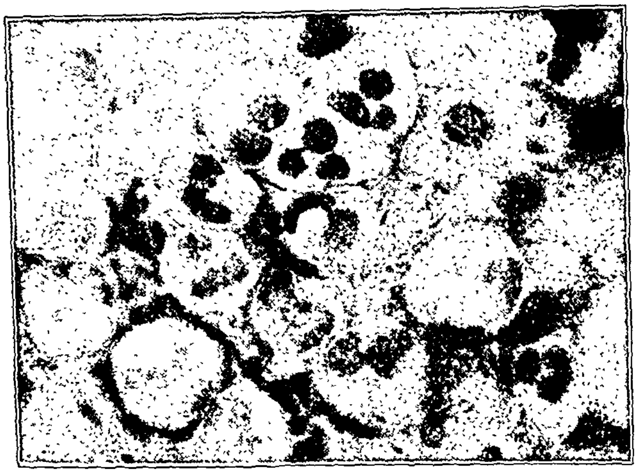

Fig. 4.—Photomicrograph, slide II, Fig. 1, many pus cells, no endamebas. This and Fig. 4 show that the material on the side of the tooth at the indicated places contained comparatively few endamebas.

But the destructive process continues until more and more of the peridental membrane is destroyed, laying bare the root of the tooth and the inside of the bony socket. As the pocket gets deeper and larger there is more and more pus formed. This, no doubt, is very much influenced by decomposition of food that may be forced into it and by the bacterial flora of the mouth. Later the tooth is held only by a small amount of tissue at the bottom of the socket, gets loose, and finally, after years of more or less suppuration, it is lost and the alveolar process, no longer needed to support a tooth, is absorbed. In fact, a great deal of it is removed by the long-continued suppuration to which it has been exposed before the tooth is actually lost. There is more or less soreness, pain, aching and discomfort, and gum boils often form, but the real condition usually is not recognized. The amount of blood lost and of pus produced and swallowed during the several years required for thirty-two teeth lost from this disease to slough or rot out, must be enormous.

We have studied sections and dissections of the diseased tissues in all stages of the disease, and have found the endamebas invariably at the very depth of the lesion. Though some are passing off with the pus, they are many times more numerous in the edge of the living and dying periosteum than in any other place. Figure 1 is a drawing of an old tooth with a pyorrhea pocket on one side, from which we made preparations from different parts and made photomicrographs of representative fields (Figs. 2, 3, 4, 5, 6 and 7). It is seen that though only a few endamebas are present in material from the surface, and consisting chiefly of bacteria, spirochetes and pus, they are present in very large numbers in the edge of the living tissue where Nature is resisting and the destruction is progressing. It should be noticed that this is practically beyond the pus line. What more evidence of pathogenicity do we need?

TREATMENT

Ipecac and its alkaloids, emetin and cephalin, are such perfect endamebacides that nothing better could be hoped for. They have long been employed successfully in the treatment of amebic dysentery, but that disease did not offer such good opportunity to work out dogmatic rules of treatment as the present one does. A given line of treatment can be undertaken, and the effect on the endamebas in the mouth can be watched from day to day or from hour to hour if desired. We have experimented on a large number of patients, watching carefully the effect on the endamebas of different sized doses, different intervals between doses, etc., and feel prepared to lay down fairly definite rules of treatment.

Our experiments with emetin have been limited to its use hypodermatically and later to its use by mouth (internally), with the idea of producing sufficient concentration of it in the body fluids to kill the endamebas in the diseased tissue. We have not tried injecting it into the pockets, or local application, which has been employed with success by Smith and Barrett.[2] We can understand that some particular pocket can be treated locally with as great, or possibly greater, success than by systemic administration of the drug, but if we consider the real condition it would seem that it is not reasonably possible that all the endamebas in all the lesions could be destroyed in this way. When the disease has reached the stage to be recognized by the patient or by the physician or dentist on ordinary examination, it is usually far advanced in one or more places, and there are usually many more lesions or pockets in the earlier stages, all infected with endamebas. We doubt whether one could find all the small lesions in most cases of pyorrhea, much less make local application to them. Certainly it would require long and patient expert work to destroy all the endamebas in the mouth, and that is the object of specific treatment. It would not profit the patient nearly so much to disinfect or cure his bad lesions and leave many small ones to progress and finally get as bad as those that had been cured. It would, in fact, be necessary to

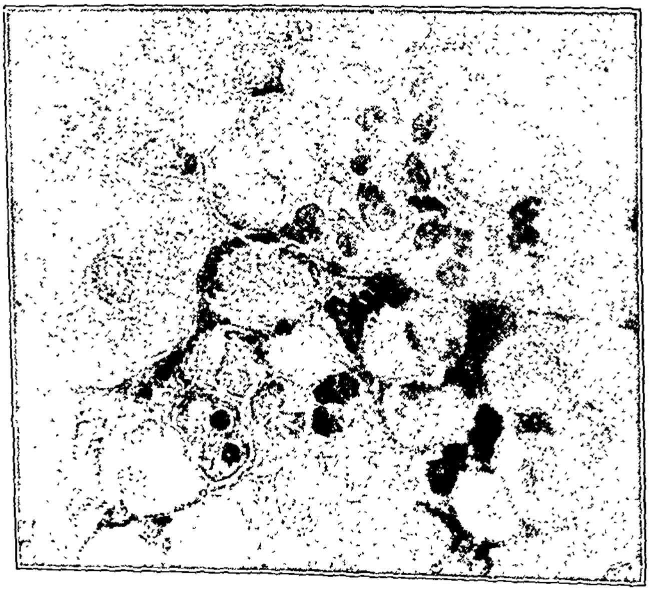

Fig. 5.—Photomicrograph, slide III, Fig. 1. Many pus cells, one endameba.

make applications at frequent intervals until the lesion entirely healed, or else it would be promptly reinfected from the endamebas constantly thrown off from the less extensive lesions. Probably the greatest good to be derived by the patient from the treatment is from saving his teeth that have not lost much of their peridental membrane and supporting alveolar process. The others may be of limited value after the disease is cured.

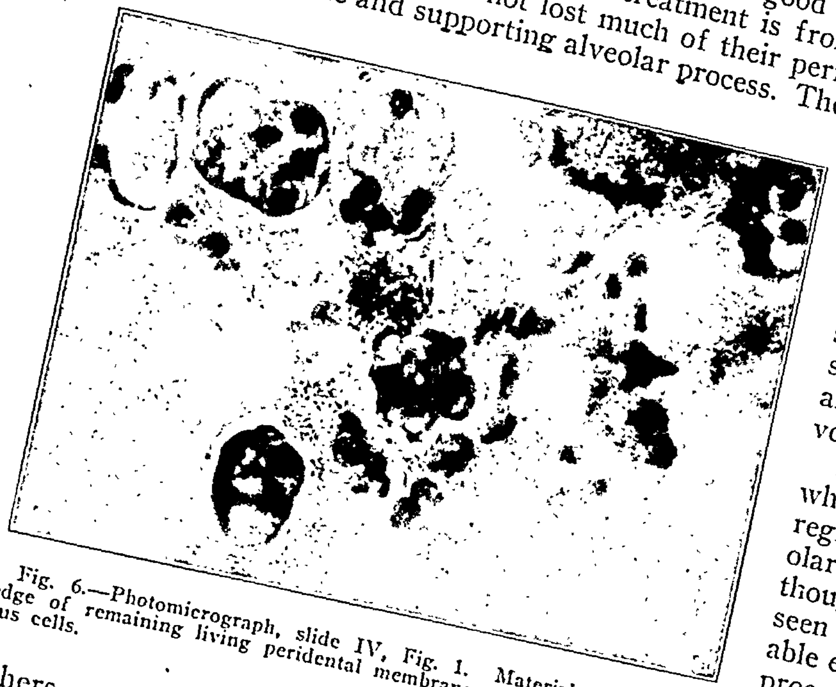

Fig. 6.—Photomicrograph, slide IV, Fig. 1. Material scraped from edge of remaining living peridental membrane—many endamebas, few pus cells.

Rogers[6] was the first to employ emetin hypodermically as an endamebacide. He found it strongly endamebacidal in dilutions of 1 to 100,000. Therefore there would seem no good reason for employing doses larger than about ½ grain for a normal-sized adult. We have not found that a dose larger than ½ grain (up to 3 grains) given hypodermically each day will cause the endamebas to disappear any more rapidly than this amount will do. Less than this amount is sometimes not sufficient. In special instances it may seem desirable to use somewhat larger doses, but for all ordinary cases ½ grain is the proper daily dose.

Endamebas disappear from all lesions following from one to three days of treatment in more than 90 per cent. of all cases. They disappeared in 99 per cent. of our cases following at least six days of treatment. All cases should have at least three days of treatment and none need have more than six. Give ½ grain emetin hydrochlorid hypodermically each day for from three to six days, depending on the case and stage of the disease.

Coincidentally with the disappearance of endamebas the soreness, pain or discomfort and the amount of pus formed rapidly decrease. The tendency to bleed from slight trauma usually ceases within forty-eight hours, and in almost all cases the patient recognizes, and feels confident of, the beneficial effects within a few days. If a physician feels skeptical as to the specific beneficial effect of emetin, he can remove his skepticism by treating and observing a few patients. Both he and the patient are convinced of the efficacy of the treatment within a short time.

After the endamebas have been destroyed by the emetin treatment, however, there are still left the lesions which will require days, weeks or months to heal. Probably no two lesions or pockets in a given case in which many teeth are involved are exactly alike in size, shape, depth, amount of tooth and alveolar process denuded of periosteum, etc. One or more early lesions may be shallow and may have never reached the alveolar level. Others are deeper. One extends all around the tooth, another runs to the end of the root on one side, while the tissue on the other side is all right. In one instance the edge of the alveolar process only is denuded of periosteum; in another the bone and root are uncovered to the bottom of the socket, and in still another there has been considerable destruction of the periosteum covering the outer surface of the alveolar process, giving rise to gum boils, sinuses, etc. In the last stages the tooth is loose in its socket and is held in place perhaps only by a small amount of dead, diseased or dying membrane in the very bottom.

It is an important question in this connection as to whether the periosteum or a substitute tissue can be regrown to fill the space between the root and the alveolar process after it has once been destroyed, even though we stop the destructive process. We have not seen any evidence that this can occur to any considerable extent. If it cannot, then the part of the alveolar process that has been denuded of periosteum will have to be absorbed or removed by Nature (or artificially by proper operative treatment) before complete healing takes place and the gum attaches to the remaining peridental membrane. All the time there must necessarily be some pyorrhea. This will require weeks or months in many instances, and during this time the lesions offer most favorable soil for reinfection with endamebas. On account of the great prevalence of the disease, and therefore the many sources of the parasite, such a patient with our present habits could hardly be expected to escape reinfection more than a few days, and certainly not as long a time as would be required for many of the lesions to heal. This would seem to take away the hope of complete cure. Daily hypodermics of emetin cannot be continued indefinitely on account of impracticability and the discomfort they cause, if for no other reason.

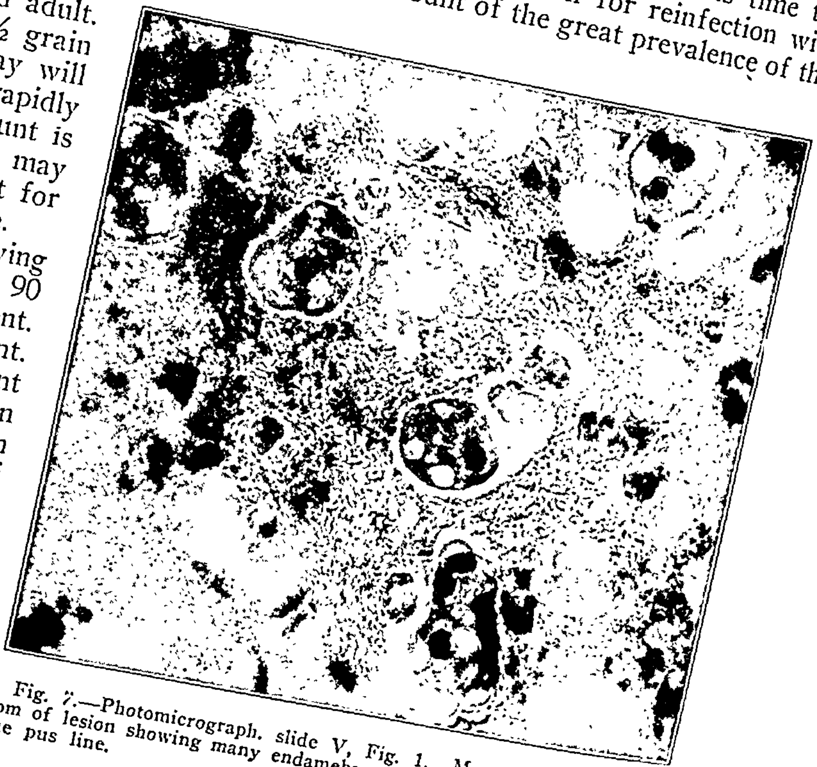

Fig. 7.—Photomicrograph, slide V, Fig. 1. Material from very bottom of lesion showing many endamebas, and bacteria but almost beyond the pus line.

---

[6] Rogers: Brit. Med. Jour., June 22 and Aug. 24, 1912; Therap. Gaz., 1912, xxxv, 837.

Reinfection can be avoided, no doubt, to some extent by exercising great care not to put things in the mouth that may have been contaminated by others. Such things as drinking and eating after others should surely be avoided. But greater protection can be secured from ipecac (or emetin if preferred) applied by the patient. Fluid extract of ipecac kills these endamebas when diluted 200,000 times. We first instructed patients to use a drop or two of ipecac on the wet toothbrush as a dentifrice in the usual way at night. Force the solution formed with the saliva between the teeth and spit out the excess. On account of the fact that pure fluid extract of ipecac frequently irritates the mucous membrane, we have lately prescribed the fluid extract diluted ten or more times with alcohol. One drop of this on the wet toothbrush furnishes a much stronger solution than is absolutely necessary to kill all endamebas with which it comes in contact.

Showing that this use of ipecac promises to destroy endamebas that may have been recently planted superficially, and therefore protects considerably against reinfection, we have had patients use it without any other treatment having been given, and in a number of instances endamebas disappeared from shallow lesions, which entirely healed. Of course, it does not affect those in deep lesions, and is not to be recommended for treatment of the disease. In the light of our present information it should be continued indefinitely for prophylaxis, both by those who have the disease, and especially by those who haven't it. Perhaps a still better way to use it would be to put a drop or two of fluid extract of ipecac in half a glass of water and thoroughly rinse the mouth with it each night before retiring.

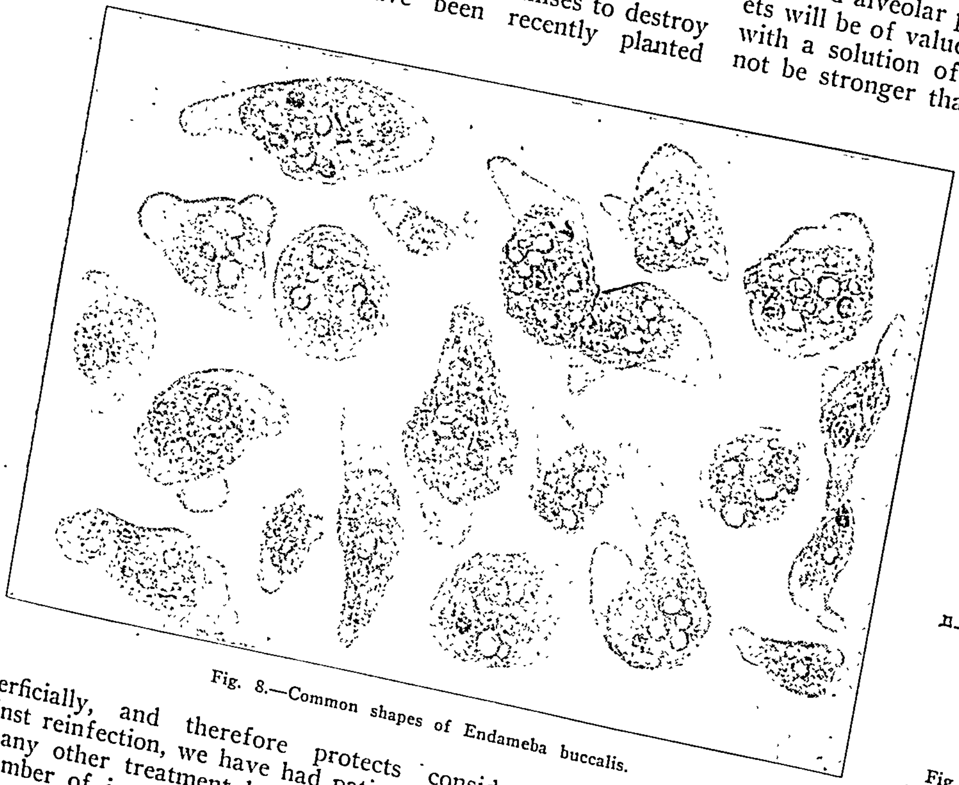

Fig. 8.—Common shapes of Endameba buccalis.

In spite of prophylaxis, however, relapse or reinfection has occurred in one or more of the lesions in about 12 per cent. of our cases within four weeks of the time when the treatment with emetin was given. We formerly thought that a single dose of emetin should be given about once a week to all patients to kill the parasites in any such instances, but we have later learned that one dose only of emetin seldom destroys endamebas when present. We now feel sure that in cases in which endamebas reappear the full course of emetin should be repeated. Perhaps the best plan for those not prepared to make the necessary microscopic examination to determine whether the endamebas have reappeared, would be to repeat the course of emetin every three or four weeks for at least one or two times in all advanced stage cases. It should be understood that no case should be considered cured, not only until the endamebas have disappeared, but until all the lesions have healed and the pyorrhea has stopped entirely. Those who expect to accomplish this result in a few days will surely be disappointed in most instances.

No doubt proper dental treatment, consisting of cleaning and scaling the roots, removing dead and denuded alveolar process, and cleaning out large pockets will be of value. Frequently irrigating the pockets with a solution of fluidextract of ipecac which need not be stronger than one drop to four ounces would be suitable for this purpose. Most patients soon learn to do this for themselves pretty well if instructed and provided with the ipecac and proper dental syringe (Berlin abscess syringe).

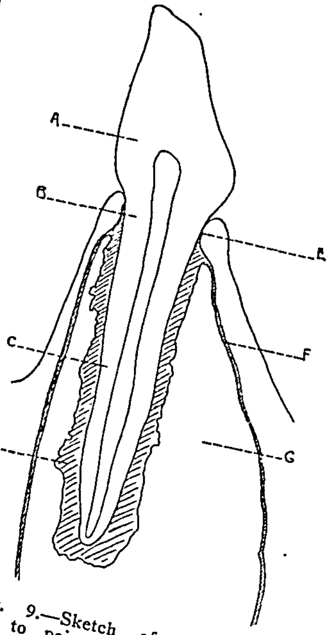

Fig. 9.—Sketch of normal tooth to point out peridental membrane, the seat of the endamebic disease.

We have used emetin made by Burroughs and Wellcome; Mulford; Parke, Davis & Co.; Mallinckrodt, and by Lilly, with apparently equally favorable effect on the disease. The sealed ampules each containing the required dose in solution seem to us to be the most convenient form for ordinary use. In most of our experiments we have been obliged for reasons of economy to prepare our own solutions from the bulk emetin.

During the past two months we have experimented extensively with a preparation of the alkaloids of ipecac that can be taken by mouth without producing nausea, and we are now prepared to announce that, in most instances, at least, it is as efficient in proper doses as emetin given hypodermically. This will make treatment available and practical for a great many more people who have the disease.

The preparation known as Lloyd's reagent, discovered by J. U. Lloyd,[7] has the property of removing all the alkaloids from neutral or acid aqueous solutions of a drug by adsorption. When thus combined with the reagent, which is essentially aluminum silicate,[8] the alkaloid is promptly set free in alkaline solution. It is not liberated in the acid gastric juice, but is set free and absorbed when it reaches the alkaline intestinal juices. The only commercial preparation of the alkaloids of ipecac made in this way that we know of is supplied by Eli Lilly & Co. in the form of tablets, each representing 10 grains of powdered ipecac and called Alcresta ipecac. We have tried one tablet three times a day, two tablets three times a day, and three tablets three times a day. One tablet three times a day does not destroy the endamebas in the mouth in many cases in a week or ten days. Two tablets three times a day destroys all demonstrable endamebas in six days or less in practically all cases. This represents only about ⅔ grain of emetin, and when we consider that it requires considerably larger doses of most alkaloids administered by mouth to produce the same effect as smaller doses administered hypodermically, we could hardly expect smaller doses than this to be successful. Three tablets three times a day destroy all demonstrable endamebas in from four to six days. One patient still had endamebas in one pocket after the fourth day, but this is one instance in which emetin given hypodermically also failed. We have been unable to discover the cause. They disappeared from other lesions and there was apparent improvement in this lesion, but the endamebas persisted in spite of two courses of emetin and one course of the Alcresta ipecac tablets. This form of ipecac does not cause nausea, but there is frequently more or less abdominal discomfort produced by it and also some looseness of the bowels. These symptoms have not been sufficient in any of our cases to make the treatment impractical. We should expect, however, to find an individual occasionally who could not take it satisfactorily, and also those who would not absorb enough of the drug to destroy their endamebas on account of the diarrhea produced, carrying it through the intestinal canal too rapidly.

SUMMARY

1. Pyorrhea dentalis and alveolaris is practically a universal disease, which leads to the loss of the teeth by a long suppurating process. All people have it sooner or later. It begins in early adult life or earlier.

2. The specific cause of the disease is *Endameba buccalis* and possibly other species, which infect and destroy the peridental membrane. The pyorrhea results largely from the secondary infection.

3. The demonstrable endamebas can be destroyed by giving ½ grain of emetin hydrochlorid hypodermically for three to six successive days.

4. Apparently equal endamebacidal effect is produced by two or three Alcresta ipecac tablets (Lilly) taken by mouth three times a day for four to six successive days.

5. The lesions require variable lengths of time to heal, but many could not reasonably be expected to heal in less than several weeks or months.

6. The treatment must be repeated from time to time until the lesions all heal, on account of relapse, or probably reinfection of the lesions as a result of the great prevalence of the infection.

7. Injecting ipecac or emetin into the worst lesions ought to be of service and can be carried out by patients in many instances.

8. Rinsing the mouth thoroughly with a solution of fluidextract of ipecac is believed to protect, to some extent, against reinfection, and actually cures the disease in its earliest stage in some instances.

THE USE OF SKIN GRAFTS IN THE AMBULATORY TREATMENT OF ULCERS

REPORT OF FIFTY CASES *

JOHN STAIGE DAVIS, M.D.
Fellow American College of Surgery; Instructor in Surgery, Johns Hopkins University
BALTIMORE

INTRODUCTION

In the outpatient department of every large surgical clinic there are a great number of patients with ulcers of varying etiology, many of them of long standing. The treatment of these ulcers is usually carried out in a routine manner with the idea of getting through with the dressings as quickly as possible. What has been the result? Some of the patients have been cured; some have continued at the same clinic for many years, being satisfied with the temporary comfort of the dressings; others have drifted to neighboring clinics, with no better results, and finally return, only to repeat the round; while still others give up in disgust and treat themselves at home, only returning to the dispensary during acute exacerbations.

Taking into consideration the unsatisfactory results ordinarily obtained in the treatment of these patients, the economic waste to the hospital in the time taken to do the dressings and the materials used is enormous. The wage earning capacity of the patient is nearly always considerably lowered, and in some instances their work has to be discontinued. Serious consideration has often been given to the matter, as either condition is of utmost importance to these poor people. It seemed to me that the results might be improved, and the restoration of the full earning capacity hastened if each wound could be studied separately and treated by what we may call "intensive methods."

About fourteen months ago a trial was made of this idea in the Johns Hopkins Dispensary, and I was given the opportunity to study and treat a large number of these wounds. Many old and well-proved methods were used, as well as a number of new, and some hitherto untried, methods. Such favorable results were obtained that special rooms were set aside for this work and every facility given. Among a number of methods for accelerating the healing of ulcers the *transplantation of skin* was tried on a series of cases.

It has always been taught that the first essential for success in skin transplantation was absolute rest with immobilization of the part grafted. I fully agree with this principle as the ideal procedure, and believe that it should always be carried out when possible. The use of skin grafts as ordinarily done in hospitals on clean wounds, with patients in bed and having the maximum of good food, good nursing, cleanliness, fresh air, and above all, complete rest, is comparatively simple to the experienced surgeon. On the other hand, take the patients who come to the outpatient department. They are usually poorly nourished; the houses in which they live are often overcrowded and unsanitary. They are, as a rule, unable to stop their work, except for the time taken off for dressings. Many of them should be in the hospital, but there is little chance for even the few who desire admission to secure beds, as there are very few beds available for chronic ulcers. In short, rest, the factor of greatest importance in the treatment of these cases, which is emphasized by every writer on the subject, has to be entirely eliminated. With all these unfavorable conditions in mind, I began gradually to prepare certain wounds with the idea of grafting. Fortunately the first case grafted, that of a long-standing varicose ulcer, was, to my surprise, a complete success, and that success stimulated further trials.

---

* Read before the Southern Surgical and Gynecological Association, Dec. 17, 1914.

* From the Surgical Out-Patient Department of the Johns Hopkins Hospital.

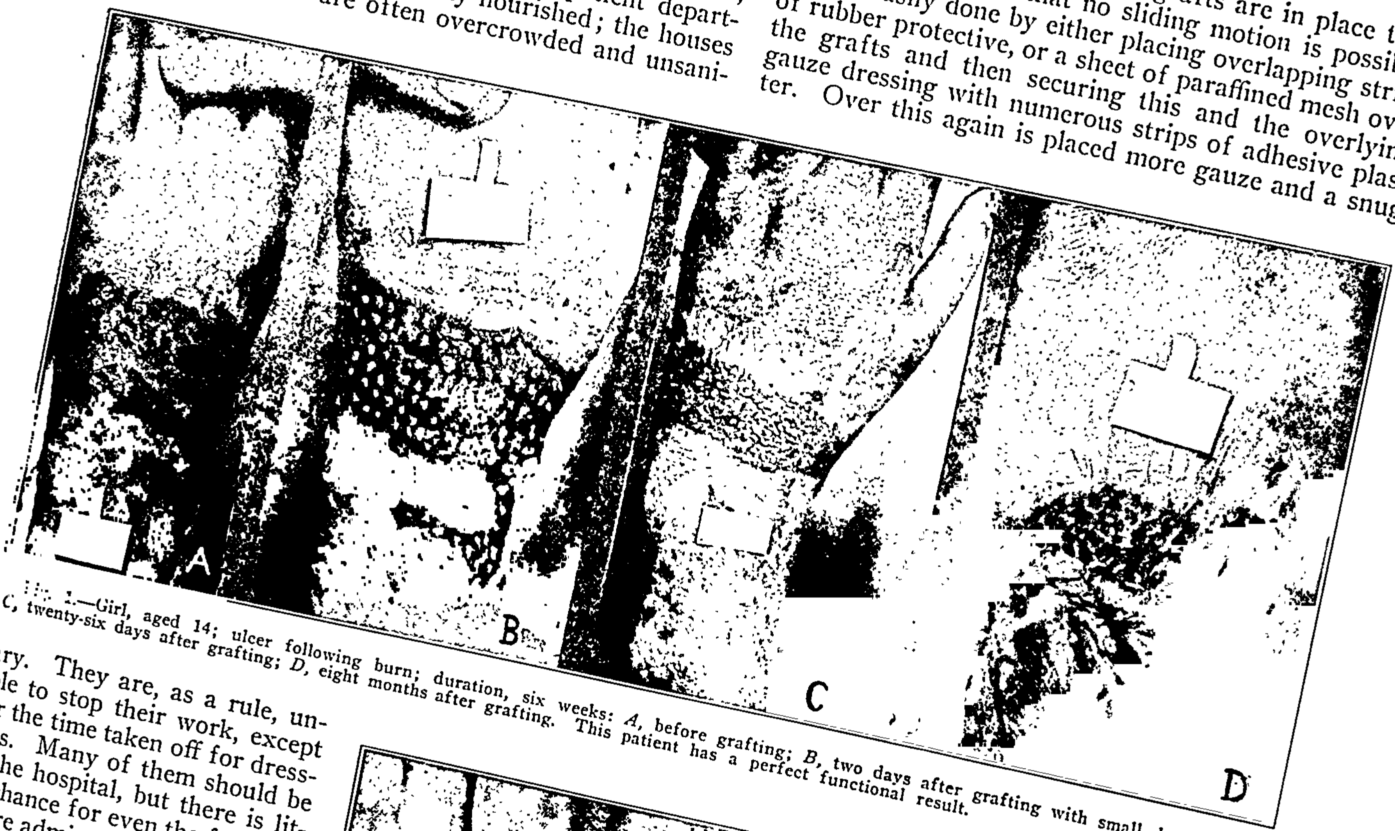

Fig. 1.—Girl, aged 14; ulcer following burn; duration, six weeks: *A*, before grafting; *B*, two days after grafting with small deep grafts; *C*, twenty-six days after grafting; *D*, eight months after grafting. This patient has a perfect functional result.

All of the grafts were placed on undisturbed granulations. I will not discuss at this time the methods used to bring the granulating wounds into a healthy condition; suffice it to say, that many operative methods and local applications were used to accomplish this purpose. The technic of cutting, applying and dressing the grafts was that ordinarily used.[1]

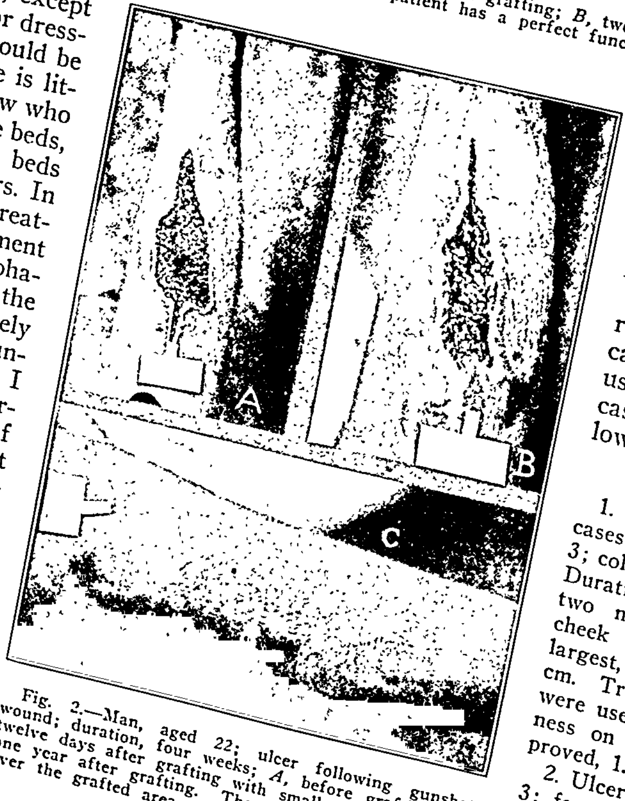

Fig. 2.—Man, aged 22; ulcer following gunshot wound; duration, four weeks; *A*, before grafting; *B*, twelve days after grafting with small deep grafts; *C*, one year after grafting. The skin is freely movable over the grafted area, and the result is excellent.

It is obvious that when the grafts are in place they must be secured so that no sliding motion is possible. This is easily done by either placing overlapping strips of rubber protective, or a sheet of paraffined mesh over the grafts and then securing this and the overlying gauze dressing with numerous strips of adhesive plaster. Over this again is placed more gauze and a snug gauze bandage, and finally a muslin or crinolin bandage. Sometimes thin strips of splint wood were incorporated in the dressings. Each patient considered in this series has continued his or her daily occupation.

This report will analyze the results obtained in the first fifty cases in which grafts were used. For convenience the cases may be divided as follows:

SUMMARY OF CASES[2]

1. Ulcers Following Burns; 8 cases: Male, 4; females, 4. White, 3; colored, 5. Ages, 11 to 50 years. Duration, three weeks to twenty-two months. Situation, leg, 6; cheek and wrist, 1 each. Size, largest, 16x6 cm.; smallest, 2x3 cm. Treatment, small deep grafts were used on 7; and whole thickness on 1. Result, well, 7; improved, 1.

2. Ulcers of Leg; 9 cases: Males, 3; females, 6. White, 8; colored, 1. Ages, 39 to 61 years. Etiology. Six were varicose ulcers with markedly enlarged veins. Three were luetic ulcers with enlarged veins in one. Duration, three weeks to twenty years, continuously; off and on, three years to twenty-five years. Situation, middle third, 2; lower third, 7; right leg, 2; left leg, 6; both legs, 1. Size, largest, 8x17 cm.;

[2] Some of the lesions referred to in this report are, according to definition, granulating wounds. To my mind there is a distinction without a difference between a sluggish granulating wound and an ulcer covered with granulations, whatever the etiology may have been.

smallest, 2.5x1.5 cm. Treatment, small deep grafts were used on all. Results, well, 6; improved, 2; unimproved, 1.

3. Ulcers, Postoperative; 17 cases: Males, 12; females, 5. White, 16; colored, 1. Ages, 12 to 84 years. Etiology: The ulcers followed amputations, operations for ingrown toe-nail, epitheliomas and infections. Duration, four days to three months. Situation, finger, cheek, forehead and forearm, 2 each; leg, breast and scalp, 1 each; toe, 6. Size, largest, 19x5.5 cm.; smallest, 3.5x2 cm. Treatment, small deep grafts were used on 16; Thiersch grafts on 1. Result, well, 14; improved, 3.

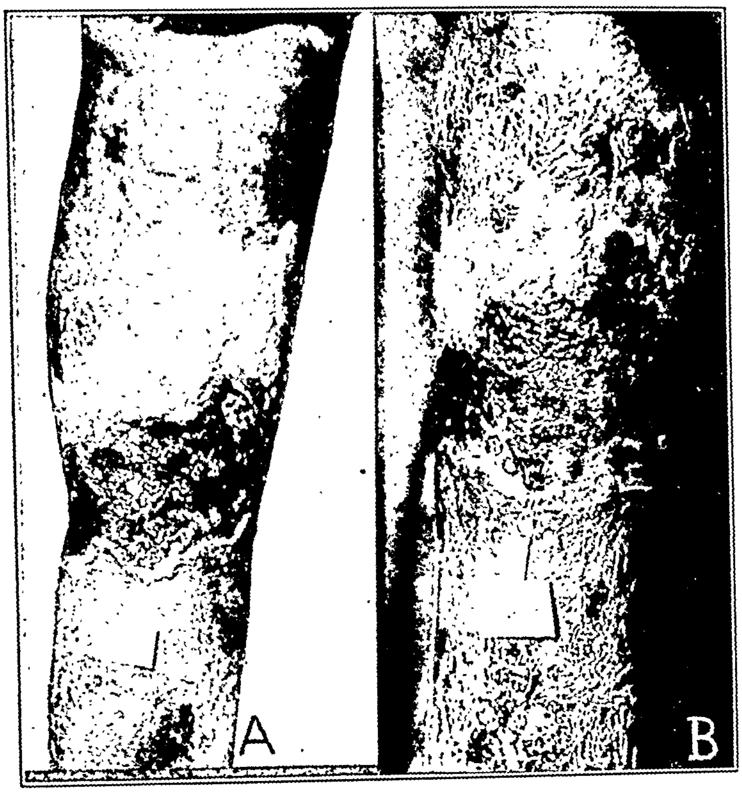

Fig. 3.—Man, aged 50; ulcer following burn; duration, twenty-two months: *A*, before grafting; *B*, one and one-half months after grafting with small deep grafts. Note the solid healing in the midst of scar tissue.

4. Ulcers, Traumatic; 9 Cases: Males, 7; females, 2. White, 7; colored, 2. Ages, 11 to 63 years. Etiology: Injuries of various kinds. Duration, two weeks to ten months. Situation, finger, 3; leg and ankle, 2 each; foot and wrist, 1 each. Size, largest, 8x6.5 cm.; smallest, 1.5x1.5 cm. Treatment, small deep grafts were used on all. Result, well, 7; improved, 1; unimproved, 1.

5. Ulcers, Miscellaneous; 7 Cases: Males, 5; females, 2. White, 5; colored, 2. Ages, 13 to 80 years. Etiology, following infection and frost bite, 2 each; trophic, ice bag necrosis, and tuberculosis of chest wall, 1 each. Duration, two months to eight years. Situation, foot, 4; leg, abdomen and chest wall, 1 each. Size, largest, 7x5 cm.; smallest, 2x2 cm. Treatment: Small deep grafts were used on all. Result, well, 2; improved, 2; unimproved, 3.

General Summary: Males, 31, females, 19. White, 39; colored, 11. Ages, 11 to 84 years. Duration, few days to twenty-five years. Size, largest, 8x17 cm.; smallest, 1.5x1.5 cm. Treatment: Small deep grafts were used on 48; Thiersch grafts on 1; whole thickness grafts on 1. Result, well, 36; improved, 9; unimproved, 5. Of those wounds which were improved by grafting but not completely healed, 5 were situated on the foot and 4 on the leg. Of those which were unimproved, 2 were on the leg, 2 on the foot and 1 was on the chest wall.

REMARKS

All of the grafts were autografts. Small deep grafts were used on most of the wounds, as the operative procedure is simple, and furthermore, no other type of graft could have been successful on many of the wounds grafted.

In some instances, in which the grafts were placed close together, the ulcers were covered with epithelium within a week. When a partial grafting was done, or when only a portion of the grafts were successful, a second grafting was required to fill the areas not covered.

Several graftings were done in all instances of failure, without result. It is interesting that several of these wounds were subsequently grafted in the hospital, without success, so that the failure seemed to be due to the wound itself, rather than to the fact that the patient was not kept at rest.

I feel confident that the percentage of takes would have been considerably larger had the cases been selected as to situation, cause, etc., but in order to test the procedure, ulcers in many situations, and of varying etiology were grafted. As might be expected, the ulcers on the feet and legs were more difficult to heal than those in other situations, and the failures were almost entirely confined to those regions.

I have been able to observe some of these patients for over a year after grafting, and there has been no recurrence in a single instance in an area successfully grafted. In one or two cases with marked varicose veins, small ulcers on other portions of the leg have occurred, but not in the grafted area.

CONCLUSIONS

From the results obtained in the first fifty cases in which grafts were used in the ambulatory treatment of ulcers, I feel that we have added to our armamentarium a method of treatment which has hitherto been used only on patients resident in the hospital. In other words, the successful use of grafts in the out-patient department will make for hospital economy, and will also hasten the return of many patients to full wage earning capacity.

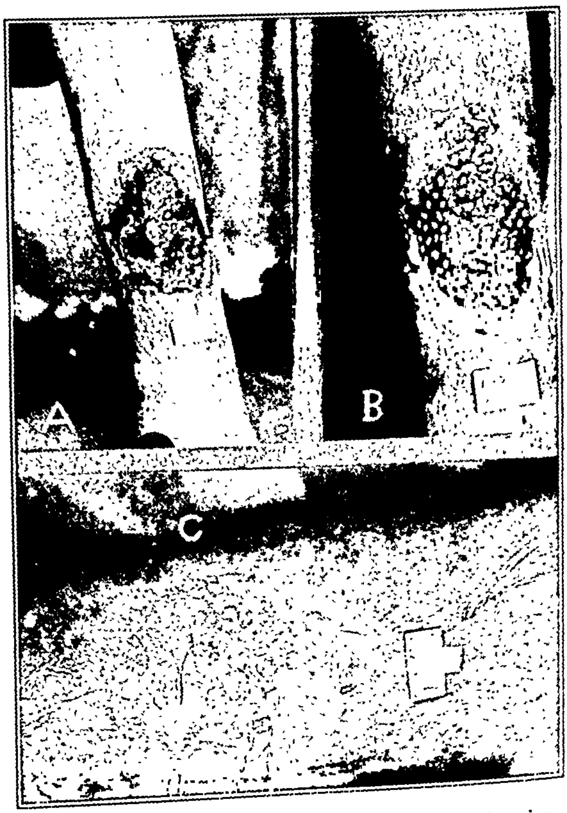

Fig. 4.—Woman, aged 46; ulcer of leg, varicose; duration, twelve years, continuously: *A*, before grafting; *B*, one week after grafting with small deep grafts; *C*, five months after grafting; examination of this patient eleven months after grafting showed no tendency to recurrence. The healing was stable and the individual grafts are still plainly visible.

VERTIGO

J. GORDON WILSON, M.D.
Professor of Otology, Northwestern University Medical School
CHICAGO
AND
F. H. PIKE, Ph.D.
Assistant Professor of Physiology, Columbia University
NEW YORK

In this preliminary paper we shall endeavor (1) to outline, necessarily very briefly, a conception of vertigo which appears to us to be based on anatomic and physiologic data, and (2) to point out how this conception aids in the diagnosis and treatment of cases of vertigo. No attempt will be made to enumerate the diseases in which vertigo is a more or less conspicuous symptom, for it appears to us that with a clear conception of what vertigo is there will be less necessity for any such elaborate and detached enumeration. It is unnecessary to apologize for discussing this subject, for the significance of vertiginous attacks offers difficulties both to the general practitioner and to the specialist in different branches of medicine.

Vertigo, when considered from the point of view of etiology, has been and still is a subject of great complexity. Its frequency in so many diverse diseases offers a fruitful field for speculation. The importance of its interpretation from the point of view of diagnosis need not be insisted on. We all know that it is most elusive in response to treatment. One difficulty in regard to its interpretation lies in the fact that most of us have no clear conception of what vertigo is. Subjectively, we all have had experience with it. But few would be prepared offhand or even after considerable thought to define it in terms conveying any conception of its anatomic or physiologic significance. Yet without such a clear conception its diagnostic significance must be largely lost and its treatment must be haphazard.

The term "vertigo" is commonly applied to a sensation of rotation of surrounding objects or of one's self. While true that rotation is a conception of vertigo in its most pronounced form, still there are other forms in which the sensation is not that of rotation, but of a feeling of instability either of one's self or of surrounding objects. There may be the feeling, not that either we or the objects around are rotating, but that we are falling or swaying, or that the objects around us are sinking or rising.

Not all its modes of manifestation, however, can be expressed clinically in terms of instability. We are here dealing with a subjective phenomenon, and every one recognizes how difficult it is to get accurate data on subjective sensations. We all know how the same feeling may be expressed by different persons in different ways, apart from the fact that the sensation may be more marked in one than in another. Investigation has shown that from the clinical point of view we must include under the term "vertigo" sensations of many kinds: a blurring vision, a feeling of discomfort or of anxiety, fulness in the head, as after smoking; a feeling of weakness, a disturbance of consciousness; in short, a variety of sensations which, if they persist, tend sooner or later to become more pronounced as disturbances of equilibrium.

While vertigo may be traceable most frequently to some pathologic condition disturbing, either directly or indirectly, the mechanism concerned with equilibrium, there are occasions when obviously no such pathologic condition exists. For instance, it may be traceable to the possibility that the surrounding circumstances are such that should a disturbance of equilibrium result, a fall of some considerable magnitude might follow; or there may be simply the fear that, given certain eventualities, a fall would occur; for instance, looking over a bridge into a ravine, or standing on the parapet of a tower with thick mists obscuring the view. That we know the sensation to be irrational does not seem to have much weight.

When vertigo has once arisen under certain conditions, as of fear arising on our being in a dangerous position, it may easily be aroused again under conditions similar in kind though less rational in reality — probably dependent on the fact that anatomic paths once traveled are more easily traveled again.

In the monograph "Der Schwindel," Ewald defines vertigo as a depression of our static consciousness, and Wollenberg as a perplexity in regard to our condition in space, both of which definitions, as Ewald says, amount to the same in the end. We venture to suggest that such statements are so obscurely based on anatomic or physiologic data that they do not help toward a clear, satisfactory definition.

All are agreed that vertigo is related in some way to disturbances of equilibrium. In order to get a clear conception of what vertigo is, and where the disturbance which causes it may arise, it is necessary to have a conception of the paths along which impulses which maintain equilibrium may pass. To preserve equilibrium impulses are constantly coming to the brain from four chief peripheral sources: (1) the ear, (2) the eye, (3) impulses from muscles, tendons and joints, and (4) impulses from the skin, touch and pressure. These impulses and probably others as well, for example, tactile hairs,[1] result in muscle coordination whose most important function is to preserve equilibrium.

We are all agreed that vertigo bears some relationship to a disturbance of equilibrium. But extensive nerve lesions as in ataxia can make difficult or impossible standing or walking without the help of the eyes, without, however, causing vertigo. The tabetic with his eyes shut has instability. He then may have the sensation of vertigo, but he does not fall because he has vertigo. He falls because he experiences a sudden unexpected loss of afferent impulses from the eyes on which he has been depending to reinforce the other impulses which, unaided, are insufficient to maintain his equilibrium. He has vertigo because the sudden closing of the eyes has intensified the mental confusion resulting from the inadequacy of the impulses from the muscle, tendon, joint and skin, which inadequacy has been compensated for by the visual impulses. In the tabetic the muscular incoordination which is the primary factor may appear without vertigo. In the labyrinthine irritation, the instability is the outward manifestation of the vertigo, which vertigo is, or has been, present and may precede the instability.

Vertigo arises from a confusion or dissociation of the impulses on which the subject bases his conception of his position in space. By far the most important of these impulses concerned with the conception of the position in space, or change of position in space, arise from sense organs in the head segment, the otic labyrinth and the muscular and retinal portions of the

---

[1] Vincent, S. B.: Jour. Comp. Neurol., 1913, xxiii, 25.

eyes. In the tabetic, the mechanism of the head segment is not primarily disturbed, but the proprioceptive (muscle, tendon, joint) and the skin sensations are disturbed.

Ataxia may lead to disturbance of equilibrium, but we may have ataxia without vertigo, or vertigo without ataxia. Both ataxia of a certain sort and vertigo are due to disturbances of afferent impulses concerned with equilibrium, but the ataxia is due to a loss in a group of afferent impulses, while vertigo is due to a disturbance of the normal association of certain groups of afferent impulses, especially those from the head segment. An animal after double labyrinthine removal may have its objective signs of vertigo reduced by throwing out other afferent impulses and so reducing the factors which cause the disharmony. Although for purposes of brevity, we are retaining the term "ataxia" in the present discussion because of its universal use, we wish to point out here that it is a very inexact term at present and should be more clearly defined.

It will, then, be noted that what we insist on is that it is not instability alone which constitutes vertigo on its subjective side; it is the rising into consciousness of the sensation of instability; it sometimes is the fear that such an instability may occur, or a fall be possible. There may be no outward objective symptom of vertigo; or there may be incoordination, and the consequent muscular endeavor to maintain equilibrium.

Normally, the afferent impulses which maintain equilibrium are harmonized subconsciously, and it is only when disorganized that they ordinarily attract our attention. The explanation of this is obvious. They are so essential to man's existence and so constant in their activities that Nature has arranged that they work subconsciously; otherwise their insistence on recognition and conscious adjustment would be a serious detriment to man's mental development. But, as in many other subconscious activities, consciousness may enter in either as a controlling or disturbing element, for example, through memory and emotions. Such a disturbing influence from a higher mechanism may cause disharmony, and so there arises psychic vertigo.

In the cerebrum these constant afferent impulses are, under ordinary conditions, associated, or to use a better term, harmonized or integrated, to preserve the equilibrium. If for any reason they become dissociated or disharmonized or disintegrated, the conscious confusion that results is vertigo. The motor incoordination which forms the objective symptoms of vertigo is a result of this dissociation.

Vertigo for the present may be considered as the confusion resulting from the coming into consciousness of afferent impulses concerned with equilibrium which ordinarily are associated (integrated), but now for some reason have become dissociated. Of the impulses coming in from the peripheral organs mentioned, the most important is the ear, and any slight disturbance of the labyrinth will produce severe vertigo. On the other hand, a gross lesion of the third and fourth groups mentioned above may exist without vertigo. Disturbances of the eye are midway between the two; and probably lesions here are largely influenced by the close association of eye movements with the labyrinth. We should elaborate this point, as it is fundamental to a conception of our views. The physiologic action of the labyrinth is primarily to preserve the knowledge of the position of the head in space and reflexly to maintain equilibrium. To do this the labyrinth is closely related to the musculature of the body, especially the muscles of the head, and the relationship is more clearly discernible in its action on the freely movable muscles of the eyes. An observable outcome of this relationship is that, no matter how the head is turned, the eyes involuntarily are readjusted. Otherwise, the outside world would move with each movement of the head and endless confusion result. Mechanical irritation of the labyrinth with the head at rest, for instance, with hot water, results in a message from a receptor which, normally interpreted, indicates that the body is rotating and calls for certain movements of readjustment. But in this instance the inflowing messages from Groups 2, 3 and 4 are uninfluenced by this irritation and contradict the messages sent in from the labyrinth and resist the demand for readjustment. So there results a confusion in the integrating mechanism arising from this dissociation of peripheral messages; impulses which normally work together are no longer in harmony; and the person, becoming conscious of the disharmony, experiences the sensation which we call vertigo.

Up to a certain point rotation may be carried on, as in a swing, and compensatory movements occur by which means the subconscious impulses are able to adapt themselves to these impulses and no vertigo results. But let the rotation be so great that the impulses from the last three groups no longer fall into line with those arising from rotation, and the controlling power of the cerebrum no longer suffices—then vertigo results. Practice and age are in this an important factor.

Visual vertigo does not so often come under the observation of the clinician as labyrinthine. It can often be produced if we look at a large mirror which is moving without our knowledge. Double vision or errors of refraction cause vertigo because they give false impressions of position in space. The eye muscles, partly because of their close relationship to the labyrinth, play a greater part in vertigo than the other muscles of the body.[2] Their incoordination arising from any cause or the nystagmus which arises when the labyrinth is stimulated is a manifestation of this.

Not only does vertigo arise from disturbance of the peripheral sense organs, but lesions involving their central paths will also produce it. So disturbance of the complex vestibular path, or of the great coordinating mechanism for the unconscious sensations from the muscles—the cerebellum—will give vertigo. One thing that has been impressed on us by experiment is the importance of pressure on the eighth nerve or in the posterior fossa as a cause of vertigo. Clinicians have paid too little attention to the effect of pressure, which need not be very great to produce signs of vertigo.

So far as the areas in which this integration takes place are cerebral, cerebral lesions will cause vertigo, and there is sufficient evidence to show that vertigo does arise from lesions of the cortical mechanisms. So a tumor of the cerebrum may set up an excitation giving a sensation of position in space at variance with impulses from the eye or ear, and vertigo results.

Again, it may occur in a hyperexcitability of the nervous system. So in neurasthenia, in which we have probably a decreased neural resistance in certain paths and systems due to disturbed metabolic processes, we may have vertigo. Here it may follow that the impulses, say from the two eyes or from the two ears, vary in intensity, and vertigo results. Ordinarily, these slight differences in the intensity of the impulses from the two sides may not rise above the threshold value of the reflex arc, and no symptoms follow.

---

[2] Wilson and Pike: Proc. Soc. for Exper. Biol. and Med., 1913, x, 81.

We may therefore have vertigo due to: (1) organic lesions, or (2) functional disturbance.

Now as the diagnosis of a functional disturbance implies the consideration and elimination of organic lesions, in all cases of vertigo we have to examine at least the four sources mentioned above. And as of these the labyrinth is the most important, the condition of the ear must always be considered. Very slight irritation of the sensitive labyrinth will produce vertigo and muscular incoordination. Even when the muscular phenomena are manifest in the eyes alone more or less vertigo is present. It must be noted that in slight cases we can inhibit the vertigo just as we can inhibit a labyrinthine nystagmus. In such cases the dissociation of afferent impulses is reassociated through conscious processes, and the objective as well as subjective phenomena are controlled. The instability is the outward manifestation of the vertigo or rather of the subconscious state from which the vertigo arises. But the otologic aspect of the problem is not confined to the internal ear. It extends to the vestibular nerve and its central connections, some of which are known, but the greater part are still in doubt.

As equilibrium is a function of the labyrinth, so vertigo is one of the most important symptoms of its disease. We may distinguish: (*a*) direct vertigo, due to lesion of the vestibular apparatus, and (*b*) indirect vertigo — disturbance of the vestibular tract, for instance, from gastro-intestinal disturbance.

In both of these, the sickness and vomiting may be due to the spread of vestibular irritation to a neighboring mechanism or, in the indirect vertigo, from the stomach itself. It is not the intention at this time to elaborate these points, but rather to indicate how the otologist attacks the problem. This we can best do by outlining briefly a few of the cases that have come under observation—our remarks being directed toward methods of diagnosis and of treatment.

Case 1.—*History.*—W. G. K., man, first seen December, 1912, complains of repeated attacks of vertigo with nausea and vomiting during the last four years. These are increasing in severity and frequency so that now he is frequently incapacitated for work. There is a constant feeling of uneasiness. He is very subject to "colds in the head," and when these occur an attack often comes on. He has had a course of bromids for over a year. There is no history of syphilis.

When first examined he had occasional subjective sensations of movement of rotation, but no nystagmus was observed. During a severe attack objects go to right; the patient feels himself going to right but falls to left. If he lies on right side vertigo is diminished. Observation during attacks showed: (1) nystagmus, slow to left; (2) turning eyes or head to left, vertigo less; to right, vertigo increased; (3) skin cold.

Examination during interval when no pronounced vertigo, showed: Romberg to left, no nystagmus; hearing, right, normal; left, markedly diminished, diminution of tones at both ends of scale but especially for lower tones. Rinné, negative; Weber, to right; bone conduction diminished. Both tympanic membranes slightly thickened and retracted; left slightly congested. Nasopharynx, markedly congested; numerous swollen follicles; synechiae in recessus pharyngeus (Rosenmuelleri). Left eustachian tube swollen and opened with difficulty; right normal.

Diagnosis, Treatment and Results.—Nasopharyngitis; tubal congestion on left side; left labyrinth affected. Nasopharynx and tube treated, synechiae broken down, follicles destroyed and zinc chlorid (from 2 to 5 per cent.) applied. Catheterization. Sodium bromid, 7½ grains, twice a day. The treatment calls for no particular remarks. The sodium bromid was stopped after a fortnight. The nasopharynx rapidly improved and the tube became less congested. With this improvement the vertigo disappeared and the hearing improved.

Present Condition, June, 1914: The patient has received no treatment for several months. Hearing is improved in left ear. Both tubes are equally patent. There have been no attacks of vertigo; once or twice when patient had cold in the head there was a feeling that it might come on.

The symptoms in this case point to a combination of internal and middle ear deafness. We believe that there is here a hypersensitive labyrinth probably due to vascular changes similar to those found in the nasopharynx and middle ear. Increase of extra labyrinthine pressure on a susceptible labyrinthine mechanism may produce vertigo. Slight increase of pressure may not do so; the pressure must bear a definite relation to the threshold value for stimulation of the vestibular nerve.

The following points are worthy of emphasis:

1. Patient falls to the left: In labyrinthine disease the patient falls to the side of the lesion. Bárány has stated certain laws in regard to the relation of the quick phase to falling. But as we have pointed out elsewhere,[2] this general rule holds: falling occurs in direction of slow phase of nystagmus.

2. Apparent movement of self to right: Nystagmus during attack slow to left. This is in agreement with the rotation law that apparent rotation of one's self is always in direction of rapid phase of nystagmus.[3] As a corollary, if patient's history show the subjective feeling of movement of self to right and on examination no nystagmus be present, we can assume that the nystagmus would correspond to this law, that is, be slow to left. This is an indication of the ear affected — subjective rotation to right — ear affected left. One may here note how difficult it is to get a distinct history of subjective sensations even from intelligent patients, and further, how much less reliable are the subjective sensations of apparent movement of external objects.

3. Sensations of apparent movement or rotation can persist after or without nystagmus.

4. Turning eyes to left, direction of slow phase of nystagmus, vertigo less: Quick phase of nystagmus alone can be inhibited and inhibition of quick phase inhibits rotatory sensations of self, of external objects and diminishes vertigo.[4]

5. In disease of the labyrinth the patient lies on the sound side; turning to the diseased side makes the vertigo worse.

The importance of pressure or variations of pressure on the labyrinth or on the vestibular nerve from whatever source as a cause of vertigo is not fully appreciated even though not uncommon, for example, after catheterization or Politzerization. We find that Högyes[5] more than a quarter of a century ago pointed out the association and explanation of vertigo from pressure in the ear, and we find that such an aurist as Politzer[6] and such a neurologist as Babinski[7] have noticed the effect of such pressure and the relief following its removal. More recently Bárány[8] has pointed out the possibility of its occurrence. The reason of this non-appreciation of the importance of pressure is not far to seek. The modern aurist still clings to the idea that the stimulation of the nerve endings in the semicircular canals is due to endolymphatic currents, even though Mach and Crum Brown long ago pointed out that such currents were inconceivable in such minute canals.

[4] Bárány: Monatsschr. f. Ohrenh., 1906, xl, 193.

[5] Högyes: Arch. f. d. ges. Physiol., 1881, xxvi, 558.

Case 2.—*History.*—Man, aged 55, admitted to Wesley Hospital, November, 1912, complaining of vertigo. The first attack was three years ago, at which time he was dizzy and felt faint. He was then treated for left ear deafness by middle ear inflation with eustachian catheter and air pressure. After two weeks of treatment the vertigo left. He was free of discomfort for seven or eight months; then came a second attack which was less severe. About one year ago he had a third attack, less severe than the second. He was first seen by one of us in the present fourth attack, which came on about four weeks ago. He ascribes this attack to excessive fatigue. In the evening while in his office he was suddenly seized with dizziness; the room appeared to rotate and he was compelled to lie down. The severe vertigo lasted about three minutes, during which time he felt as if he were being turned round and round, but the direction of apparent rotation could not be accurately ascertained. This was the first time he had had a distinct sensation of rotation.

Since then he has been more or less dizzy all the time with occasional violent attacks during which a distinct sensation of apparent rotation of self and external objects is present and tinnitus may be increased. Vertigo is so constant and so subject to increase that he has had to abandon his practice. The symptoms are more marked in the evening. At night in the dark he often walks with a staggering gait. When lying down with his head braced he is relieved to some extent, but movement seems to increase his trouble. Reading or writing aggravates the attacks. When the dizziness is severe he feels unable to locate the position of the head, for instance, the angle at which it is; this he describes as inability with eyes shut to locate the head in space.

Present Condition.—Right ear normal for low voice and whisper; watch heard at arm's length; Rinné positive; high tones normal; membrana tympani normal; tube patent. Left ear: hearing deficient, traced to an explosion ten years ago; watch heard at 12 inches; Rinné positive; high tones deficient; bone conduction diminished; membrana tympani normal; tube normally patent. Romberg to left; no nystagmus; no increase in blood-pressure; eyes and other organs normal.

Comment.—The symptom of more or less constant vertigo is frequently associated with irritation of some part of the vestibular tract. In this case we believe that the vertiginous state from its association with auditory impairment was due to varying pressure on the left vestibular division of the eighth nerve or its terminations probably from disturbances of circulation. In such conditions good results are obtained from pilocarpin followed, if necessary, by iodids. The tendency recently has been to decry the value of pilocarpin, but there are many competent observers who have found it very serviceable. It is not our intention here to discuss its action, but among recent publications reference may be made to the work of Dixon and Halliburton.[9]

Treatment and Results.—Pilocarpin 1/20 increasing to 1/6 grain to obtain the physiologic action of the drug. The results were satisfactory. The violent attacks completely disappeared and the patient went home very much improved and was soon able to resume his work. One of us has kept in touch with this patient since, although he lives at some distance. The reports have been satisfactory until this recent communication:

July 7, 1914: "For the last six weeks the vertigo has returned in a mild form, appearing before dinner or just after and lasting until retiring. The postnasal catarrhal symptoms, manifested mostly by hawking and spitting with which I have been troubled almost all my life, do not appear any worse than usual. I do not believe the catarrh has anything to do with the symptoms of vertigo. The ear inflation you remember, before I came to you, made the vertigo worse, but the first and second attacks, years ago, seemed to be relieved by the middle ear inflation treatment. My general health for summer is as usual. I have thought of calling on you again should the vertigo continue, but as I have said, it is mild."

It would be easy to multiply such cases. The following case exemplifies another variety:

Case 3.—*History.*—H. W., man, aged 35, admitted to Wesley Hospital, Nov. 24, 1913, complained of vertigo and headache, which he has had for three months. The headaches are chiefly frontal. The vertigo is so severe that he is compelled to sit or lie down and hold on. An attack comes on at least once a day, lasts for an hour and is accompanied by nausea and vomiting. During the attack objects apparently go round in a circle (to right?). Up to ten days ago he had difficulty in swallowing and liquid food frequently returned through the nose.

Patient had syphilis three years ago; he has had mercurial treatment for six months, and recently one injection of salvarsan.

Present Condition.—The patient's walk is unsteady, but there is no marked ataxia. Romberg is questionable though with eyes shut he sways considerably. During an attack with his eyes shut he falls to the right and slightly back. There is a spontaneous nystagmus on looking to the left. With eyes shut and with palm down his right hand pointed to the right. He touches point of nose and other parts of body with fair accuracy. Slight paralysis of right facial and of right side of soft palate. Taste impaired. Left vocal cord paralyzed. Tongue deviates to left. Pupils react to light and accommodation. Hearing good in both ears and range unimpaired as tested by forks.

Nystagmus: Cold water in right ear for twenty seconds gave marked nystagmus slow to right, lasting three minutes. Vertigo is so marked that with eyes shut the patient feels himself falling and holds on to chair.

Cold water in left ear for forty seconds gave slight nystagmus lasting one minute. After the cold water in left ear he pointed accurately with his right hand, to the left with his left hand.

Both in blood and cerebrospinal fluid, Wassermann was strongly positive.

Diagnosis and Treatment.—Basilar syphilis involving the right seventh and right vestibular and right tenth nerves, and left tenth and twelfth nerves. Mercurial injections and inunctions were given.

The vertigo disappeared and the patient left the hospital December 9, improved.

The Physician as a Sanitary Policeman.—The present day physician wants to know not only what is ailing his patient, but also how his patient acquired the disease, whether any other persons are exposed to contagion from the same source, whether the patient himself is a danger to his friends and relatives, and whether the disease will spread throughout the entire community or can be confined to the single case in hand. He owes a responsibility not only to his patient but to the community. He is not only the caretaker and medical adviser of the sick. He is also the guardian and protector of the well. Each practicing physician is or should be a sanitary policeman for the protection of the community against contagion.—Frederick R. Green, *Northwest Medicine.*

THE CHEMICAL EXAMINATION OF DUODENAL CONTENTS AS A MEANS OF DIAGNOSIS IN CONDITIONS OF JAUNDICE *

BURRILL B. CROHN, M.D.
NEW YORK

It is now almost four years since I first began to study the contents of the duodenum as a means of diagnosis in various conditions of pathologic interest. During this time, over 120 analyses have been made; included in this series is a group of fifty-two cases which presented the common symptom of jaundice. As the number and variety of these cases of icterus increased, it became more and more obvious that there existed in the duodenal tube a valuable instrument for gathering additional data bearing on the differential diagnosis of these conditions. It is logical and rational that a tube which can enter the duodenum and rest opposite the exit of the bile and pancreatic ducts should bring home most instructive data pertaining to the patency or non-patency of these structures. As the disease processes that cause the varieties of jaundice vary in each type of case, just so do the duodenal contents vary, until there becomes clearly evident a duodenal picture characteristic of each type of disease. An idea of the number of variations possible may easily be gathered by a glance at the following list of alternatives:

1. Both ducts may be closed.
2. Both ducts may be open.
3. The bile duct may be open, the pancreatic duct closed.
4. The bile duct may be closed, the pancreatic duct open.
5. The bile duct may be partially closed, the pancreatic duct open.
6. The bile duct may be open, the pancreatic duct partially closed, or the pancreas diseased.

As every disease gives a fairly constant duodenal picture, so conversely, the establishment of definite duodenal data points to certain recognized pathologic processes.

The technic of duodenal aspiration is by now so familiar to the medical public that a detailed description need not be entered on at this moment. I have in two previous publications[1] described in detail this technic. Suffice here to say that the Einhorn duodenal tube was utilized, being swallowed by the patient at night, and left in situ until morning. Then, two hours after the administration of a milk test meal, the contents of the duodenum were steadily aspirated for five minutes, measured, titrated and chemically examined.

We may proceed to discuss the duodenal picture characteristic of each pathologic process:

CHOLECYSTITIS AND CHOLELITHIASIS

This group (Table 1) comprises twelve patients suffering from gall-stones and gall-bladder infections, who have in the course of their disease evidenced jaundice at some time as a symptom. Cases of stone impacted in the common duct and giving the picture of continuous obstruction are separately discussed in the next subdivision.

As is well known clinically, we may note a gall-bladder full of stones, or various degrees of cholecystitis, without the occurrence of icterus at any time. But it is much more usual to observe a transient or more permanent jaundice, usually at the time of the acute attack, and usually explained as the passing of a stone through the cystic or the common duct. In this series of duodenal examinations the findings are constantly those of open bile and open pancreatic ducts. The bile, even when collected at the time of jaundice, is abundant in the duodenum, usually heavy, viscid and dark green, and an excess of mucus is visible. It would seem that a stone passing down the ducts does not at any time more than slightly obstruct the lumen. The pancreatic duct is always patent; in two of the twelve cases, a distinct diminution of the strength of the ferments pointed strongly to a pancreatitis as a complication.

TABLE 1.—CHOLECYSTITIS AND CHOLELITHIASIS

Case	Bile	Ferments	Amylase, c.c.	Trypsin	Lipase, c.c.
1. Cholelithiasis	+	+	10	1: 5,800	0
2. Cholelithiasis-cholecystitis	+	+	12	1:12,000	6.3
3. Cholelithiasis	+	+	30	1: 1,000	10.0
4. Cholelithiasis	+	+	24	1:18,000	3.6
5. Cholelithiasis (after operation)	+	+	0	1: 5,000	1.0
6. Cholelithiasis (pancreatitis)	+	+	0	1: 3,000	0
7. Cholelithiasis (stone in cystic duct)	+	+	2	1: 4,300	0.6
8. Cholelithiasis (repeated attacks)	+	+	18	1:30,000	0
9. Cholelithiasis	+	+	30	1: 6,000	8
10. Cholelithiasis (pancreatitis suspected)	+	+	20	1:10,000	9.9
11. Cholelithiasis	+	+	18	1:10,000	3.0
12. Cholelithiasis	+	+	45	1:30,000	13.5

CATARRHAL JAUNDICE

Opportunity was offered for duodenal examination in only one case (Table 1), this, however, during the height of the jaundice. An abundant thin yellowish bile was obtained, containing normal pancreatic ferments.

IMPACTED COMMON DUCT STONE

Six cases were studied (Table 2). In five of them bile was found in the duodenum; in three of the five cases the full golden yellow bile coloration was replaced by a lighter yellow tint as of partial obstruction of the duct. The pancreatic ferments were present in full amount. In only one case was the obstruction so complete that no bile entered the intestine. This case was one of a very large calculus, firmly imbedded in the lower portion of the ductus choledochus; back of this stone were crowded several other smaller ones, also firmly set in the duct.

The retention of a permeable lumen in the common duct in cases of stone is not surprising, for it has long been known to clinicians that such obstruction caused by a stone is rarely a complete one. A positive test

in the stool for bilirubin, when found, has been regarded as a point in favor of the diagnosis of benign versus a malignant condition at the area of obstruction. In a case of protracted jaundice with clay-colored stool, bile in the duodenal contents, even when diminished in quantity, speaks strongly for calculus, just as its complete absence furnishes strong presumption of malignancy.

STRICTURE OF THE COMMON BILE-DUCT

Three cases of post-operative strictures of the bile-duct were studied (Table 2). In all three, drainage of the choledochus had been practiced; the delay in the closure of the laparotomy sinus had led to the duodenal examination. In two instances no bile was found; pancreatic ferments were abundant. The stricture was evidently above the point of junction of the bile and pancreatic ducts; also it was a complete one.

TABLE 2.—CATARRHAL JAUNDICE

Case	Bile	Ferments	Amylase, c.c.	Trypsin	Lipase, c.c.
1. Acute catarrhal jaundice	+	+	30	1:20,000	?
COMMON DUCT STONE					
1. Common duct stone (passed on the day succeeding duodenal exam.)	+	+	12	1: 1,000	0
2. Multiple stones, recurring after operation	+	+	15	1:10,000	3.9
3. Common duct stone	+	+	15	1:20,000	5.4
4. Common duct stone (hepatic cirrhosis)	+	+	27	1:30,000	—
5. Common duct stone	+	+	18	1:10,000	9
6. Multiple common duct stones	0	+	12	1:10,000	6

* Blood present in the duodenal contents.

In the third case, while the laparotomy sinus persisted in giving exit to bile, duodenal examination demonstrated a fairly free flow of bile into the intestine, only a slight diminution being noted. The pancreatic ferments were again normally present. In this case, the physical condition of the patient being poor, secondary operation for closure of the sinus had been delayed because of the fear of a secondary or newly formed carcinoma of the bile-duct. The free flow of bile removed in great part this fear; radical intervention was again attempted and stricture of the bile-duct, together with more calculi, was found.

Thus it is seen that postoperative stricture of the bile-duct resulting from the operation of choledochotomy may be complete or incomplete. Complete obstruction of the duct may here be mistaken for carcinoma of the biliary system, though the latter condition has never been seen clinically in my limited experience to occur anew so soon after a primary operation for calculus. A carcinoma, however, may have been overlooked at the primary operation. Partial stricture of the choledochus following choledochotomy makes improbable the existence of a neoplasm and allows the surgeon to extend the time for a natural closure of the abdominal sinus.

NEW GROWTHS INVOLVING THE BILIARY SYSTEM

There are fourteen cases in this series (Table 3), comprising both carcinoma and sarcoma, subdivided into two groups: (1) new growths not involving the pancreas or its excretory ducts, and (2) new growths originating in or involving the pancreas and its duct. The first group includes neoplasms that implicate the biliary system in its course from the beginning of the extrahepatic portion to its entrance into or alongside of the pancreas. There are three such illustrations in this series. (Cases 1, 2, and 3, Table 3.) These are cases of cancer of adjacent organs involving the choledochus by direct extension. They invariably present complete absence of bile from the duodenum; the pancreatic duct is, as would be expected, always patent.

The second group includes those new growths involving the pancreas and its ducts. Eleven cases are mentioned under this division, including carcinoma and sarcoma. (Cases 4 to 14, inclusive, Table 3.) Six of these eleven cases (55 per cent.) presented complete absence of both bile and pancreatic ferments from the duodenum. The diagnosis possible when both ducts are completely obstructed is an absolute one, as no condition has yet been seen which can be confounded with it.

In the remaining five cases, the diagnosis from the duodenal examination was more complicated, owing to the fact that secondary ulceration of the new growth had released some of the pent-up secretions. Yet in four of these five cases the complete absence of bile at some time made possible the diagnosis of neoplasm. In the fifth, an ulcerating tumor of the papilla of Vater, and examination of the duodenal contents demonstrated the presence of abundant bile and pancreatic ferments, in spite of persistent jaundice. (Case 8, Table 3.) Fever, intestinal hemorrhage and rapid progressive emaciation, however, corroborated an evident clinical diagnosis.[2]

In a series of over 120 general cases, blood in the duodenal contents has been encountered only three times, two of these cases being proved carcinomas of the papilla of Vater, and the third a case of abdominal new growth whose exact nature was not ascertained. The association of bloody duodenal contents with new growth is evident from these figures, yet it must be borne in mind that this series includes no instances of duodenal or gastric ulcer of non-malignant type. Bondi,[3] in a much smaller series of cases, reports finding blood in many instances, and denies its significance as an indication of ulceration. Chase and Myers,[4] in a series of twenty-nine cases, found no blood in any of their examinations, nor did Frank[5] or Einhorn,[6] working with fairly large series. I would be inclined to attribute the frequent finding of blood by Bondi to a difference of technic, too much force being brought to bear in aspirating the contents of the duodenum. Further data, however, should be collected before bloody duodenal contents can be accepted as an evidence of ulceration, or new growth.

In review of the fourteen cases of neoplasm, thirteen presented a complete closure of the bile-duct; this is a reliable sign of the diagnosis of new growth. Six cases gave the additional evidence of closure of the pancreatic duct, further localizing the lesion at the junction of the bile and pancreatic systems in the head of the pancreas. The latter sign is an infallible one.

6. Chronic endocarditis; jaundice	+	+	18	1: 4,300	1.5

PANCREATITIS

In one case of acute suppurative pancreatitis, bile was scant; only a trace of one of the three principal ferments of the gland was present. In four instances of chronic pancreatitis the diagnosis was made by the finding of diminished ferments in the duodenal contents (Table 4). The diminution in the strength of the ferments was unquestionable and marks a deviation from the normal figures for the enzyme values as found in this large series.

As regards bile, the free entry of bile into the duodenum is no index of the extent of the disease; in two instances bile was entirely unobstructed; in the third case bile was only scantily present (on another examination, absent). This was a case of chronic sclerosing pancreatitis, resulting in the complete strangulation of the bile-duct and pancreatic tissue by the cirrhotic process. The fourth case was complicated by a small, probably secondary carcinoma at the head of the pancreas near the choledochus. In this case, no bile was found in the duodenum and the ferments were also found markedly deficient. The laboratory diagnosis of combined neoplasm and chronic inflammation was confirmed at the necropsy.

---

[2] This subject is more fully considered in an article published in the American Journal of the Medical Sciences, 1914, cxlviii, 839.

[3] Bondi: Arch. f. Verdauungskr., 1913, xix, 692.

[4] Chase, A. F., and Myers, V. C.: The Examination for Diagnostic Purposes of the Enzyme Activity of Duodenal Contents, Arch. Int. Med., December, 1913, p. 628.

[5] Frank: Arch. f. Verdauungskr., 1912, xviii, 121.

[6] Einhorn: Am. Jour. Med. Sc., 1914, cxlviii, 490.

Thus it is seen that the duodenal contents afford a good basis for the diagnosis of pancreatitis, both in the diminution of enzymes and, when it occurs, diminution of the bile.[7]

HYPERTROPHIC CIRRHOSIS OF THE LIVER

Six cases were encountered in the course of four years. The result of duodenal studies is an almost uniform finding of a superabundance of bile, and an overactivity of pancreatic ferments (Table 4). When quite typical, one cannot mistake the chemical evidence. The bile is thin, light yellow and watery, and flows in large amounts; yet there is no dilution of the strength of the ferments, for here the highest figures, particularly for trypsin, are seen.

MISCELLANEOUS CASES (Table 5)

In this category appear:

1. Three cases of syphilitic hepatitis, with jaundice. In two of them, bile and enzymes lacked any abnormal characteristics. In the third (Case 4, Table 5) the typical chemistry of a non-specific hypertrophic cirrhosis occurred.
2. A case of hemolytic jaundice, acquired type; duodenal contents were normal.
3. A case of pylephlebitis.
4. A case of chronic endocarditis and enlarged liver, with jaundice. In these cases nothing abnormal was noted.

SUMMARY

Passing in review the most evident features of duodenal content examinations in the various pathologic conditions, we note the following:

Cholecystitis and cholelithiasis usually cause temporary, and then only partial, diminution in the bile outflow; pancreatic ferments remain normal unless a complicating pancreatitis is present.

Catarrhal jaundice has no characteristic changes.

In impacted common duct stone, even in the presence of long-standing jaundice, bile and ferments usually enter the duodenum quite readily. Only one exception to this rule has so far been noted. The real value of this report lies in its contrast with that in neoplastic obstructions.

In benign, postoperative stricture of the bile-duct, the obstruction to bile may be partial or absolute.

In thirteen out of fourteen cases of icterus due to neoplasm (93 per cent.) the obstruction to bile was absolute. In six instances (43 per cent.) the external pancreatic secretion was, in addition, completely shut off. Secondary ulceration of the new growth may, for a time, allow leakage of small quantities of one or the other secretion. Rarely, as in tumors of the pancreas itself, no obstruction to the ducts is observable, and the enzymes of the gland may themselves be normally present.

Blood in the duodenal contents is strongly suggestive of new growth.

Hypertrophic cirrhosis of the liver, with long-standing jaundice, shows not only no obstruction to bile, but on the contrary, a hypersecretion of both bile and ferments.

In pancreatitis, the entrance of bile into the duodenum is frequently obstructed; in advanced cirrhosis of this organ, the obstruction to bile may be a complete one. Pancreatic ferments readily enter the duodenum, but the marked diminution in the strength of these ferments is characteristic of the disease.

To the clinician at the bedside there is no more difficult problem to solve than the causation of a long-continued jaundice. There may be as much, if not more pain with neoplastic obstruction of the bile-ducts as with impacted calculi. Courvoisier's law of a tense and enlarged gall-bladder as an index of new growth is valuable when positive; the inability to feel an enlarged gall-bladder in persons difficult to palpate often leaves this valuable sign in doubt. Chronic pancreatitis, a not very uncommon disease, may give a clear history of pain and may present a large, tense gall-bladder with persistent and severe icterus. In all three conditions disturbance of nutrition and loss of weight occur. Intestinal hemorrhage, associated with a remittent temperature, speaks strongly for an ulcerating neoplasm. The finding in the stool of free fat and abundant undigested muscle fibers, when they do occur, is characteristic of pancreatitis.

Fortunately, the duodenal contents are often of the greatest value in those most difficult and frequent cases in which pathognomonic clinical signs are absent. If the chemical examination shows both ducts open, a benign stenosis is most likely; partial closure of the bile-duct with open pancreatic duct usually points to an impacted common duct stone. Complete closure of the one or the other duct generally means neoplasm, particularly when blood is present in the duodenal contents. Complete closure of both ducts occurs only in new growth. Definite diminution of ferments points clearly to pancreatitis; this is usually accompanied by some diminution of bile.

Lastly, and with greatest emphasis, it must be said that when the duodenal content examination is not well defined, pointing to a result of a definite pathologic process, the interpretation of the laboratory findings must be influenced by the clinical points of the case, as well as by the examination of the stool.

One of the most vulnerable points in duodenal content diagnosis is in the following type of case: A middle-aged man presents the clinical picture of obstructive jaundice probably of malignant origin. The examination of duodenal contents shows the presence of both bile and ferments, the latter in undiminished strength. This finding would indicate a benign rather than a malignant condition. And yet, should blood be present in the stools, grossly or chemically, should irregular fever and leukocytosis occur, the case may more rationally be diagnosed as an ulcerating carcinoma, probably of the papilla of Vater. In such an instance, a knowledge of the pathology of such tumors must be recalled, and their tendency to ulcerate and necrose be remembered. The duodenal findings must be overruled by the stronger clinical evidence, testifying to the fact of evident ulceration, hemorrhage and ascending infection of the bile passages. If the duodenal content examination be repeated, one may be fortunate enough, as has more than once occurred to me, to find complete absence of bile; this is a confirmation of the clinical diagnosis. Fortunately, in about 80 per cent. of the cases of tumor, complete absence of bile is ascertained at the very first examination.

All in all, rules may be formulated for the occurrence of certain findings in each of the pathologic conditions usually encountered; these rules are based on the *majority* of the chemical examinations in such cases; exceptions to the rules, as to all biologic rules, do occur.

---

[7] In a subsequent paper, the subject of pancreatitis, its duodenal findings and metabolism studies will be more fully considered.

ILLUSTRATIVE CASES

To illustrate concretely the value of duodenal content examination in differentiating icteric conditions, a few well-chosen examples are appended.

Case 1.—(From the medical service of Dr. N. E. Brill).—A. B., man, aged 43, had suffered for twelve years from loss of appetite, with occasional attacks of nausea and vomiting. Two weeks before being seen he suddenly noted jaundice, and before entering the hospital had several attacks of mild abdominal cramps. Duodenal content examination showed abundant bile and ferments. A diagnosis of benign stenosis, probably of stone, was offered. Within a few days the icterus began to clear up; the patient was kept under observation for several weeks, and discharged eventually with the diagnosis of cholelithiasis.

Case 2.—(From the medical service of Dr. E. Libman).—L. K., a woman aged 68, suffered for four months with jaundice, pruritus, loss of weight and occasional attacks of abdominal pain. Repeated examinations of duodenal contents revealed complete absence of both bile and ferments. Blood was present in the aspirated material; a definite diagnosis of new growth was made. Advancing anemia, melena and the later occurrence of signs of pancreatic gland destruction (typical stool changes) occurred. The necropsy demonstrated a typical advanced carcinoma of the terminal portion of the bile-duct invading the pancreas.

Case 3.—(From the surgical service of Dr. Charles Elsberg).—M. S., a woman aged 48, suffered for three months with weakness, emaciation and jaundice. Duodenal contents demonstrated complete absence of both bile and ferments; blood was also present. A definite diagnosis of tumor was made. This was confirmed at the operation, at which a large new growth was felt involving the duodenum and head of the pancreas.

Case 4.—(From the medical service of Dr. N. E. Brill).—L. J., man, aged 48, complained for eight days of painless jaundice. His physical examination was negative except for slight hepatic enlargement. Duodenal examination demonstrated the presence of both bile and ferments. A diagnosis of catarrhal jaundice was offered; within a few days the jaundice began to disappear and the patient was discharged, apparently well.

Seven weeks later, he was readmitted to the hospital, deeply jaundiced, running a septic type of temperature and showing blood in his stools. Duodenal contents now demonstrated complete absence of bile; ferments were normally present. The duodenal diagnosis was now one of new growth, with ulceration. At the necropsy an ulcerated carcinoma of the papilla of Vater was ascertained.

It is evident that the first duodenal examination was made at a time when advanced ulceration had liberated the ducts. The second examination, a few weeks later, and after renewed growth on the part of the tumor, more nearly approached the typical chemical data of neoplasm.

Case 5.—(From the service of Dr. N. E. Brill).—S. R., man, aged 37, suffered for seven weeks with jaundice and diarrhea. He had had at the beginning of his illness an attack of abdominal cramps. Loss of weight was marked. The physical examination revealed an enlarged liver and palpable gall-bladder. Duodenal examination showed absence of bile and diminished pancreatic ferments. A diagnosis of sclerosing pancreatitis was made. A confirmatory duodenal examination, made some days later, showed some bile entering the intestine and pancreatic ferments again markedly diminished. At the necropsy chronic intralobular pancreatitis was definitely established as the cause of the symptoms.

GASTRO-INTESTINAL STUDIES

VI. THE IMPOSSIBILITY OF INTERPRETING THE FINDINGS OBTAINED BY THE CUSTOMARY EXAMINATION OF THE TEST MEAL *

MARTIN E. REHFUSS, M.D.
PHILADELPHIA

It is my purpose in this paper to show that it is practically impossible to interpret correctly the findings, or rather the figures obtained from a test meal extracted in the usual manner. The literature is full of the inconsistencies encountered in ordinary gastric testing and strange results, oftentimes in discord with clinical symptoms, have caused the clinician to rely less and less on the examination of the test meal as an index of gastric function. And yet the examination of the gastric juice must always remain the only true method in the determination of gastric function. Two things stand out prominently in the whole category of functional testing: (1) the fact that a definite stimulus produces under identical conditions practically always a constant result; and (2) anatomic and pathologic changes result almost always, although not invariably, in change in function. If the gastric response did not in a way reflect the condition of the organ, it would be the first organ which does not follow known physiologic laws. As the urine will, despite the efforts of certain clinicians, represent and reflect the condition of renal permeability and renal work, so must the secretory output of the stomach reflect the condition and working response of that particular organ. But it is as absurd to expect information of gastric function from the examination of a single specimen at an isolated phase as it is to obtain an accurate idea of renal efficiency from the examination of a single specimen after the administration of phenolsulphonephthalein, for example. That it is working, perhaps we can say; how it is working, it is impossible to say. The examination of the gastric juice must remain, together with a determination of its motor function, the true methods for estimation of gastric function, and newer knowledge only begins to suggest the multitude of causes which can react on the elaboration of the secretion—the condition of the mucosa, the actual tonicity of the vagus and sympathetic filaments, the condition of hyper- or hypo-activity of the ductless glands, the elaboration of hormones and secretagogues, the intactness of the evacuating system, the presence of inhibitory or stimulating, toxic, chemical, or irritating substances in the blood, and finally, the question of excretion—which all play a part in elaboration and subsequent character of the gastric secretion. But more than this, the addition of ulcerous, inflammatory and neoplastic products all lend, in a certain sense, their properties in adding to or modifying the final product. The discussion of these points is entirely out of place in this paper. The important point is the impossibility of interpreting the findings after the routine method employed at present.

In the literature the idea of making a fractional examination of gastric digestion is by no means new. Perhaps to Hayem belongs the credit of studying most carefully the secretory output in various conditions, but his method was crude and his curves show the irregular intervals necessitated by such an examination. Practically all examinations which were conducted on the gastric secretion in the human subject used the method by which the subject received a definite test meal which was emptied in ten minutes on one day, on the following day in twenty minutes, on the third day after thirty minutes, and so on, until the entire cycle of gastric digestion was completed. Many authors have investigated the gastric secretion at various periods, Ewald and Boas,[1] then Reichmann,[2] v. Jaksch,[3] and Kornemann,[4] in 1885, published a most comprehensive series of observations on the digestion of milk in a healthy young man of 20. After habituating his subject to the passage of the tube, he commenced his series, removing the milk on successive days after increasing time intervals.

---

* From the Laboratory of Physiological Chemistry of the Jefferson Medical College.

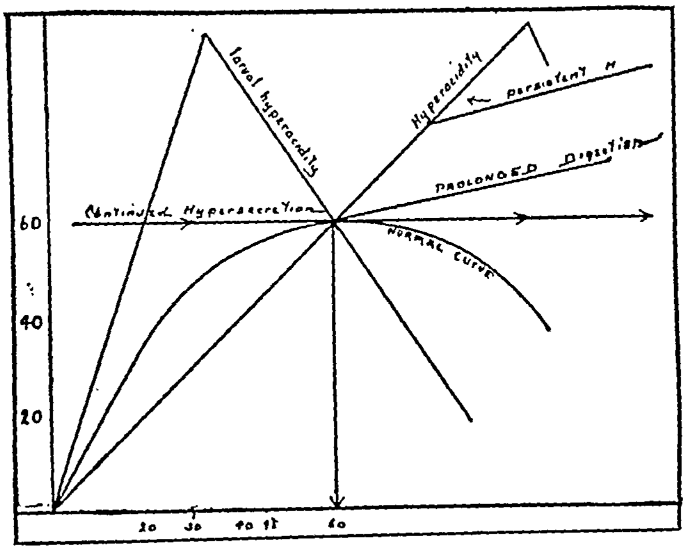

Fig. 1.—Possibilities in the interpretation of normal figures of the one-hour examination.

Von Jaksch[3] records a series of tables indicating the effect of milk, tea, carbohydrates and meat in children. These were administered and removed at various intervals by means of the sound. His observations are of interest and he shows that the position of the high point differs according to the diet ingested. He makes the statement, however, that after the administration of weak tea and saccharin, free HCl is detected in 78 per cent. of the cases in three-quarters of an hour, but after feeding milk or meat he could detect its presence in the first quarter of an hour.

Schule's[5] observations are quite complete, but unfortunately restricted to four individuals, although they are repeated, and different articles of diet were investigated. After tea and toast, for instance, while the majority of high points were encountered at sixty minutes, several were found at forty-five and seventy-five minutes, respectively.

Kornemann[4] gives fifty minutes as the point at which the free HCl reaches its height after the administration of a test breakfast. With 35 grams of roll and 250 grams of tea, he finds the stomach empty in two and one-half hours.

Ehrenreich,[6] perhaps, published the first satisfactory results of a complete examination of the gastric cycle and utilized for that purpose a Nelaton catheter. He showed that examinations at quarter-hour intervals demonstrated that the pepsin concentration rapidly reached its maximum (after twenty to thirty minutes) and then had a tendency to remain constant, while the acid concentration reached its maximum only after seventy minutes. Gregerson[7] criticizes the method, inasmuch as apparently a great deal of saliva and mucus is formed by Ehrenreich's method. Some twenty-two cases were enumerated by Ehrenreich, insufficient to draw any interpretation of the interesting findings which he recorded.

Gregerson's cases, while few in number, are interesting and instructive, but the method, as were other methods enumerated above, is entirely impractical.

The value of the fractional tube lies in the fact that by means of its weight, the tip seeks the bottom of the stomach by gravity; secondly, with few exceptions, it is well borne and if the patient is encouraged to expectorate any saliva, the specimens are clean and representative of the gastric contents, while at any moment the entire gastric content can be evacuated. It is therefore absolutely impossible to form any opinion regarding the interpretation to be drawn from an examination of the gastric juice in the one-hour interval.

1. This point records but one phase in the ever changing cycle of gastric digestion.
2. A large number of observations have shown that this point is by no means the high point or the representative one.
3. Many changes may both precede or follow this point.
4. Many forms of hyperacidity, hypersecretion, occult bleeding are entirely overlooked in this way.
5. Delay in digestion may mean that figures at the one-hour point may be doubled at the second hour.
6. No idea of evacuation or the motor function of the stomach can be obtained by this method.

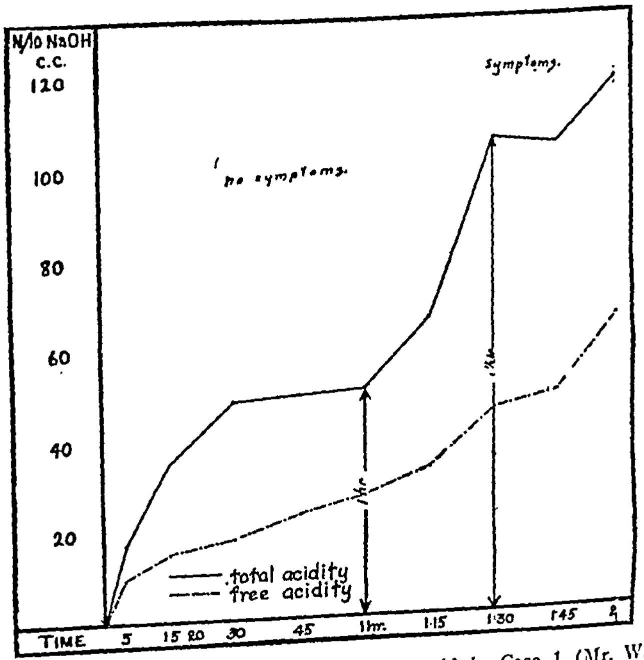

Fig. 2.—Curves of total acidity and free acid in Case 1 (Mr. W.). Note the difference in the figures at the period and the findings at one and a half hours.

7. That entirely erroneous conclusions may be drawn must be evident from the following cases.

These cases are drawn from more than 300 complete fractional examinations of the entire gastric cycle after the administration of the Ewald meal and almost 200 fractional examinations after the administration of

various food substances, in normal individuals. They are merely given to demonstrate the impossibility of drawing any conclusions from the customary gastric examination. For instance:

1. The test meal at the one-hour period reveals normal total acidity and free acid figures.

So-called normal total free acid figures at one hour may mean (1) perfectly normal digestion, such as has been recorded elsewhere; (2) but it may mean something entirely different. A glance at the diagram (Fig. 1) will show the possibilities (1) a normal curve; (2) high figures following this point, in reality the tardive hyperacidity of the French, either sustained or abrupt and with or without hypersecretion; (3) it may mean an absolute constant acidity such as is seen in certain hypersecretion or obstructive cases; (4) it may mean hyperacidity after the manner of the so-called Strauss larval hyperacidity preceding the one-hour point and falling at that point to or near normal. At the same time all forms and types of motor aberrations may occur.

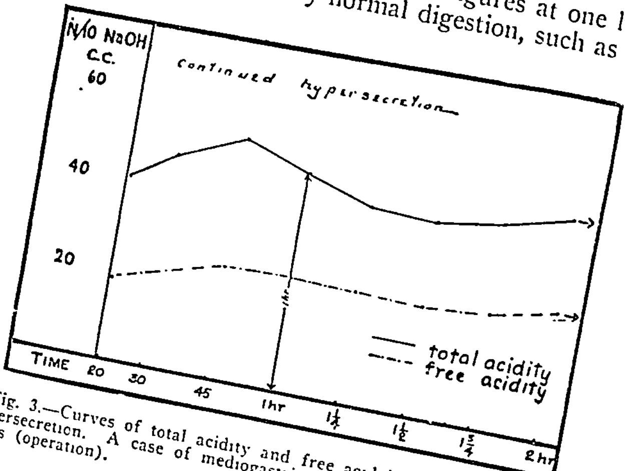

Fig. 3.—Curves of total acidity and free acid in Case 4. Continued hypersecretion. A case of mediogastric contraction from gastric adhesions (operation).

A. Normal figures at the one-hour point may be followed by hyperacid figures at the two-hour point. This s illustrated by the cases in Table 1.

ABLE 1.—TOTAL ACIDITY AND FREE ACID AT ONE- AND TWO-HOUR PERIODS

Case 1. Mr. W.			Case 2. Mr. E.		
Time, Hours	Total Acidity	Free Acid	Time, Hours	Total Acidity	Free Acid
1/12	17.2	10.0	1/6	16.0	8 5
1/4	35.2	15.4	1/4	14.0	8.0
1/2	48.1	18.0	1/2	17.0	8 0
3/4	49.0	23.2	3/4	37.5	28.5
1	54.4	27.0	1	53.0	44.5
1 1/4	66.0	33.0	1 1/4	69.0	60.5
1 1/2	106.0	45.3	1 1/2	94.0	85.5
1 3/4	104 5	48.3	1 3/4	93.0	83.0
2	118.6	64.7	2	85.0	76.0
			2 1/3	19.0	11.5

In these cases, the discrepancy between the one-hour findings and the curve is pronounced. Case 1 (Fig. 2) shows two-hour figures more than double those obtained at the one-hour point and an added factor, hypersecretion, was observed. Furthermore, all the subjective symptoms occurred after the one-hour point. n the second case the symptoms were pronounced late digestion and the patient was free from symptoms at the one-hour point.

B. Normal figures at the one-hour point may be preceded by hyperacid figures. Such a case is shown in Table 2, which emphasizes the possibilities of the so-called Strauss larval hyperacidity.

TABLE 2.—NORMAL TOTAL AND FREE ACIDITY AT ONE-HOUR POINT PRECEDED BY HYPERACIDITY

Time, Hours	Case 3, Mr. F. Total Acidity	Free Acid
1/12	6.7	Trace
1/4	19.8	7.5
1/2	25.3	14.0
3/4	75.7	53.3
1	43.7	24.0
1 1/2	18.2	9.5
1 3/4*	24.5	11.5

* Stomach empty—hypermotility.

C. Normal figures at the one-hour point may be only part of a continued hypersecretion or obstructive phenomenon. This is seen in the cases in Table 3.

TABLE 3.—NORMAL FIGURES AT THE ONE-HOUR POINT

Case 4 (Fig. 3)			Case 5		
Time, Hours	Total Acidity	Free Acid	Time, Hours	Total Acidity	Free Acid
1/3	40.7	18.5	1/12	49.9	36.4
1/2	47 0	....	1/6	57.1	45.2
3/4	50.3	25.6	1/4	59.2	42.0
1	48.2	25.9	1/2	60.8	45.4
1 1/4	43.5	25.0	3/4	58.2	44.0
1 1/2	42.7	24.3	1	61.2	46.0
1 3/4	44.9	25.7	1 1/4	62.9	47.8
2*	48.4	28.5	1 1/2	61.7	47.2
			1 3/4	67.6	44.6
			2	68.4	49.6
			2 1/2	68.0	48.6

* Marked hypersecretion throughout.

Therefore normal figures at the one-hour point might be of varied significance, depending on the secretory phenomena which have preceded or followed this point.

The first variety, namely, the normal figures at one hour, followed by figures indicating hyperacidity in later phases of digestion, is particularly common.

2. Hyperacid figures at one hour may be of varied significance depending on the character and duration of the findings, and this is only revealed by fractional testing. The cases in Table 4 (Figs. 4 and 5) both reveal figures indicating a hyperacidity at one hour but a study of the curve will reveal the difference in their significance.

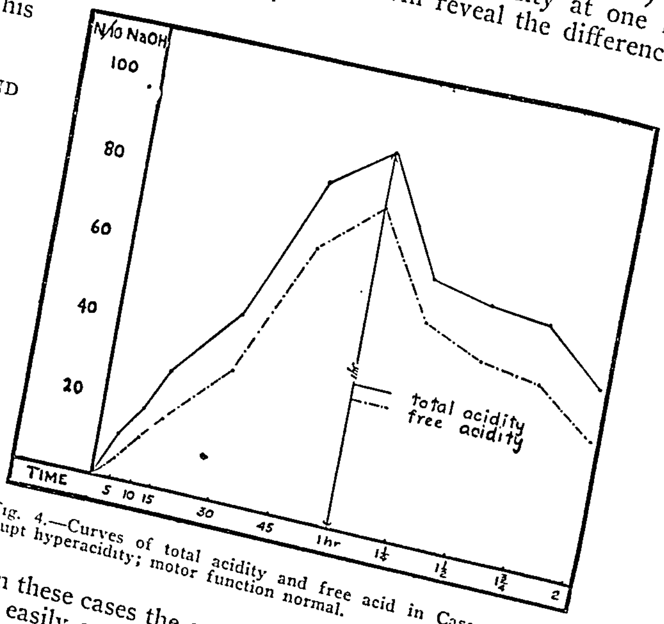

Fig. 4.—Curves of total acidity and free acid in Case 6 (Mr. J.). Abrupt hyperacidity; motor function normal.

In these cases the one seen to be more or less abrupt was easily controlled by simple dietetic measures; the other dominated the entire gastric phase after the ¾-hour period and was accompanied by hypersecretion.

3. Subnormal figures at the one-hour point may indicate in general a subnormal curve. They may also

Grosser,[7] on a careful critical review of the data, concludes that the balance of evidence from this kind of experiment is in accord with the view that no difference exists whether the phosphorus is supplied in organic or inorganic form.

Hart, McCollum and Fuller[8] found that in the case of growing pigs the quantity of phosphorus necessary is not dependent on the nature (organic or inorganic), but on the needs of the animal. Pigs fed on rations with extremely low phosphorus content at first developed as well as controls, but later there was loss of weight, followed by collapse. Supplementing this low phosphorus diet with either calcium phosphates or organic phosphorus compounds sufficed to produce normal growth and development. The phosphorus in the organic form gave no better results than the inorganic phosphates. McCollum, Hart and Humphrey,[9] working with a cow, conclude that neither the form nor quantity of potassium, magnesium or phosphorus in the diet affected the percentages of these elements in the milk.

Fingerling,[10] comparing the influence on the milk secretion of the feeding of organic phosphorus with that of inorganic phosphorus, found no influence on the quantity, amount of total solids, or percentage of calcium and phosphorus. The organic phosphorus was fed in the form of lecithin, phytin, casein and nucleic acid, and the inorganic as disodium phosphate. He concludes that the organism can satisfy its needs just as well with inorganic phosphates as with organic phosphorus. Other investigators (Wendt,[11] Holsti,[12] Gregerson[13]) have shown that the organism can synthesize organic phosphorus compounds out of inorganic phosphates. In regard to the relative ease and completeness of this synthesis, Fingerling has carried out some very interesting experiments on geese, and McCollum, Halpin and Prescher on hens.

Fingerling[14] selected a flock of geese and fed them during one year on food containing practically no organic phosphorus but only inorganic phosphates. The next year they were fed on a diet rich in organic phosphorus. It was found that the number of eggs laid, their weight and content in lecithin, nucleic acid and phosphorus were the same on the organic-phosphorus-free diet as on the one rich in organic phosphorus. McCollum, Halpin and Prescher[15] found hens capable of synthesizing complex phosphatids, for when fed on a phosphatid-free diet, they laid eggs containing the normal content of lecithin.

The recent experiments of Osborne and Mendel[16] on the amino-acids necessary for maintenance and growth are evidence in the same direction. Rats can be maintained and grow on a diet of phosphorus-free protein and an inorganic salt mixture, and when the growth curve diverges from the normal on this diet, it can be restored by the addition of butter-fat,[17] which contains no phosphorus.

We see that the evidence is very convincing of the view that the animal organism can synthesize its complex organic phosphorus constituents from inorganic phosphates, and that organic phosphorus is of no more value as a food than inorganic. If the organic phosphorus compounds possess any particular efficacy over the inorganic, it is probably due to their containing substances that are necessary in traces to normal nutrition, and not to their organically bound phosphorus. These materials are undoubtedly furnished by any ordinary mixed diet, and in cases in which the introduction of phosphorus is desired to attempt to make possible the synthesis of organic phosphorus compounds in the body, the inorganic phosphates are entirely suitable for this purpose.[18]

ALBUMIN IN THE SPUTUM AS A DIAGNOSTIC AID *

C. BRUCE LOCKWOOD, M.D.

DETROIT

The suppression and cure of tuberculosis depend largely on an early diagnosis of the malady. Any laboratory method, therefore, which would be of value in our diagnosis, since both history and physical findings are often inadequate, would be very desirable.

Among the various methods for the diagnosis of tuberculosis which have been exploited from time to time is one, the albumin-sputum method, which has attracted attention off and on for nearly sixty years, but which never yielded sufficient satisfactory results to warrant its general adoption by clinicians.

REVIEW OF LITERATURE

In 1855 Biermer,[1] investigating this subject, always found albumin positive in acute bronchitis, in pneumonia and in edema of the lungs, but negative in chronic bronchitis and in tuberculosis, the latter showing much mucin.

Renk[1] found albumin negative in chronic bronchitis but always positive in acute bronchitis, pneumonia and tuberculosis, the latter showing from 0.11 to 0.49 per cent.

Bamberger,[1] Panow, Starkow and Lanz found considerable albumin in bronchitis and emphysema, as well as in tuberculosis.

Wanner, after boiling with salt solution and acetic acid, found much albumin in tuberculosis, while there was only a trace or negative in chronic bronchitis and in asthma.

Beranzon and Young[1] found albumin in both tuberculosis and bronchitis.

The observations of Roger and Levy-Valensi[2] gave stimulus to numerous investigators, including Lantz and Hertz,[3] Lecaplain,[4] Terreira,[5] Lesieur and Prires,[6] and many others, all of whom came to the conclusion that a negative test excluded tuberculosis, while a

positive test rendered the case very suspicious, but not absolutely confirmatory, since a positive test might occasionally be obtained in other conditions such as pneumonia, edema of the lungs, bronchopneumonia and cardio-renal disease, and that the test is generally negative in acute and chronic bronchitis.

Fishberg and Felberbaun,[7] often found the quantity of albumin infinitesimal or absent in chronic fibroid tuberculosis, but present in active cases, the amount bearing considerable relation to the activity of the process.

Fullerton,[8] investigating 100 cases, noted wide variations in the amount of albumin. He found that tuberculosis generally shows considerable albumin, but that in a small percentage of cases little or no albumin occurs, and that a positive reaction occurs in various diseases of the respiratory tract, such as pneumonia and bronchitis. He concluded that the albumin reaction was not reliable in diseases of the respiratory tract, and of only limited value in tuberculosis.

S. Acs-Nagy[9] decided that the determination of albumin has little importance for practical diagnosis.

J. Kauffmann[10] speaks highly of it, and applies it along with the tuberculin reactions. He found the test negative in bronchitis, but positive in kidney disease and pulmonary edema.

B. O. Works,[11] after precipitating with Esbach's reagent, concluded that most active tuberculosis cases show 2 per cent. or more, while improved cases show less than 2 per cent. and that a negative reaction excluded tuberculosis.

Scott[12] concluded that the test is of no value in the routine diagnosis of tuberculosis, because the reaction occurs in many other affections of the respiratory tract, and is negative in about 10 per cent. of positive pulmonary cases.

Berkovitz and Rudas,[13] who estimated the albumin by both the Kjeldahl and Esbach methods, found that the quantity of albumin in the sputum in respiratory diseases varied between two wide extremes, and concluded that it was of no diagnostic value.

E. Gelderblom[14] states that an increase or decrease of the albumin content of a tuberculous sputum points to an aggravation or improvement of the disease.

E. Hempel-Jorgensen[15] states that the results are not uniform. He found albumin negative in two out of fifteen tuberculous cases. He decides that considerable albumin might indicate tuberculosis, but all other inflammatory or destructive processes of the respiratory tract must be excluded, and concludes that the test is of little positive diagnostic value.

Holm and Himmelberger,[16] estimating the albumin by precipitating with potassium ferrocyanid and centrifuging, in their first communication concluded that the determination of the albumin in the sputum is one of the most important aids in diagnosis and prognosis of tuberculosis that has been introduced in recent years. Later[17] they seemed less enthusiastic, and stated that a negative reaction excludes tuberculosis, but a positive reaction is always present in pulmonary abscess, bronchopneumonia, lobar pneumonia and pulmonary edema, and a negative reaction is generally present in pharyngitis, bronchitis and asthma.

METHODS

The technic for estimating and detecting the albumin in the sputum has not been uniform, the earlier investigators chiefly using the more accurate Kjeldahl method, while most of the workers in the last four years have used slightly different technic of precipitating the mucin with dilute acetic acid, filtering and applying various albumin tests to the filtrate, such as the nitric acid contact test, the potassium ferrocyanid test, boiling, and for a quantitative determination, the Esbach test.

In all my cases I have first precipitated the mucin by mixing well one part of sputum with one part of 3 per cent. acetic acid and allowing to stand for some time, then adding one part of water, making a mixture of 33⅓ per cent. sputum, mixing well, filtering through gauze and then through a fine filter paper and using the clear filtrate.

Reasoning on the assumption that in tuberculosis there is a digestion of lung tissue, in Tables 1 and 2 I have attempted to compare the albumin and products of albumin digestion found in tuberculous cases, and also to compare the precipitate obtained regarding the stage, duration and activity of the disease.

The clear 33⅓ per cent. filtrate was placed in an Esbach tube to the U mark, then filled to the R mark with a phosphotungstic acid solution, moderately agitated and allowed to stand twenty-four hours, when reading was taken, multiplied by 3 (dilution) and changed to percentage.

COMMENT ON TABLES

From the tabulations it will be seen that albumin was found positive in all cases examined, and while the average quantity was found higher in the tuberculous cases, there was such a wide variation in the quantity in both the tuberculous and non-tuberculous that this could not possibly be used as a diagnostic aid.

It will also be seen that the quantity of albumin in the tuberculous cases seemed to bear no relation to the duration, stage, temperature or number of bacilli present. It might be stated that in those cases in which two precipitation tests were made, the tests were only one and two days apart, yet a wide variation is noted in the result.

In Cases 19 and 29 inclusive, Table 1, and 5 to 14 inclusive, Table 2, the filtrate was also tested for albumin by the Heller test, and by adding a drop or two of potassium ferrocyanid and noting the cloud, with the result that all the non-tuberculous were as positive as the tuberculous, with the exception of Case 19, which was negative to potassium ferrocyanid, but positive to the nitric acid contact test.

In the foregoing observation, albumin was practically always present in sputum, regardless of the disease.

In tuberculous patients, the amount seemed to bear no relation to the stage, duration or activity of the disease process, and it now seems, therefore, that the albumin reaction or the quantitative determination of albumin in the sputum had no practical value in the diagnosis of respiratory affections.

603 Kresge Building.

Preventogram.—"So long as there is a neighbor who cultivates thistles, dandelions, etc., in his fields or lawns, it is well nigh impossible for the careful, industrious neighbor to secure the freedom he pays for by his own care. Parents have a right to insist that their children be not infected by a careless neighbor's children."—Pittsburgh *City's Health.*

INFECTIVE LYMPHOID GROWTHS OF THE LARYNGOPHARYNX, SECONDARY TO SINUS SUPPURATION

A PREVIOUSLY UNDIFFERENTIATED TYPE OF LYMPHOID HYPERPLASIA *

W. E. CASSELBERRY, M.D.
Professor Emeritus of Laryngology and Rhinology in Northwestern University Medical School; Laryngologist to St. Luke's Hospital
CHICAGO

The present conviction that rheumatoid, cardiac and pyemic diseases emanate from foci of infection often situated in the tonsils, and the occurrence, which I have repeatedly noted, of nasal sinus suppuration, together with secondary infective tonsillitis, and again, with infective hyperplasia of the minor lymphoid groups, render important the evidence which serves to establish the microbic origin of the lymphoid enlargement, and tends to substantiate the sinus disease as the primary source of infection.

Though typical sinus suppuration makes itself obvious, the discharge need not amount to actual pus, the disease being prevalent in attenuated, yet virulent forms, which are readily overlooked.

The particular qualities noted as characterizing infective lymphoid hyperplasia are: a conspicuous enlargement of the smaller clusters and single follicles, an apparently diffused lymphoid infiltration of adjoining tissue, and a decided disposition, in consequence, to redevelopment after excision. In addition to these, recognition of its situation as being in the pathway of a sinus discharge is almost essential to distinction from ordinary follicular hypertrophy.

In the vicinity of the eustachian orifice, a favorite site for this type, it infiltrates the folds and fills the fossae, baffling efforts at eradication and leading to deafness by obstruction of the tube. In the lateral angles of the pharynx, it forms great pale welts which may rival the tonsils in size and even merge with them by overriding the posterior pillars. In the tonsillar region, it brings jointly into prominence adjoining groups of follicles, some in front of the tonsil on the plica, others below its lower pole, giving the tonsil an appearance of having overflowed its bounds. In the tonsil itself, the hyperplasia, if not large, may be obscured by pillar and plica, and unless sinus suppuration be found, an infective tonsillitis may not be distinguishable from that of common retention. Even the suggestive presence of a semipurulent instead of cheesy substance in the crypts, and oversensitive congested or thickened pillars, are not wholly distinctive. Again, though more rarely, as in the second case herewith, the tonsil is the seat of a large and perniciously active hyperplasia which infiltrates and overlaps the usual bounds and which, though benign, has an aspect of semimalignancy. It is not to be inferred that ordinary enlargement of the tonsil is microbic in origin, being neither perniciously active in growth nor disposed to infiltrate or overrun its bounds. Nor does it originate late in life; whereas, the infective lymphoid growths, in both cases herewith, originated after the fifty-fourth year.

In the larynx while, as a rule, it produces only moderate thickening, in rare instances the small follicles on the rim of the larynx undergo an immense hyperplasia, developing into tumor-like growths which occupy the space of the laryngopharynx, being heretofore of unknown origin, and only vaguely described under the mistaken[1] term "lymphoma."

---

* Read at the thirty-sixth annual congress of the American Laryngological Association, 1914.

It is this tumor-like formation in the laryngopharynx which we have found definitely in two cases, by cultural, microscopic and vaccine methods, to be of microbic origin, having found also the infiltrating type of hyperplasia at the eustachian orifice to partake of the same nature. A fair inference from these findings, considering clinical similarity, points to the hyperplasia at the other sites named as of like infective origin. Leukemia was excluded by the absence of any involvement of the lymphatic glands, and malignancy was negatived by the microscopic test which showed, in each instance, "a simple hyperplasia of lymphoid tissue similar to that of the tonsils."

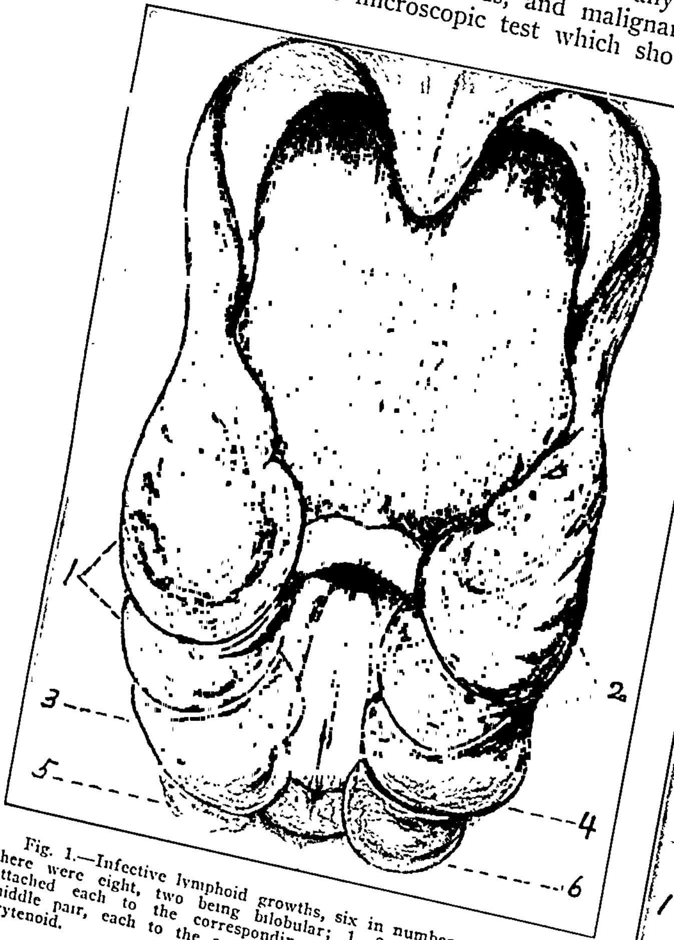

Fig. 1.—Infective lymphoid growths, six in number, appearing as if there were eight, two being bilobular; 1, 2, upper pair, bilobular, attached each to the corresponding pharyngo-epiglottic fold; 3, 4, middle pair, each to the aryepiglottic fold; 5, 6, lower pair, to the arytenoid.

Case 1.—In the laryngopharynx of the first patient there were six separate growths appearing at the surface as eight in number, arrayed four on each side (Fig. 1), the upper two of which were merged in one broad base attached astride the corresponding pharyngo-epiglottic fold, tapering thence upward to the lower pole of the tonsillar fossa. These are designated double upper growths 1 and 2, right and left, respectively, forming the upper pair composed each of two lobes. None of the attachments, however, nor indeed the lower growths, could be discerned until the removal of one or more above. Then the middle pair, appearing third from the top and designated 3 and 4, was found to be attached, each to the corresponding aryepiglottic fold, and the lower pair, 5, quite small, and 6, to the posterior plane of the corresponding arytenoid. These are among the sites specified by Heitler[2] as containing a few lymphoid follicles. Not being visible, the follicles are usually ignored, but evidently they are liable to infection, resulting in hyperplasia which, in minor degree, is not uncommon, and accounts for an aspect of chronic laryngitis and its accompanying "sinus cough," which, though obstinate before, is found, after the sinus disease is remedied, simply to have disappeared; and which, in major degree, though rare, accounts for the present large overgrowths.

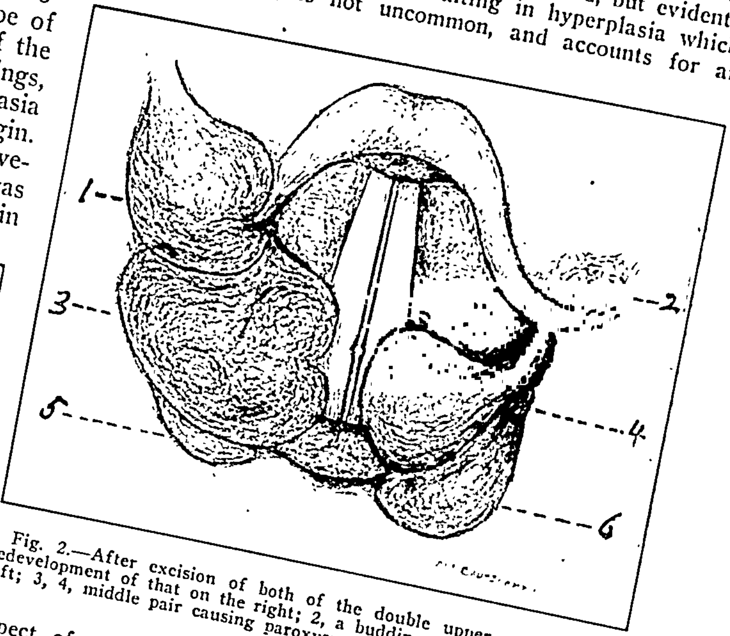

Fig. 2.—After excision of both of the double upper growths; 1, a redevelopment of that on the right; 2, a budding redevelopment on the left; 3, 4, middle pair causing paroxysmal dyspnea; 5, 6, lower pair.

Viewed alone, and considering the total absence of faucial tonsils, which I enucleated years ago, the double upper growths, 1 and 2, by reason of their pyriform contour, smoothly enveloped borders and rudimentary crypt-marked central area, suggested compensatory or aberrant tonsils, such as Rosenberg's[3] "tonsillæ succenturiata"; and the striking similarity in structure of the first specimen removed

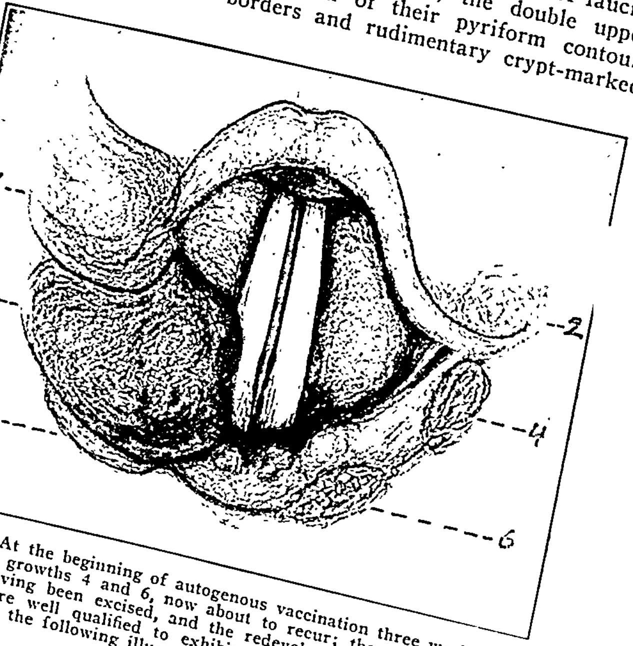

Fig. 3.—At the beginning of autogenous vaccination three weeks after excision of growths 4 and 6, now about to recur; the original growth, 3, never having been excised, and the redevelopment, 1, both growing actively, were well qualified to exhibit the efficacy of the vaccine as portrayed in the following illustrations.

caused the patient, who is himself a well-known physician, to remark that Nature seemed determined that he should have tonsils. But, viewed in their entirety, the theory of compensation became untenable by reason of the improbability that minute lymphoid follicles would, within a period of six months, so late in life as the fifty-fourth year develop without definite cause into overgrowths so unusual in multiplicity, situation and size. Besides, there seemed no end to their development as, three months later, 3, 4 and 6, having grown to impinge on the glottis, the already labored breathing became aggravated by paroxysms of dyspnea, spoken of as "choking spells."

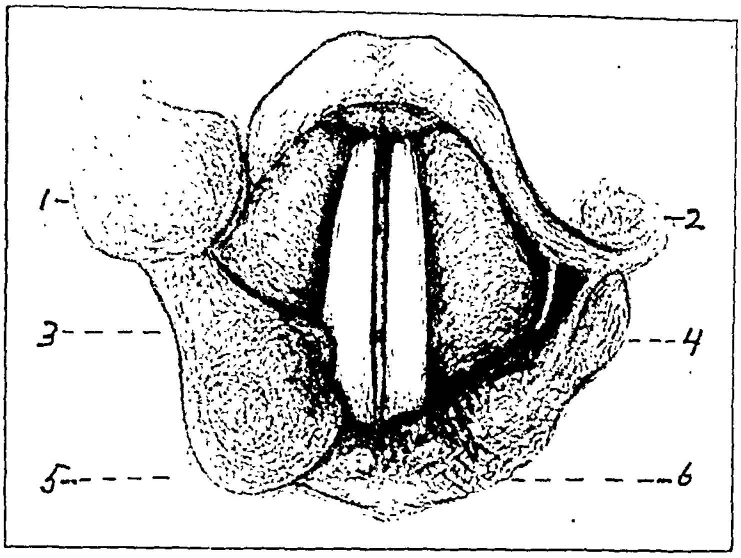

Fig. 4.—Two days after the first administration of vaccine; the original growth, 3, and the redevelopment, 1, already show reduction; the wrinkled surface near the budding redevelopments, 4 and 5, indicates an inner shrinkage so rapid that the mucosa could not keep pace.

The complete surgical removal, in November and December, 1913, by the process of snaring, with upward traction, of both of the upper double growths, amounting to two-thirds of the total volume of growths, abated the dyspnea but little, but did lay bare the mechanism of the paroxysmal attacks, in that the middle pair, 3 and 4, were found to sag toward the glottis, so that any inspiratory effort would draw them closer together across the opening of the larynx, like a pair of folding trap-doors (Fig. 2). The removal late in January, 1913, of one of this pair, 4, on the left, but not its partner, 3, on the right, though also taking 6 from the left, remedied temporarily the difficulty in breathing and afforded an interval during which treatment by Roentgen ray was applied externally to the neck. It had little or no effect, however, inasmuch as a redevelopment of double growth 1, which had already commenced, steadily progressed to the extent of one-third its former size (Fig. 3), a redevelopment of double growth, 2, became manifest, and original growth, 3, which had not been excised, grew even alone, to embarrass the breathing.

It was in face of this discouraging prospect that the report of the bacteriologic examination of the double growth, 2, was received from Dr. E. C. Rosenow, who reported "the presence in the tissue, in large numbers, in almost pure culture, of *Streptococcus haemolyticus;* the predominating presence of the same streptococcus in the associated spheno-ethmoidal sinus discharge; and the presence of the same microbe in the eustachian lymphoid hyperplasia."

Although foreshadowed by the coexistence of the recurrent eustachian hyperplasia, then just coming under our suspicion of being infective, the plain inference from the bacteriologic findings, that the laryngeal growths actually were microbic in origin, presented itself as a pathologic novelty. Aside from the unlike effects of tuberculosis and syphilis, the nearest analogy seemed to be chronic enlargement of true lymphatic glands by pyogenic organisms. Nor did the literature afford any confirmation, as in none of the few cases referred to as lymphoid tumor[4] and lymphoma,[5] or by the non-committal term "polypus," was any cause discovered.

As the need was great, however, a practical confirmation was sought and found by a trial of the autogenous vaccine. Though an initial dose of 50,000,000 was advised, 500,000,000 were taken. The effect was comparable only to that at which one marveled in the early days of diphtheria antitoxin. The change commenced within twelve hours, with relief from irritation, and was marked within two days by visible diminution of the redeveloped growth, 1, and original growth, 3, while the strangely wrinkled aspect of the left aryepiglottic fold (Fig. 4) marked a very rapid reduction of its swollen substance.

The further retrocession under semiweekly doses of 50,000,000 is best told by reference to Figures 5 and 6, showing at biweekly intervals an uninterrupted reduction, which proceeded further, to a practical disappearance of all the growths; and within the year since elapsed they have shown no disposition to return.

Lest an overimpression of the efficacy of the vaccine be conveyed, mention should not be omitted of the limitations found. The infective lymphoid hyperplasia at the eustachian orifice of the same patient, though containing the same micro-organism, but not in pure culture, did not yield to the same vaccine. The great pale welts in the pharyngeal angles yielded little or none, and have since grown still larger at their lower ends, instead of smaller, which refutes any idea of a belated Roentgen-ray effect, nearby, on the laryngeal growths. And the sinus discharge, which had never been more than moderate, and had previously been reduced by surgical drainage, though further diminished by the vaccine, never entirely ceased, and has now resumed its average state.

There were limitations also in the second case, in which, nevertheless, autogenous vaccination filled a similar need. In anticipation of a full report, a brief comparison of salient features will at present suffice.

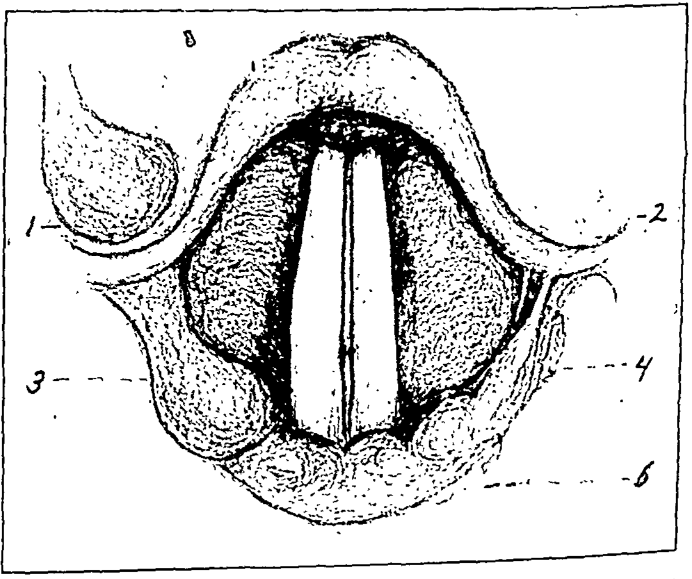

Fig. 5.—At the end of two weeks; conspicuous reduction of growth 3, of redevelopment, 1, and of budding redevelopments, 2, 4 and 6.

Case 2.—Strikingly similar was a lobulated tumor-like lymphoid growth almost equal in size, and corresponding in position, to double growth 1. It showed a like tendency to recurrence after excision, and in the tissue the same *Streptococcus haemolyticus* was found predominating.

[5] Browne, Lennox: The Throat and Nose, etc., London, Ed. 5, Plate vi, Fig. 48, p. 410; ibid., Plate vi, Fig. 50, p. 416.

The conditions, however, were dissimilar, in that the lingual tonsil was the site of a pair of tumor-like growths; that on the right, after excision, soon showed redevelopment. And the faucial tonsils presented an extreme degree of hyperplasia of the infiltrating type described above, the one on the right after excision also showing redevelopment. The hyperplasia, which had begun only after the sixtieth year, soon becoming obstructive, was still perniciously active, as shown by recurrences and continued growth when the vaccination was commenced. The dose was not so large, nor the effect so prompt, but all activity soon ceased, the budding redevelopments gradually subsided, and the unoperated growths slowly, although only in part, subsided, the half or so which remained assuming more the phase of ordinary hypertrophy. To emphasize our present point, the vaccine verified the infective nature of the hyperplasia by arresting its infective activity.

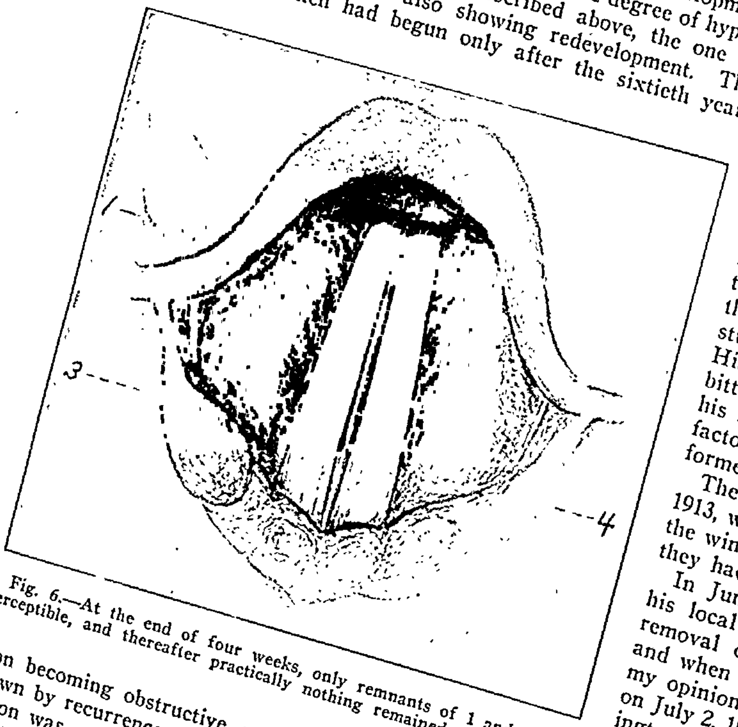

Fig. 6.—At the end of four weeks, only remnants of 1 and 3 were perceptible, and thereafter practically nothing remained.

In partial explanation of the limitations, the more detailed bacteriologic findings in the first case indicated that a mixed and varying microbic flora presented, at certain sites, difficulties to which the vaccine was not adapted.

To the laryngeal growths, however, it was adapted, and it verified convincingly their microbic origin. To watch these growths, from time to time, threaten the very portal of life, in double array, and then to see them "fold their tents, like the Arabs, and as silently steal away" was a revelation in vaccine therapy, open to no other interpretation.

Vaccination Against Typhoid in the Italian Army.—This vaccination is not compulsory in the Italian army, but over 7,000 were vaccinated in 1913. The antityphoid vaccine was mixed with antiparatyphoid vaccine and the morbidity after ne injection was 4.4 per thousand; after two, only 2.7, and fter three injections, 0.3 per thousand, while the non-vacnated developed typhoid or paratyphoid in 35.3 per thousand, with a mortality of 7.1 per thousand. During the latter part of the year the dosage was reduced and the morbidity varied in different districts from zero to 0.29 per thousand, with no mortality. The chief of the medical staff is now endeavoring to have the vaccination made compulsory throughout the army.

SCIATICA A SYMPTOM OF APPENDICITIS

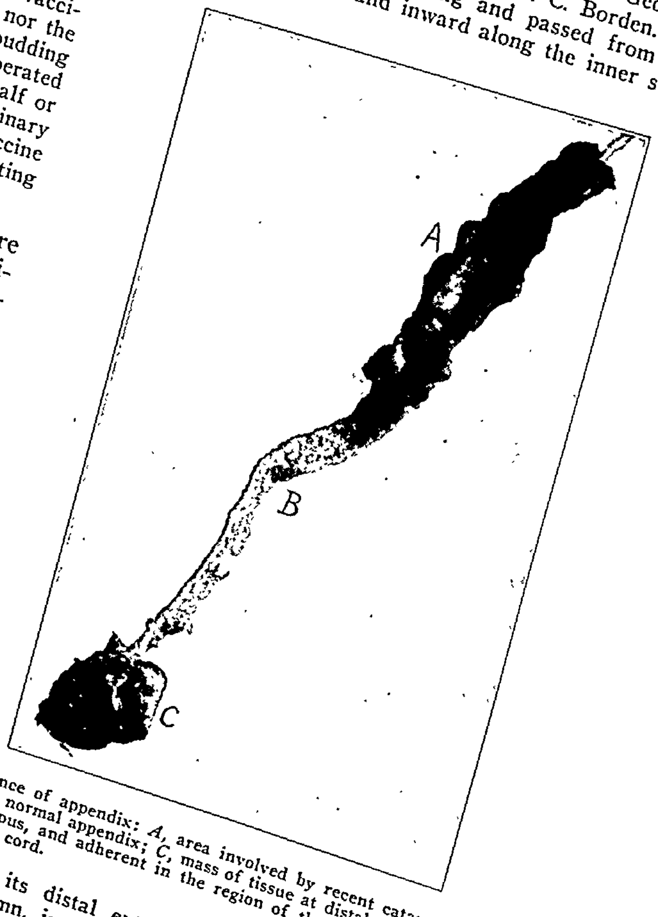
B. M. RANDOLPH, M.D.
WASHINGTON, D. C.

History.—Mr. B., farmer, aged 48, first consulted me in the summer of 1911. Up to the preceding spring he had enjoyed quite good health. At that time he was taken with an acute illness, which confined him to bed for more than a week, and which was accompanied by fever, and was regarded at the time as an attack of "sciatic rheumatism." Since then his health had been poor. He had lost weight, had dyspepsia, suffered from palpitation, and was unable to work as formerly. He was anxious about himself, and thought he might have heart disease or cancer. A careful study of his case failed to bring out a clear-cut diagnosis. His diet and hygiene were regulated, and he was given a bitter tonic. His condition improved greatly, he regained his normal weight, and was able to do his work quite satisfactorily, though he had to be more careful of himself than formerly.

The patient reported again in the summers of 1912 and 1913, when there were some minor matters to be adjusted. In the winter of 1913-1914 his health and vigor were better than they had been since his first illness.

In June, 1914, he had an acute abdominal attack, which his local physician diagnosed as appendicitis, and advised removal of the appendix. He delayed taking this advice, and when he was able to travel, came to Washington to get my opinion. I advised him to submit to the operation, and on July 2, 1914, appendectomy was done in the George Washington University Hospital by Dr. W. C. Borden.

The appendix was very long and passed from its cecal attachment backward and inward along the inner surface of the ilium, its distal extremity being situated against the spinal column, just to the inner, median side of the right common iliac artery, and in close proximity to the upper division of the lumbosacral cord. At the tip of the appendix was an adherent mass the size of a hazelnut. which was



Appearance of appendix: *A*, area involved by recent catarrhal inflammation; *B*, normal appendix; *C*, mass of tissue at distal end of appendix, containing pus, and adherent in the region of the upper division of the lumbosacral cord.

ruptured in removal, liberating pus. The odor of the pus pointed to a colon infection.

The wound was drained. The patient was very ill for a few days after the operation, but from then on made satisfactory progress, and was discharged cured, Aug. 12, 1914.

Pathology.—The specimen is a very long appendix. At its proximal portion for a distance of an inch and a half the mucosa is swollen and injected, and presents the ordinary appearance of a catarrhal appendicitis. From this area out to the distal extremity there is no sign of inflammation, either recent or ancient. Indeed, the mucosa is rather paler than normal, and the walls exceptionally thin, as if it had been stretched for a long time. The mass at the extremity of the appendix, when separated from the surrounding adhesions, has a smooth surface, and on section presents the appearance of organized fibrous tissue. On its surface is a whitish-gray area about 1 mm. in diameter. The wall of the pus cavity presents a ragged appearance. The cavity is continuous with the lumen of the appendix. Near the tip of the appendix the mucosa is thickened and indurated.

For the following report and the accompanying photograph I am indebted to Dr. J. B. Briggs, professor of bacteriology and pathology in George Washington University: "The lymph-gland-like structure at the distal end of the appendix, with its eroded interior continuous with the lumen of the appendix, had a strip excised from one side. This section extended from the periphery, or peritoneal border, well into the lumen within the solid mass, and included a small (⅓ mm.) opaque yellowish 'tubercle-like' lesion visible on the external surface.

"Microscopic sections, stained in hematoxylin and eosin, and in van Gieson, showed alike the following characteristics:

"The main mass is composed of smooth muscle, from its arrangement evidently the hypertrophied muscular coat of the appendiceal wall. The exterior, or peritoneal region, showed a fairly loose connective tissue structure, in which many small round cells were embedded, with no particular vascular dilatation and, strangely enough, nothing but a loose accumulation of round cells to account for the well-defined tubercle-like focus seen on the surface by the naked eye. Toward the interior of the mass the zone of tissue bordering on the lumen was composed of a loose etiolated tissue, necrotic at its innermost margin, and loosely infiltrated nearest the muscle with round cells; nearest the lumen with a very few disintegrating pus cells. No necrotic process invading the muscularis was visible. The remains of the mucosa, aside from the etiolated connective tissue, could not be located.

"*Comment.*—The enlargement at the tip of the appendix is evidently the remains of an intra-appendicular abscess of long standing, and the evidently hypertrophic muscular appendicular wall speaks for a long-continued condition of hypertrophic pressure within the appendicular lumen. The relief of this pressure (evidenced by the reestablishment of the lumen of the sac in continuity with the lumen of the appendix), having provided an issue for the pus and inflammatory exudates, has left behind remarkably little trace of the earlier acute infectious inflammatory processes."

SUMMARY

It seems to me certain that the initial attack of right-sided "sciatic rheumatism," which ushered in this man's illness, was in reality an attack of acute appendicitis, with peripheral pain in the sciatic nerve due to the proximity of the inflammatory focus to its fibers of origin. The case brings home to us that so-called *sciatica* is a symptom, not a disease, and most often the etiologic factor is to be found above the level of the sacrosciatic notch.

The microscopic findings in this case are exceedingly interesting, illustrating in a rare fashion the means by which Nature protects the body against the effects of bacterial invasion.

SOFT TUMOR OF THE URINARY BLADDER

E. G. Ballenger, M.D., and
O. F. Elder, M.D., Atlanta, Ga.

The injection of sterilized air or oxygen into the bladder makes it possible to demonstrate *soft tumors* of this viscus. While others have directed attention to this fact previously, we believe that the two illustrations shown herewith may not be without interest. In Figure 1 the bladder was filled with air and the roentgenogram taken. Figure 2 is a photograph of the tumor after its removal. The actual diagnosis was first made by cystoscopic examination; we thought of treating it by fulguration. The roentgenogram led us to believe that the size of the tumor indicated its extirpation.

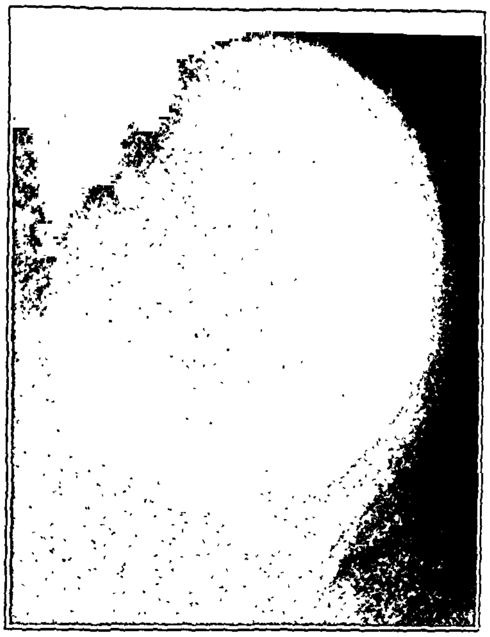

Fig. 1.—Papilloma of bladder. Roentgenogram (by Dr. J. S. Derr) after distending the bladder with air.

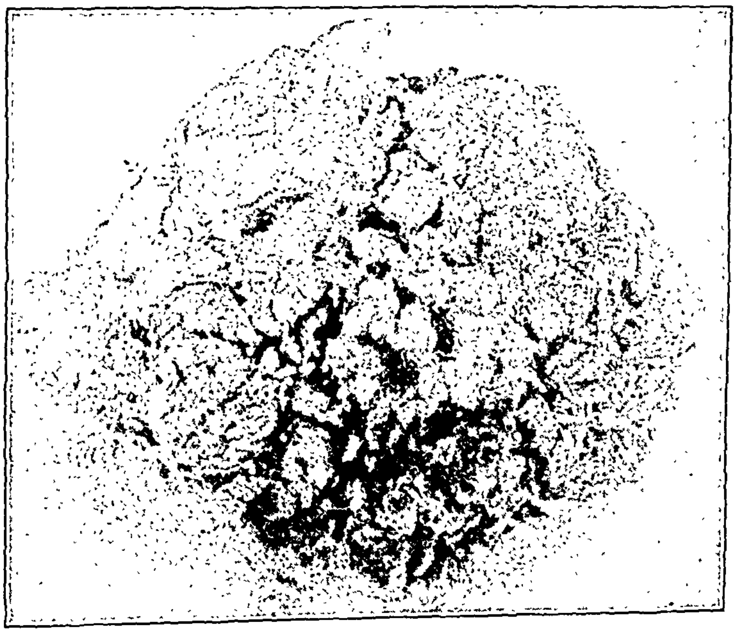

Fig. 2.—Tumor of bladder after its removal. Actual size 2¼ inches in diameter.

If the growth returns we shall employ the fulguration treatment before it has attained such a large size. The pathologist who examined the specimen reported that it was a benign papilloma.

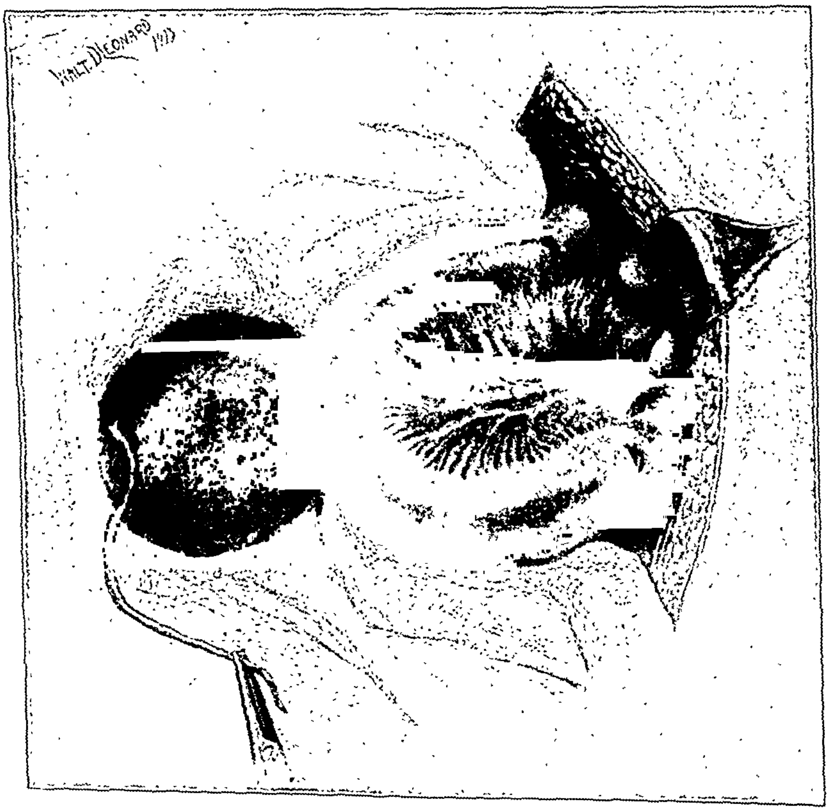
Applications of the Study of History.—History maketh a young man to be old without either wrinkles or gray hair; privileging him with experience of age, without either the infirmities or inconveniences thereof. Yea, it not only maketh things past present, but enableth one to make a rational conjecture of things to come. For this world affordeth no new accidents, but in the same sense when we call it a new moon, which is the old one in another shape; and yet no other than it hath been formerly. Old actions return again furbished over with some new and different circumstances.—Fuller.

A CASE OF OBSTRUCTION OF MECKEL'S DIVERTICULUM

C. M. Watson, M.D., Pittsburgh
Surgeon to Presbyterian Hospital

Mr. W., merchant, admitted to the Presbyterian Hospital about noon, November 1, was referred by his physician with a diagnosis of recurrent appendicitis. The following history was obtained from the patient himself: Twenty years ago, when 18, he had an attack of severe cramp-like pain in the lower right quadrant of the abdomen, accompanied and followed by tenderness in this area. He did not vomit. Since then similar attacks have been recurring with increasing frequency. After the first attack he had no more trouble for nearly a year. He has had temperature elevation at times. The trouble has always been preceded by constipation and relieved by bowel movement. The pain and tenderness have always been in the same location, and have never been associated with vomiting. He thinks the latter attacks, although more frequent, have not been so severe as the early ones.



Meckel's diverticulum, with cord-like remains of the remainder of the omphalomesenteric duct.

The present trouble began the night of October 30, two days previous to admission, being in no way different from the previous attacks and no more severe. The bowels had moved several times. He had, when I first saw him, no temperature elevation, and his pulse was normal. His expression was one of comfort, which interrogation confirmed. He had been taking liquids and soft diet with no evidence of gastric disturbance. There was no distention but rather marked tenderness over the right lower rectus a little below and to the left of McBurney's point. My diagnosis was in harmony with that of those who had seen him before, with the possibility of enteroliths in the appendix to account for the pain and tenderness without temperature. There seemed no reason for immediate operation, more particularly as he had taken food but a short time before. The leukocyte count at this time was 13,500.

The following morning, his condition contrasted strongly with that of the previous day. He appeared very ill, and was vomiting frequently small quantities of fluid. Preparation for immediate operation was ordered, and before this could be made, the vomiting became fecal in character, and of considerable quantity.

After thorough lavage, ether was administered and a right rectus incision made. The presenting intestine was distended and deeply congested, while the abdomen contained much free fluid serous in character and slightly stained.

Toward the pelvis a tense band was felt, the weight of much of the distended small bowel resting on it. This was divided between clamps, releasing a loop of ileum fixed low in the abdomen, and which presented at its apex a saccular tumor of about the size of a small orange. This proved to be a Meckel's diverticulum fixed at its distal portion by the cord-like remains of the balance of the mesenteric duct. The sac communicated with the ileum at its anterior aspect near the mesentery.

Four factors entered into the mechanics of the obstruction which was an acute flexion: the weight of the tumor itself; its fixation by the remains of the fetal duct; the conversion of this into traction by the weight of the superimposed intestine, and the rotation about the axis of the bowel due to the point of attachment of the diverticulum.

The diverticulum was removed from the bowel between clamps, and the latter closed in a transverse direction with three rows of sutures. The prolonged traction on the intestine had drawn its walls into a sort of process at the point of attachment, which enabled us to make a strong closure without narrowing the lumen. A tube was placed in the pelvis.

But a small amount of ether was required. Operation was completed in forty-five minutes. The patient's condition for the first forty-eight hours following operation was entirely satisfactory, and in marked contrast to that just previous. There was no further vomiting, nausea or pain. The appearance of comfort and well-being had returned. On the third day, however, the pulse gradually became weaker and more rapid without a corresponding temperature elevation or return of pain or vomiting. Death occurred on the fourth day. No necropsy was obtained. The specimen was globular, about the size of a small orange with an opening communicating with the bowel about half an inch in diameter. Distally it was continuous with the obliterated remains of the balance of the duct. The diverticulum contained three foreign bodies—two dense enteroliths and a piece of wood ¾ inch in length. This man during the previous twenty years had been attended by a number of physicians and always with the diagnosis of appendicitis.

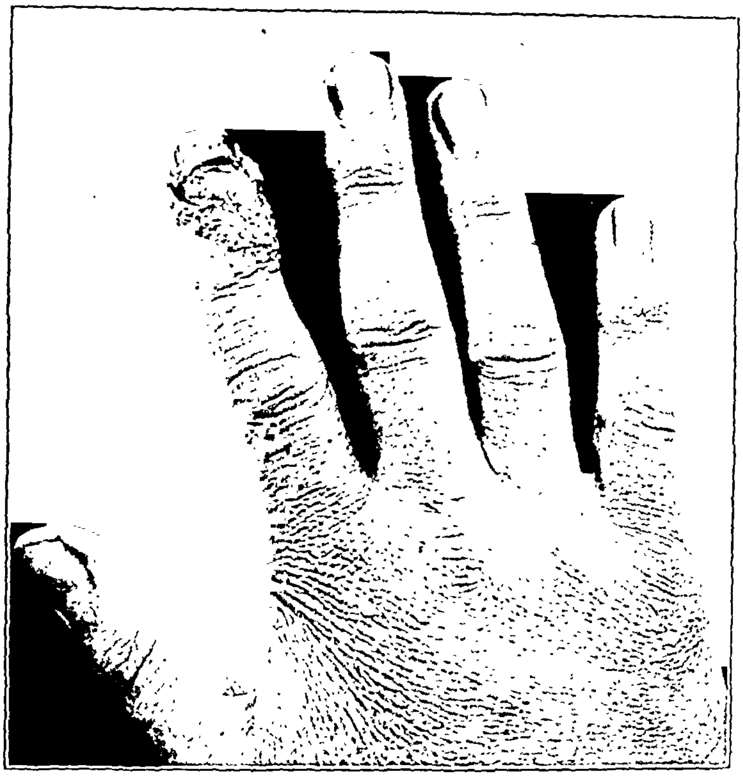
516 Federal Street.

The Practical Man and the Scientist.—Some one has defined the practical man as one who practices the errors of his forefathers. He is tied down to his preconceived opinions, not being enough of a dreamer to get away from them. He will be able to get through the world without receiving many hard knocks; but he will not inaugurate profound changes and advances in human life. That will always be left for the scientist who refuses to be satisfied with what is and who is always seeking a new sort of fact to destroy his own and his contemporaries' equilibrium.—R. D. Carmichael, *Science.*

CHANCRE OF THE FINGER

Andrew J. Gilmour, Ph.B., M.D., New York
Consulting Dermatologist, Manhattan State Hospital; Assistant Attending Dermatologist, New York City Children's Hospital and Schools

J. C., white man, aged 38, single, waiter, a native of Switzerland, Feb. 18, 1912, noticed a swelling just to the inner side of the nail of the right index-finger. This increased in size along the inner side of the terminal phalanx and became so painful that after ten days the patient found it necessary to stop work. March 13, 1912, he visited one of our hospitals and an incision was made. Ten days later a second incision was made and the wound was curetted, at which time the patient says he saw bone. No pus was obtained. Following the incision the swelling became smaller, and on June 7, 1912, it appeared as represented in the accompanying photograph. The condition of the nail is well shown.



Chancre of the Finger.

A photograph taken the same date as the chancre showed a marked papular rash that had been present three weeks.

I have previously seen two cases of chancre of the finger treated by incision before the diagnosis was made.

133 East Fifty-Seventh Street.

Raynaud's Disease in Stone-Cutters Using Pneumatic Tools.—D. E. F., aged 26, married, with good family and personal history, except that he was neurotic, found that frequently and only when cutting stone with a pneumatic tool, the index and middle fingers of his right hand would become white, cold and numb. This instrument, which oscillates from 900 to 1,600 times per minute, transmits strong vibrations to the hand of the operator. The patient told me of a fellow laborer who was similarly affected by using the same kind of tool. Other treatments having failed, I prescribed daily applications of decoction of capsicum. This was done by keeping the fingers for half an hour wrapped in gauze saturated with the decoction. The attacks ceased, apparently as the result of the treatment.—Charles H. Cargile, M.D., Bentonville, Ark.

The Indispensable Animal Factor.—To be a good animal is the first requisite to success in life, and to be a nation of good animals is the first condition to national prosperity.—Herbert Spencer.

New Instruments and Suggestions

A NEW METHOD OF SYRINGE TRANSFUSION

Lester J. Unger, M.D., M.A., New York

Those who have witnessed or performed syringe-cannula transfusions realize the difficulties associated with the procedure. It was to obviate these, and at the same time lose none of the valuable features of the method, that I set out to devise my instrument.

DIFFICULTIES OF THE SYRINGE-CANNULA METHOD

The chief difficulties are: 1. The cannulas are repeatedly handled because (*a*) the syringes are being constantly connected and disconnected, and (*b*) they are pulled on when blood is aspirated, and pushed on when blood or saline is injected. When one considers the amount of handling necessitated in the transfusion of a syringeful, or 20 c.c., of blood, the large number of times the cannulas are jarred is evident. It is in the fact that the cannulas are handled *frequently and directly* that we find the cause of their dislodgment from the vein.

2. The second great difficulty is the risk of clotting. This occurs if the cannulas are not regularly flushed with saline after the withdrawal or injection of blood, or if the procedure is carried out too slowly. Delay will also cause clotting in the syringe before it has been entirely emptied of blood.

3. Two men, equally expert, are necessary. The assistant must be as well acquainted with the method as the operator, since their functions are identical.

The instrument I have devised eliminates the *causes* of the difficulties experienced in the syringe-cannula method. Fundamentally, it is a stop-cock, which alternately connects a syringe for blood to the donor and at the same time a syringe with saline to the recipient; then by turning the cock the syringe with blood is immediately connected to the recipient and the syringe with saline to the donor.

THE INSTRUMENT

A cock which has four outlets constitutes the central part of the instrument. The outlets are designated as follows (Fig. 2): (1) blood outlet (*B*); (2) saline outlet (*S*); (3) recipient's outlet (*R*); (4) donor's outlet (*D*).

1. Blood outlet (*B*). To this, is directly attached a 20 c.c. "Reformed Record" syringe (*Syr*). Through this outlet, b means of the syringe, the blood is aspirated or injected.

2. Saline outlet (*S*). To this is attached a long piece o rubber tubing, the other end of which has connected to it syringe for saline. The exact length of the tube is immaterial. It should, however, be long enough to get the assistant who is attending to the injection of saline out of th way of the operator. The material of which the tube i made is likewise unimportant, since nothing but salin passes through it. Instead of a plain syringe, a slightl modified Wechselmann salvarsan apparatus may be used The latter, by means of two ball valves, allows of the ready filling and emptying of the syringe, and eliminates the necessity of disconnecting it.

3 and 4. Recipient's and donor's outlet (*R* and *D*). To each of these is connected a paraffined rubber tube, 1¾ inches long, which has attached to its other end a metal connecting piece. This, in turn, fits the recipient's and donor's cannula. The tubing is a piece of catheter (No. 15 French) which is paraffined according to the method described by Dr. G. E. Brewer. They are sterilized, and then for a few seconds immersed in boiling paraffin. The tube is then shaken in the air in order to distribute the paraffin equally, to get rid of the excess, and to hasten hardening.

The cock is so arranged that the central stopper (*C S*) can be rotated only through an arc of 45 degrees. This range of rotation allows of three possible positions, in two of which two simultaneous circuits exist; in the third no circuit whatever is present. Naming the positions according to the flow of blood and the circuits according to the outlets they connect. we have:

1. Donor's position (Fig. 2) establishing, (*a*) donor blood circuit, and (*b*) recipient saline circuit.
2. Recipient's position (Fig. 3) establishing (*a*) recipient blood circuit, and (*b*) donor saline circuit.
3. Intermediate position, establishing no circuit—all outlets are shut off.

1. Donor's position (Fig. 2). If the cock be turned toward the donor as far as it will go, the instrument will be in the donor's position. A channel (donor blood circuit) between the donor's vein and the Record syringe is established for the aspiration of blood. At the same time, another channel (recipient saline circuit) exists, through which saline is injected into the recipient's cannula in order to insure its patency.

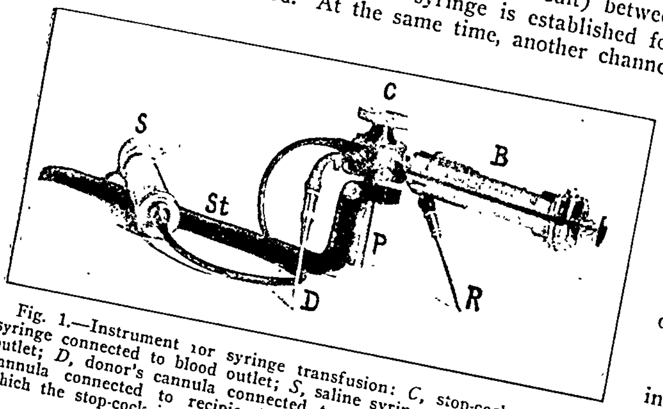


Fig. 1.—Instrument for syringe transfusion: *C*, stop-cock; *B*, blood syringe connected to blood outlet; *S*, saline syringe connected to saline outlet; *D*, donor's cannula connected to donor's outlet; *R*, recipient's cannula connected to recipient's outlet; *St*, stand; *P*, pedestal by which the stop-cock is raised or rotated.

2. Recipient's position (Fig. 3). If the cock be turned toward the recipient as far as it will go, the instrument will be in the recipient's position. Here again, two channels exist, one through which the blood is injected into the recipient (recipient blood circuit), and one (donor saline circuit) which connects the donor with the saline syringe so that this circuit can be kept patent.

It is this *immediate and continued* flushing with saline of that part of the system through which blood is not passing that insures freedom from clotting.

3. Intermediate position. If the cock be turned midway between the donor's and recipient's positions, the instrument is in the intermediate position, and all the outlets are closed off.

The instrument is supported by a stand, which is merely a mechanical device to hold the cock stationary and to permit of its adjustment to various heights in conformity with the levels of the veins.

TECHNIC

After having firmly fixed the stand to the table, the cock, with the tubing attached to the donor's and recipient's outlets, is fastened to the stand. The saline apparatus, from which all air has been forced out, is connected to the saline outlet. The cock is put in the donor's position (Fig. 2), and here also the air is forced out by means of saline. By raising, lowering, or rotating the pedestal, to which the instrument is attached, and by proper placing of the arms, connections to the cannulas can be made without difficulty.

Into the recipient's vein is inserted a large cannula, which is then connected to the recipient's outlet. Since the cock is in the donor's position, saline can be slowly injected into the recipient, thereby insuring the patency of this cannula. Into the donor's vein is inserted a cannula which is now attached to the donor's outlet. It is important to insert the cannula so that it points toward the donor's hand rather than the tourniquet. Blood immediately runs out of the blood outlet, forcing the air ahead of it. Into this outlet, a Record syringe is placed and blood aspirated. When the syringe is filled, the cock is turned into the recipient position (Fig. 3), and the blood injected. Since the assistant is always very slowly injecting saline, he is now flushing the circuit which was used in getting the blood into the syringe. As soon as the 20 c.c. of blood have been injected, the cock is turned back to the donor's position, and the syringe refilled. This is continued until the desired amount of blood has been transfused. The syringe need not be changed after each injection, but may be refilled until it begins to work with difficulty. Before the syringe is disconnected, the cock should be turned to the intermediate position so that there is no loss of blood.

After connections have been made to the cannulas: 1. The operator (*a*) aspirates and injects blood, (*b*) changes the syringe when necessary and (*c*) turns the cock back and forth. 2. The assistant merely slowly forces saline out of his syringe. 3. The nurse cleans the Record syringes as fast as they are used, and places a clean one in easy reach of the operator.

EXPERIMENTAL WORK

I have repeatedly transfused dogs and have found the instrument to work admirably. The first tests were simply artery-to-vein transfusions of about 300 c.c. of blood. In the second group of experiments much larger amounts were transfused. In order to obtain a greater quantity of blood, so that the amount would at least equal that of the usual human transfusion, the following procedure was carried out: After a primary artery-to-vein transfusion, which was arbitrarily set at about 300 c.c., a secondary one, in which the original recipient was made the donor, was immediately performed. In this way, the original recipient was able to furnish not only part of his own blood, but also that received. By this method, as much as 700 c.c. were transfused at one time. By adding a tertiary transfusion, a total amount of 1,460 c.c. was passed through the instrument in an experiment. Finally, vein-to-vein transfusions were done. Here also primary transfusions were resorted to in order to increase the amount of blood obtainable. In all the experiments, I was limited only by the amount of blood the dogs could furnish. At the end of each experiment, the circuits were tested with saline and found to be patent.

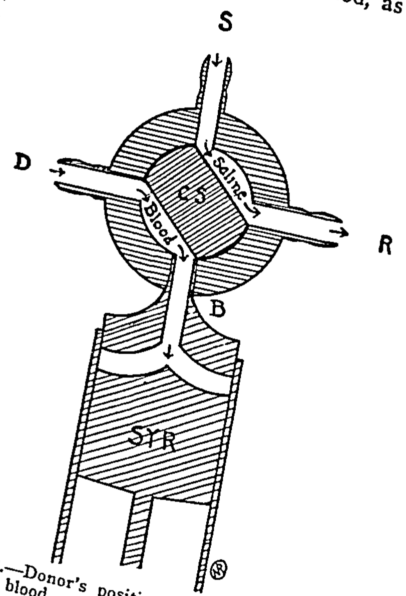

Fig. 2.—Donor's position: *D*, donor's outlet; *B*, blood outlet; *Syr.*, blood syringe. Blood passes from donor's vein through *D*, out at *B* into *Syr.* *S*, saline outlet; *R*, recipient's outlet. Saline is forced from saline syringe through *S*, out at *R*, into recipient's vein. Channel between *D* and *B*, donor blood circuit; that between *S* and *R*, recipient saline circuit. *CS*, central stopper (rotates through an arc of 45 degrees).

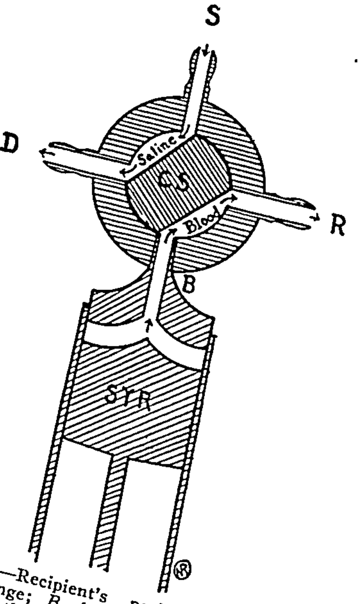

Fig. 3.—Recipient's position: *Syr.*, blood syringe; *B*, blood outlet; *R*, recipient's outlet. Blood is forced out of *Syr.* through *B*, out at *R*, into recipient's vein. *S*, saline outlet; *D*, donor's outlet. Saline is forced from saline syringe through *S* out at *D* into donor's vein. Channel between *B* and *R*, recipient blood circuit; that between *S* and *D*, donor saline circuit. *CS*, central stopper.

This method will be applied to man as soon as opportunities present themselves.

ADVANTAGES OF THIS METHOD

The instrument I have described overcomes the difficulties experienced with the syringe-cannula method, by striking at their causes.

1. The frequent handling of the cannulas is eliminated because connections are made not directly to them but to the cock. For this reason the cannulas ought not to be dislodged.
2. Clotting is avoided because the entire system is regularly and instantly flushed with saline, and the length of time the blood is outside of the body is reduced to a minimum. In none of the animal experiments did clotting occur.
3. Only the operator handles the blood syringe. The function of the assistant is limited to the injection of saline.
4. Fewer syringes are needed. In one experiment, 800 c.c. of blood were transfused, only two syringes being used. It is advisable, however, to have about four to meet emergencies.
5. It is time-saving because it reduces the manipulations; it minimizes the time the blood is outside of the body, and it allows of the injection of saline simultaneously with the aspiration or injection of blood. When indicated, a more rapid transfusion can be done by this than by any other method. The rate of the flow can, however, be varied at will. Blood can be sent across as slowly as one wishes, because the patency of the circuits can be relied on.

I wish to express my thanks to Dr. F. S. Mandlebaum, who so generously afforded me the privileges of the pathology laboratory of the hospital, and to Drs. Shapiro, Rosenthal and E. Mayer, who were of great assistance in the animal experimentation.

Mount Sinai Hospital.

A DEVICE FOR HOLDING SOLUTION BOTTLES IN OPERATING ROOMS*

Donald C. Balfour, M.D., Rochester, Minn.

Each bottle shown in the accompanying photographs has as its feature a combination handle and corking device which can easily be detached from the bottle and sterilized. The chief advantage, therefore, is that the handle being sterile, the surgeon or assistant may readily obtain more iodin before or during an operation without the soiling of gloves. To those using the benzin, iodin and alcohol method of skin preparation, for which the apparatus is especially adapted, other points of advantage are quite obvious, for instance, evaporation is prevented (the handle being equipped with a spring), solutions are not wasted, bottles are not broken, and time and trouble are saved the operating room personnel.

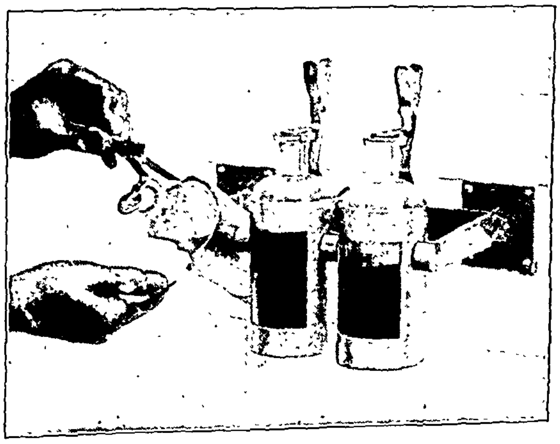

Fig. 2.—Stoppers in place and bottles in use.

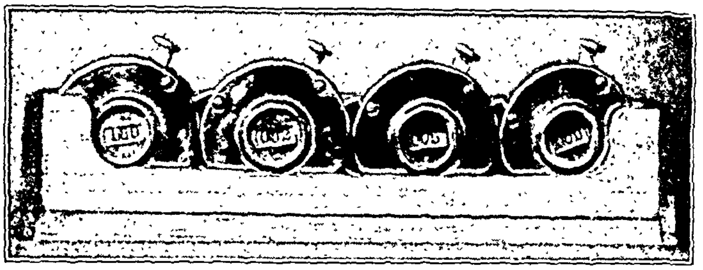
LABORATORY SUGGESTIONS

Clyde L. Cummer, M.D., and Richard Dexter, M.D.,
Cleveland

EQUIPMENT FOR SEROLOGIC WORK

In performing serologic work, certain technical methods may be evolved which will be economical of both time and labor. Each worker will naturally adapt his equipment to his own needs. We have made certain adaptations which may prove useful to others.

Removing Cotton Stoppers from Pipets.—The plugging of pipet mouth-pieces with cotton is desirable in order to avoid drawing fluid into the mouth and to prevent saliva from running into the pipet. The removal of these cotton plugs is often bothersome, especially when many pipets are used and have to be cleaned.



Apparatus for recording differential counts.

Our laboratory assistant solved the question by suggesting the use of a dentist's broach. With this fiendish instrument most of us are painfully familiar. It is merely a bit of highly tempered fine wire, roughened so that it grips whatever it touches, and is mounted in a metal handle. With it, the bits of cotton can be removed from fifty pipets in a few minutes.

Apparatus for the Inactivation of Serum.—The inactivation of specimens of blood-serum by use of heat at 56 C. (132.8 F.) is performed much more satisfactorily in a water-bath than in a dry oven. The maintenance, however, of an unprotected water-bath at 56 C. for as short a time as half an hour is not easy, even when the equipment includes a thermoregulator. We have found that the following adaptation saved much annoyance:

A so-called small "physician's incubator" (Bausch and Lomb Company) was secured which is built in the form of a cylinder, with the opening at the top. It is provided with a water-jacket of an ample capacity. A round basin 3 inches high and of circumference to fit in the incubator, was made and provided with handles to facilitate lifting it in and out. A number of small cans were secured and holes were punched in the bottoms and sides so that the water would circulate freely when they were lifted.

The large basin is brought to proper temperature outside the incubator, the small cans containing the specimen-tubes being lifted up and down to allow the water to mix freely. When the temperature is uniform throughout the bath and at the proper point, the bath is placed inside the incubator. This is prepared in advance by filling the water-jacket with hot water, between 60 and 70 C. (140 and 158 F.). We find that if the inner bath is at the correct temperature, the exact temperature of the water in the surrounding incubator does not matter greatly as long as it is hot enough to act as an insulator and prevent heat loss. The temperature of the surrounding jacket may be kept between 55 and 65 C. (131 and 149 F.) during the day with a simple Bunsen flame.

---

* From the Mayo Clinic.

With this apparatus, from forty to forty-five specimens may be inactivated at one time, if need be. Our experience has been that the temperature in the central enclosed bath remains constant for from thirty to sixty minutes without any attention whatever, and so proves somewhat of a labor-saving device. The cost of the apparatus is inconsiderable.

APPARATUS FOR RECORDING DIFFERENTIAL COUNTS

For use in making differential blood counts we have improvised a contrivance of a small wooden box made to hold upright four counting machines, on which may be recorded the number of the most prevalent types of leukocytes. The forms occurring in smaller proportions can be remembered without being recorded. With this scheme, it is not necessary to use the eyes for recording, and the total of each class is in plain view at any time.

LABORATORY BURNER

A tin can with diameter less than 3 inches is used. In the bottom three or four circular holes are made for air intakes. A microburner is placed inside the can and the rubber tubing is carried out through one of the openings. Slides to be stained may be placed across the top and the stain may be allowed to simmer. The can serves both as a support for the slide and as a shield against air-currents in case the burner is used in front of an open window.

Rose Building.

A PROCEDURE MINIMIZING THE DIFFICULTIES OF TRANSPLANTATIONS OF A GONOCOCCUS CULTURE

A. P. Ohlmacher, M.D., Detroit

One who handles gonococcus cultures is familiar with the uncertain viability of the organism. To safeguard a culture, the ordinary practice is to grow it on ascites-agar and to transplant at intervals of twenty-four to forty-eight hours. Outside of large laboratories, with a corps of special assistants, this becomes burdensome and expensive.

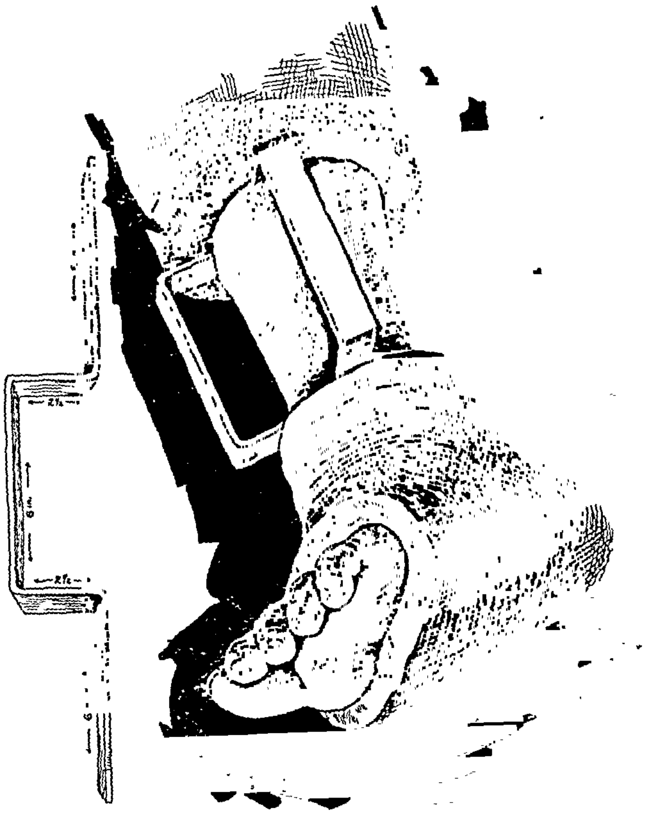
About nine years ago, while inoculating a horse to produce antigonococcic serum, and while handling numerous gonococcus cultures, I hit on a method of reducing the frequency of subcultures. By its use I found it possible to increase the interval between transplantations from seven to fourteen days, or even longer, using a solid culture medium as a substratum. The details are as follows:

Löffler's blood serum mixture of the usual formula, with bouillon neutralized according to the prevailing standard, constitutes the culture medium. It has happened in my work that horse's serum (the vehicle generally employed in commercial biologic laboratories) formed the basis, though the blood serum of cattle probably would answer equally well. It is preferable to have the test-tube slant of Löffler's medium with its original condensation water. If perchance this condensation water is lost, it may be replaced by the requisite amount of ordinary bouillon (standard neutralization). The transplantation, after one or more subcultures on ascites-agar, is effected by the platinum loop, sowing directly into the pool of condensation water, or bouillon replacing the condensation water; but not, as by the usual custom, of rubbing the inseminated loop over the surface of the slant. With its condensation water thus impregnated, the tube of Löffler's medium is capped to prevent evaporation, and without undue agitation set in the incubator. After a period generally not more than forty-eight hours, it will be found that a transparent, glistening, colorless line of culture appears above the condensation water, and by a process resembling the "creeping of salts" in strong saline solutions, it will be seen that this line of culture slowly but steadily ascends the surface of the slant, continuing for seven, ten, fourteen or even more days. From this mounting line of culture, further transplantations may be effected at a convenient interval, the length of which may be ascertained for a given gonococcus strain after a few experiments.

INTERRUPTED CAST FOR COMPOUND FRACTURES

F. P. Corrigan, M.D., Cleveland
Associate Surgeon, St. Alexis Hospital

An infected compound fracture presents to us a problem difficult in its nature. The presence of pus demands, above all, frequent dressings after complete drainage has been established. If the dressings are not changed frequently, the wound remains bathed in pus. The phagocytic cells of the freshly-exuding lymph are constantly battling against odds and their energies wasted. The value of frequent dressings can not be over-emphasized; in fact, our aim should be the maintenance, if possible, of a pus-free wound. On the other hand, firm union of the fragments demands well-secured, correct apposition. This would seem to interdict frequent changes of dressings with the movements involved. This objection is real if the ordinary splints applicable to simple fractures are used. No matter how carefully handled, each loosening and readjustment of splints endangers the apposition. A further objection is that each change of dressings necessitates the presence of the surgeon at the bedside.



Author's interrupted cast for compound fractures, with detail of hoop-iron brace.

Coincident with the increased speed in transportation and modern machinery has come a rapid increase in the number of this class of cases. The problem of maintaining absolute cleanliness and correct apposition must be solved. Malunion or no union, bone necrosis, even sacrificed limbs, are the dire results of unsuccessful treatment.

In my own work I have found the device here presented indispensable in handling cases of this class. The illustration is for the common fracture of the lower leg but the idea can be modified for other situations. It consists simply of a plaster cast built in two sections. The two sections are joined into a rigid unit by three metals bent in the shape illustrated and embedded equidistant from each other in the sections of plaster. These metals may be strips of brass, iron or steel (I have used all three). By using three strips, sufficient rigidity is obtained if they are ⅛ inch thick and ¾ inch wide. This permits the use of ordinary hoop-iron or strap-iron, which is obtainable anywhere.

The dimensions given are tentative only, but are correct for a medium-sized man; they will be altered as the judgment of the attending surgeon dictates.

The advantage secured is ready accessibility without disturbance of apposition.

The dressings can be changed by the nurse as often as desired.

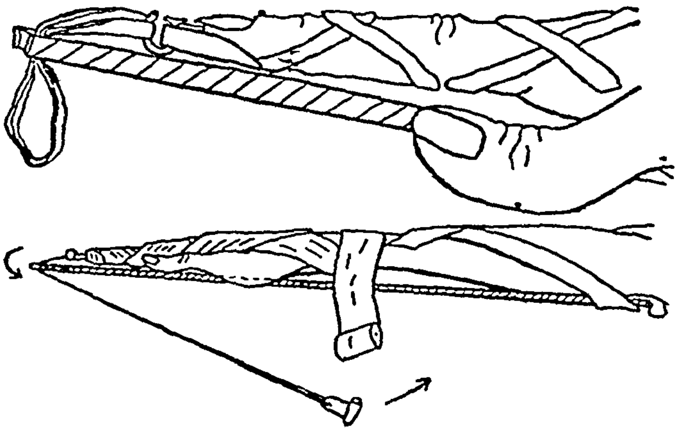
The presence of the doctor to readjust splints is not necessary.

St. Alexis Hospital.

CONVENIENT SPLINT FOR FRACTURE OF METACARPALS

Charles Auer, M.D., New York

In fracture of the hand distal to the carpals, it not infrequently happens that deformity tends to recur, especially in a fat or swollen hand, in spite of the rubber tubing and splints ordinarily used to retain the fragments, unless the latter are pressed so tightly as to cause severe pain or even necrosis in the already injured tissues. In old fractures and ununited fractures in which the injury has been overlooked and there is great deformity and callus formation, strong and continuous traction is obviously indicated to bring the parts into a line as nearly anatomic as the fibrous union will permit, and of holding it there immovably.



Convenient splint for fracture of metacarpals.

I have found the splint as illustrated satisfactory in a series of cases, including one so-called Bennett's fracture of the thumb, one compound fracture in a man weighing over 300 pounds, and several old ununited fractures with deformity.

This dressing exerts traction of any degree desired (being adjustable by changing the location of the safety-pin or by using two rubber bands instead of one) for almost any period of time without becoming disarranged or requiring much attention. It may also be applied to more than one finger.

The upper diagram shows the spiral arrangement of the adhesive bands to the finger and to a bent wire nail. Two bands of adhesive applied the same way should be used instead of the one as illustrated to give proper strength. A relaxed rubber band is shown slipped over the bent nail and lying in a nick at the end of the splint.

In the lower diagram the hand and finger have been bandaged up to the wrist and the wooden splint, which is broad at the arm and hand and narrow at the finger, applied and held by one broad band of adhesive placed as illustrated. The bandage then should be continued *including* the splint, and the adhesive tag carrying the free end of the rubber band pinned to the outside of the completed bandage as indicated by the arrow.

PRACTICAL PHARMACOLOGY*

(*Continued from page 512*)

VI

B. DEPRESSANTS: 4. OF THE CENTRAL NERVOUS SYSTEM—MORPHIN GROUP— (*Continued*)

THERAPEUTIC USES

The celebrated remark attributed to Sydenham, that few physicians would be so callous as to practice medicine without opium, suggests the variety of conditions in which the opiates are used.

Morphin stands first among drugs for the relief of pain. It often gives relief when used in doses which have hardly any other perceptible effect, but intense pain may require the use of the largest doses. Neuralgia affords one of the few examples of conditions in which other drugs are to be preferred to morphin as analgesics.

There are comparatively few conditions in which morphin is indicated as a simple hypnotic, since we now have a series of drugs better adapted for this purpose, but sleep may be afforded by relieving pain which prevented it.

Morphin is useful to prevent cough when this is not attended with free expectoration and is of sufficient frequency to prove distressing, or when it interferes with sleep. When bronchial secretion is free the cough is necessary to remove it, and interference with the cough at this time results in the accumulation of fluid in the air passages, making the patient's ultimate condition worse.

Morphin and opium are used as diaphoretics, especially in the form of Dover's powder, in which the dilatation of the skin vessels by morphin promotes the diaphoretic action of the ipecac. Morphin allays restlessness, and this is very commonly utilized in the treatment of inaccessible hemorrhage.

Opium acts locally to diminish intestinal peristalsis, and this action is utilized in a variety of conditions, many of which do not require enumeration. Opium in peritonitis serves the double purpose of relieving pain and restlessness and of immobilizing the intestine. It is useful in checking the excessive peristalsis in diarrhea.

Morphin is frequently used previous to general anesthesia to allay the nervous apprehension of the patient and to secure sleep. It also acts synergetically to chloroform and ether, less of which is required for general anesthesia after morphin than without it. The synergistic action of chloroform and morphin on the respiratory center appears to be a source of danger in their combined use. The depression of the respiratory center prevents, to a certain extent, excessive respiration accompanying variations in the depth of anesthesia. Accidental death from too rapid administration of ether is not common, with dogs, at least, after morphin; in fact, it is sometimes impossible to kill dogs by the ordinary administration of ether when they have previously received large doses of morphin.

Codein is now largely prepared synthetically from morphin, and is obtained in a purer form than it was formerly. Codein and ethyl morphin hydrochlorid are much less active than morphin, which they resemble otherwise. Codein is said to be only about one-tenth to one-twentieth as active as morphin, and while this may be true so far as the narcotic action is concerned, it is not used therapeutically in doses twenty times as large as those of morphin.

---

* This is the sixth of a series of articles on useful drugs—on practical pharmacology for the general practitioner. As soon as completed, these articles, elaborated by additional subjects, will be published in book form.

Its analgesic action is so slight as to make it much less valuable than morphin, but it does dull pain to some extent, and the probable absence of euphoria, which leads to the habit with morphin, is a distinct advantage of codein. It is said to have an especial value for the relief of abdominal and pelvic pain.

The actions of ethyl morphin hydrochlorid on the central nervous system are very similar to those of codein, and in addition it is irritant to the mucous membrane of the conjunctiva, this action being utilized in the treatment of conjunctivitis, iritis and corneal opacity, but it sometimes causes acute edema of the conjunctiva from local vasodilatation.

Ethyl morphin hydrochlorid has been exploited to some extent as an analgesic and sedative but there is no satisfactory evidence that it is equal to morphin for these purposes.

Diacetyl-morphin (heroin) differs from morphin to a greater degree than codein and dionin. Diacetyl-morphin and its action in lessening cough have been known for many years, but it was not used therapeutically until Dreser investigated it in 1898, and stated that it decreased the reflex excitability of the respiratory center toward painful stimuli, such as those which induce cough, more than it does toward carbon dioxid, the normal stimulant of the center. He also stated that it slows the rate of respiration while the depth and force of the individual respirations are increased, and he suggested that the increased force of the respirations would be of value in the treatment of bronchitis, in which the air-passages are narrowed.

Dreser experimented with rabbits, but it has been shown that his results do not apply to the use of heroin on man, and Cushny has shown recently that heroin influences the respiration exactly as morphin does; it has, therefore, no evident advantage over the older drug in the treatment of cough.

Diacetyl-morphin is much more toxic than morphin and must be used in correspondingly smaller doses. It gives rise to the habit quite as readily as morphin does, and the habit is as difficult to break and fully as injurious.

Diacetyl-morphin is said to be less actively narcotic in proportion to its activity on the respiratory center, and it is also less actively analgesic than morphin; its use should be limited, therefore, to the relief of cough, if, indeed, it were not better to use morphin or codein in these cases also.

Indian cannabis is usually classified with the morphin group, but its action is feeble compared to that of opium, and its effects are so uncertain that it is probable that there is no condition in which opium or morphin does not deserve the preference.

It is sometimes asserted that the Indian hemp of the Orient is more active than that grown in America, but a specimen grown near Philadelphia was found to be nearly twice as active as a fairly good specimen of the imported. Indian cannabis is often called hashish, but the hashish of Persia is a mixture, of which hemp is a constituent.

It is commonly stated that the resin represents the active constituents of Indian hemp, but the intensity of the physiologic action on dogs and the content of resin do not run parallel.

Cannabinol, prepared from hemp, produces hallucinations, lassitude and a desire to sleep.

Extract of Indian cannabis is a constituent of the extensively advertised proprietary hypnotic Bromidia, and it is probable that the continued belief in the value of Indian cannabis as a hypnotic is due in no small measure to its exploitation in this preparation.

It is sometimes used as a hypnotic, but it is impossible to give any nearer indication for its special field of usefulness.

DOSAGE

Morphin sulphate is analgesic in doses of from 3 to 15 mg. ($\frac{1}{20}$ to $\frac{1}{4}$ grain), the smaller doses lessening or abolishing mild pain, (such as may interfere with sleep) and intense pain requiring the larger dose. Even this may require repetition before relief is afforded, but it is preferable to use an insufficient dose and repeat it in half an hour, rather than run the danger of giving too large a dose at once.

The dose used for the relief of cough varies widely, dependent on whether it is desired to lessen the frequency of a troublesome cough without interfering with its removal of the secretion, or to abolish a severe irritative "dry" cough, which interferes with sleep. The former will require from 1 to 2 mg. ($\frac{1}{60}$ to $\frac{1}{30}$ grain) and the latter will require somewhat larger doses and more frequent repetition. Eight mg. ($\frac{1}{8}$ grain) of morphin or 0.06 gm. (1 grain) of opium in the form of Dover's powder is used for its diaphoretic effect. A single dose taken on retiring is a popular treatment for "colds." When morphin is used just prior to general anesthesia, the dose is from 8 to 16 mg. ($\frac{1}{8}$ to $\frac{1}{4}$ grain), and when used some hours previously to secure sleep and allay apprehension, the larger dose will be required usually, or the smaller dose may be used and repeated when the effect begins to pass off.

The aim with all narcotic drugs should be to secure the desired action with the absolute minimum of the drug, and it is always best to give a small dose when there is any doubt concerning the amount which will be required and repeat it if necessary.

Codein and its salts are given in doses of 0.03 gm. ($\frac{1}{2}$ grain) or more, this dose corresponding to approximately 0.003 gm. ($\frac{1}{20}$ grain) of morphin. Its use can be long continued without much fear of giving rise to the habit.

Half the dose may be used and repeated with correspondingly greater frequency when desired.

The average dose of diacetyl-morphin, or heroin hydrochlorid, is 3 mg. ($\frac{1}{20}$ grain). Its use should not be long continued because of its extreme tendency to induce the habit.

The average dose of extract of cannabis indica is stated to be 0.01 gm. ($\frac{1}{6}$ grain) and of the tincture 0.5 c.c. (8 minims), but there is no obvious indication for their use.

MATERIA MEDICA[*]

Morphin, an alkaloid obtained from opium, is the chief therapeutic constituent of the drug.

In medical literature the term "morphin" is habitually used indiscriminately for the alkaloid and its salts, but the prescriber should not write "morphin" when the sulphate, or other salt, is desired. Morphin and its salts occur in commerce as colorless or white crystals or as a crystalline powder, odorless, and having a bitter taste. The dose of the several products is comparable and from a practical point of view the only important difference to note is their solubility in water and in alcohol.

---

[*] Owing to lack of space the materia medica of morphin, opium and cannabis indica has been largely omitted. It will be included when this series is published in book form.

MORPHIN AND SCOPOLAMIN

Some years ago Schneiderlin, a surgeon connected with an institution for the insane, administered morphin and scopolamin to a patient in the institution for the purpose of diminishing the amount of general anesthetic necessary for a major surgical operation, and was surprised to find that he was able to remove a cancerous breast without administering chloroform or ether to induce general anesthesia.

After performing a small number of operations in which morphin and scopolamin were employed in this way, he suggested the use of the combination as a substitute for general anesthetics, or to render more than a few drops of the latter unnecessary for surgical operations.

Schneiderlin seems to have been under a misapprehension concerning the degree to which morphin and scopolamin are antagonistic, and to have supposed that they were synergistic only in their narcotic effects, for he placed much stress on the importance of the antagonisms in their side actions. In truth, the antagonisms between morphin and scopolamin are of minor importance, but they have an extraordinary degree of synergistic action on the respiratory center, sometimes causing paralysis in minute doses of the combination.

The morphin-scopolamin narcosis was tried by many surgeons, but the fatalities following its use were so numerous that it was abandoned by the great majority of operators, but it has been exploited in a sensational manner both in Europe and in the United States as a preliminary to childbirth. Effective doses are not very dangerous to the mother, in the hands of those who have mastered the difficult technic of its use, but labor is frequently prolonged by its use and the death-rate among the new-born from asphyxia is certainly higher than with other methods in the hands of the general practitioner.

Under no circumstances should the single dose exceed 0.01 gm. (1/6 grain) of morphin and 0.5 mg. (1/125 grain) scopolamin, nor should this be repeated until the effects have passed (several hours). The combination is strongly contra-indicated outside of special institutions, and except in the hands of those who are trained in its use.

Morphin and scopolamin do not produce total insensibility to pain when used in doses which are safe, but they induce a peculiar condition — the so-called "twilight sleep" — in which everything is quickly forgotten, so that the mother has no recollection of anything that happened during labor.

An American manufacturer combines an extract of cactus, known as cactoid, with scopolamin (or hyoscin), claiming that the danger to the heart is overcome thereby; but it has been shown by several investigators that cactus and all its preparations are inert; hence such combination can have no advantage over the simpler one. Another manufacturer has sought to avoid the decomposition of scopolamin, to which the injurious action is attributed, by the addition of an alcohol, but this is of no practical advantage.

Various combinations of opium alkaloids under trade names, including Omnopon, Pantopium and Narcophin, have been introduced with the claim that they have all the advantages of morphin without the side actions, but independent observers have not found the expensive substitutes preferable to morphin.

Therapeutics

PREVENTION IS GREATER THAN CURE

(Continued from page 513)

XIX

Diphtheria

This disease was long thought to be due to filth, because, like all sore throats, etc., it seemed to be more prevalent in dirty, damp, and crowded places. This is true only because it is not so readily eradicated from such surroundings, more cases are not discovered, and more carriers are found in such localities. Many sore throats were termed diphtheritic when they were septic, or cases of tonsillitis with membrane, or were really scarlatinal cases. Also, membranous croup was long held to be distinct from diphtheria. With the discovery of the contagium of diphtheria, the Klebs-Loeffler bacillus, it is now conceded not only that the discovery of this germ in the secretions of the throat, nose, or other parts of the body proves that diphtheria is present, but also that its absence is proof that the disease is not present, provided that the swab is properly taken and the culture made by an expert. Also, it has now long been proved that membranous croup is laryngeal diphtheria.

This throat inflammation, now termed diphtheria, has been known for centuries, having first appeared in the East and later in Europe, occurring mostly in epidemics. Now it is endemic in most civilized cities, although small epidemics, localized in certain buildings, public institutions, tenements, or schoolhouses, frequently occur. A carrier of this disease may communicate it to persons so widely separated as to make the occurrence of the disease almost unexplainable by any epidemic theory. While nearly all mankind is susceptible to small-pox, and a large majority to scarlet fever, many persons seem naturally immune to diphtheria. Also, a closer contact is apparently needed with an infected individual than in these other diseases.

As one attack of diphtheria does not cause immunity from the disease for any great length of time, and as preventive measures do not protect for any great length of time, it is difficult to eradicate this disease. Small-pox could doubtless be prevented entirely in any country in which every individual was vaccinated at least two or three times during his life. Such prevention of diphtheria cannot be expected; but a more rigid quarantine of diphtheria patients, and a greater effort made to discover carriers and isolate and treat them will render diphtheria less and less frequent.

This disease has always had a large percentage of deaths; but the death rate since the introduction of antitoxin has been constantly on the decrease, and with a better understanding of the proper dosage of antitoxin, and with the effort made to diagnose the disease early, the death rate will be more rapidly decreased. Our best sanitarians believe that for every case of diphtheria recognized, at least one sore throat that carries the Klebs-Loeffler bacillus escapes; in other words, there is an equal number of missed mild cases.

It has been shown that patients with diphtheria when coughing, or even talking, will throw diphtheria bacilli into the air, and if such are deposited on culture plates not far from the patient, diphtheria bacilli will grow. It has also been shown that the Klebs-Loeffler bacillus lives longer where it is cold and damp than where it is dry and hot. The disease is more prevalent in cold weather, and the germ does not die so readily and become non-infectious in cold, damp rooms. Besides every care to prevent the spread of infection from the patient, the bedroom should be kept warmer in cold weather than with most diseases, not only because of the foregoing fact, but also because the toxins of diphtheria bacilli are depressing, and the patient's temperature is often too low.

It has been shown that the normal hydrochloric acid in the stomach inhibits or kills the diphtheria bacilli; therefore it is exceedingly rare to find these germs in the intestines, and very rare to find diphtheritic membrane in the stomach.

In the majority of cases the tonsils, one or both, are the parts affected in diphtheria, and with the present methods of treatment, in a large portion of these cases the membrane will be limited to these regions. The soft palate is next most frequently attacked, the pharynx next, and nasal diphtheria, with proper care taken, is not very frequent. Laryngeal diphtheria is not a frequent complication to tonsillar diphtheria; it generally begins as the original point of attack.

CARRIERS

These may be convalescents from diphtheria, or may be those who have had contact with diphtheritic patients who may or may not later develop the disease, or the term may be perhaps more properly limited to those who carry the germ for months. Diphtheria germs may live a long time on books or other substances, handled, coughed, sneezed or expectorated on by a diphtheria patient, and may infect persons coming in close contact with such infected material. This method of infection may not be very frequent. Animals may carry the infection. It is doubtless a good axiom to believe that a tonsillitis with exudate is diphtheria until it is proved not to contain the Klebs-Loeffler bacillus. Such a patient should be more or less rigidly isolated, as streptococcic infection is, if anything, more readily communicated than is a diphtheria infection. Therefore, there can be no excuse for not isolating a sore throat with exudate or membrane as soon as such a case is discovered.

The subject of carriers and the length of time which the Klebs-Loeffler bacillus may remain in the throat may be studied by reference to the article of Henry Albert[1] and that of Henry Page.[2] Both of these papers give many references and quote many authorities. Albert quotes Ledingham as stating that 50 per cent. of persons affected with diphtheria have lost the bacilli by the time the local membrane has disappeared. The average length of time that the bacilli will persist in a throat is thirty days, as shown by a very careful clinical and bacteriologic study of a diphtheria epidemic by Jessie W. Fisher.[3] She found that these germs could persist for more than 100 days, and in one instance 111 days. Not every bacillus carrier shows virulent germs, but in a large proportion of such bacilli carriers the germs are virulent; therefore a bacillus carrier should always be considered able to infect others. Even if such bacilli are proved not to be fatal to guinea-pigs, they might be able to infect a human being. Dr. Fisher also discovered that a sewer could become contaminated with diphtheria bacilli, that rats living or eating refuse in this sewer could become infected, and that cats catching or eating the rats could become carriers. Cats associating with a diphtheritic patient may frequently become carriers.

Klein[4] thought that cows could become infected and could cause infection of milk, which, unboiled, could infect an individual. Infected milk certainly can cause streptococcic throats, and it would seem likely could cause diphtheria. Probably a pet dog could carry the disease as readily as a cat. Therefore the rule and regulation of every physician should be that cats and dogs should be excluded from the sickroom of a patient with any kind of sore throat; and if other cases occur in a family in which quarantine is properly carried out, not only should the throats of all persons be examined, but also the cat or dog should be suspected.

The location of the Klebs-Loeffler bacillus in carriers who are convalescing is probably most frequently in the throat, though the bacillus may be found in the nose. In those who carry these germs long they are more likely to be found in the nose. Therefore, swabs should be taken of both regions. It is quite probable that a surface swab from a tonsil may be negative while a culture obtained from probing into crypts of the tonsils or in the region back of the tonsil might show the presence of the germ. It is culpable neglect to fail to examine a patient thoroughly to ascertain if he is free from the Klebs-Loeffler bacillus.

The boards of health vary as to the number of negative cultures that will release a patient from quarantine. The safest number is perhaps four negative cultures, two from the throat and tonsils, one from crypts or back of the tonsil, and one from the nose, taken on alternate days, at a considerable interval from the use of any antiseptic washes, gargles or sprays. This would seem to prove that a patient was free from the Klebs-Loeffler bacillus. In instances in which epidemics of diphtheria have occurred and cultures have been taken from the throats of a large number of well persons in the same institution, it has almost invariably been shown that a certain small percentage of such persons have acquired the germ and are carrying it without becoming actively infected.

TREATMENT OF CARRIERS

Various methods of ridding a carrier of the diphtheria germ have been tried. Local measures vary, and may comprise painting the suspected regions with tincture of iodin or with Lugol's solution, with silver solutions, phenol solutions, or the use of various gargles, hydrogen peroxid solutions, etc., and the nasal inhalation of various thymol or iodin inhalants or sprays. There is no question that whatever else is done, some local antiseptic should be applied. Diphtheria antitoxin injection has not been very successful. Local applications in the mouth, throat or nose of antidiphtheritic serum have not been proved to be very successful. Vaccinations with dead diphtheria bacilli have been only partially successful. These various methods are described by Albert.[1] He believes that a local application to suspicious crypts of the tonsils of a "5 per cent. solution of silver nitrate will destroy all bacteria with which it comes in contact." A thorough application of a 10 per cent. solution of silver nitrate he finds will cause some destruction of the epithelium of a crypt and a fibroblastic proliferation with ultimate obliteration of the lumen, which is of course the object desired.

[4] Klein: Local Gov. Board Rep., London, 1899, xxix.

The most successful treatment of diphtheria carriers seems to be that of spraying the nose and throat with pure cultures of *Staphylococcus pyogenes aureus*. According to the reports, this spray is apparently harmless to the individual. This method was first used by Schiøtz, in 1909. Although it is not always efficient, in some instances it has removed the Klebs-Loeffler bacillus and prevented its growth so that cultures were negative to it in a week or less. It has not proved very successful in nasal cases. Discussions of this treatment are given by Catlin, Scott and Day,[5] Lorenz and Ravenel,[6] and Rolleston.[7] On the other hand, Womer,[8] after using this staphylococcus spray in forty-two cases of diphtheria carriers, comes to the conclusion that although it is harmless, it does not appreciably lessen the period of quarantine. This leaves the value of this treatment still subject to positive proof. It may certainly be tried.

Womer states that "apparently most of the carriers do not spread the disease after sixty days from the day the disease begins." The word "most" leaves this assertion doubtful as far as general practice is concerned. Any one person who carries the disease may be one that could infect others.

Wood[9] thinks that in one or two instances, in diphtheria, spraying the affected areas with live lactic acid bacilli hastened the disappearance of the diphtheritic germ. Antiseptics should not immediately be used in the throat after such spraying, as he thinks it is the live bacilli that act perniciously on the diphtheria bacillus. This suggestion is worthy of further investigation.

Miller[10] recommends that diphtheria carriers have their throats sprayed with warm formaldehyd solutions every three or four hours during the daytime. The strength which he recommends to begin with is 0.25 or 0.5 per cent. in water of a 40 per cent. formaldehyd solution. [The official Liquor Formaldehydi is a 37 per cent. solution.] This solution may be increased in strength to 1 per cent. if deemed advisable. He found that in from three to six days the diphtheria bacilli disappear from the throats of carriers thus treated. He urges that the solution be prepared fresh each day. He did not find that the kidneys were irritated by such treatment.

IMMUNITY

While it has been long known that infants and many adults seem not to be susceptible to diphtheria, it has only lately been shown that probably a large proportion of adults, stated at 90 per cent., perhaps 50 per cent. of children, and perhaps 80 per cent. of newborn infants have diphtheria antitoxin in their blood and are not likely to become ill with diphtheria. It should be noted, however, that individuals protected against self-infection may be carriers of diphtheria bacilli which can infect others. How many of these immune adults or older children have been always immune, and how many have acquired immunity by contact with diphtheria germs, is not known. Nurses and physicians who frequently care for diphtheria patients have been shown to have antitoxin in their blood, though they may never have had the disease.

A skin test has been devised, known as the Schick reaction, to determine whether or not an individual is protected against diphtheria, that is, whether he has diphtheria antitoxin in his blood. The reaction seems very positive, and distinctly shows whether an individual is artificially protected or has natural antitoxin against this disease. The test is made with a dilute diphtheria toxin of such strength that 0.1 c.c. contains one-fiftieth of the minimum fatal dose for a guinea-pig. This amount, namely, 0.1 c.c., is injected into the layers of the skin, perhaps best on the inner surface of the arm. A positive reaction should appear in from twenty-four to forty-eight hours, and is evidenced by a slight swelling and localized redness, a reddened papule which remains from seven to ten days. When this papule disappears, the skin over it may desquamate slightly, and pigmentation may remain for days and even weeks. Park states that the injection is best given with a small hypodermic syringe with a platinum point needle, that the injection must be into the skin and not subcutaneously, and that immediately after the injection there should be a raised whitish spot, which in twenty-four hours becomes bluish, with a slight edema. Schick's interpretation of the positive reaction, as just described, is that the patient has no antitoxin in his blood, or at least less than 1/30 unit of antitoxin in 1 c.c. of blood. He declares that all persons so reacting are susceptible to diphtheria, and Park agrees with him. Park,[11] in his summary on immunity in diphtheria, states that according to Hahn the interval between the injection of vaccine and the development of antitoxin is not less than three weeks, while other investigators think that it may be eight days. Persons who have a natural antitoxin show an earlier increased antitoxin production. Von Behring considers that 0.01 unit of antitoxin per 1 c.c. of blood is sufficient to protect a healthy individual, and much less may protect against diphtheria.

Park states that last year in the Willard Parker Hospital one-fourth of the inmates were diphtheria carriers, and he found that "active immunization produced a very decided increase of antitoxin in a relatively short time in all persons who had natural antitoxin." Park found that 400 out of 700 scarlet fever patients showed natural immunity by the Schick reaction; that is, 57 per cent. were immune. He comes to the conclusion that persons positively exposed to diphtheria should be passively immunized even if the toxin-antitoxin injections have been given; but he urges that the Schick test will prevent the necessity of immunizing about two-thirds of such exposed persons. In other words, a person suspected of being exposed to diphtheria should receive the Schick test. If this is positive, showing that he is susceptible, he may be passively immunized with antitoxin. If he has not been immediately, but is likely to be, exposed and

should be protected, he may be actively immunized with a vaccine. Such active immunization Park believes will last only from one to two years; hence general protection of large numbers of individuals against this disease cannot yet be urged. Park quotes Bauer as finding that the persistence of the bacilli in carriers is not shortened by active immunization.

The toxin-antitoxin injections used by Park are described in his article. The von Behring vaccine[12] "consists of a mixture of strong diphtheria toxin and antitoxin in such proportions that the toxin is just neutralized or is in very slight excess when tested on a guinea-pig." These injections are given intracutaneously, and immunity occurs in about ten days. Individuals with natural antitoxin in the blood may be more susceptible to reaction from this toxin-antitoxin vaccine than those without such antitoxin, and individuals who have antitoxin in their blood from previous infection may show a hypersensitiveness to the injection.

As just stated, patients so actively immunized are apparently protected for at least one year, while a patient who receives an immunizing dose of antitoxin is protected for perhaps not more than ten days. However, this antitoxin immunization is rapid and will generally protect a patient from one exposure to this germ.

Veeder[12] carefully reviews the literature on the subject of this vaccination, and finds that there is a marked variability of reaction to such injections, and quotes Kissling as believing that the injection should be made into the back instead of the arm, and that more dilute injections should be given, and if a milder one causes considerable reaction, a stronger one should not be used. If the milder one causes no reaction, a strong injection may be given. A "negative phase" has not been discovered; a patient who has been vaccinated with toxin-antitoxin, on subsequent exposure to diphtheria may receive antitoxin without showing hypersensitiveness. It has been shown that diphtheria carriers have more antitoxin in their blood than is found in the blood of patients who have just recovered from an attack of the disease.[13]

Von Behring[14] believed that the dose of toxin-antitoxin injected can be gaged accurately according to the weight of the individual. This he has worked out on animals.

The future advantage of this kind of protection against diphtheria lies in the fact that a foreign serum like horse serum need not be used in a patient who is a hay fever or asthma subject. It is quite probable that it would be unwise, at least at the present time, to use this toxin-antitoxin in diseased or damaged individuals, as those with a weak or diseased heart. At least, this precaution is suggested. It may later be shown that a dose so small as to give practically no reaction may still be sufficient to immunize. It is reported by Schreiber[15] that in vaccination by von Behring's method of 700 schoolchildren and 300 children in a hospital, there have been no untoward effects.

Immunizing doses of antitoxin to persons who have been exposed to diphtheria, given early, are generally successful in preventing the development of the disease. The immunizing dose for a child should probably be at least 1,000 units. Doubtless adults should receive larger doses. In the epidemic reported by Dr. Fisher, of the large number of immunizing doses given, but one person, a nurse, subsequently developed an attack of diphtheria during the period of observation. She had a mild attack at the end of two weeks. Dr. Fisher believes that two weeks is the limit of protection from a dose of immunizing antitoxin.

In the epidemic which occurred at Johns Hopkins Hospital, in 1911, Dr. Ford[15] reports that of 300 prophylactic doses of antitoxin administered, in most cases the reaction was limited to a slight urticaria. In a few instances there was some local edema, tenderness, and elevation of temperature. In five cases there were characteristic symptoms of serum disease, and in one of these cases there was typical anaphylactic shock. The patient who developed shock had previously received antitoxin, and had a history of asthma. It would have been interesting to note if all the other individuals who received the antitoxin had never been subject to asthma or hay fever: whether this shocked individual was the only one who had a history of asthma.

New and Nonofficial Remedies

The following additional article has been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Its acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

ALCRESTA IPECAC TABLETS.—Tablets containing an adsorption product of ipecac alkaloids with hydrated aluminum silicate (fullers' earth), each tablet representing 10 grains of ipecac.

Actions and Uses.—Alcresta ipecac tablets are said to be unaffected by the acid contents of the stomach, but to be decomposed by the alkaline fluids of the intestines with liberation of the ipecac alkaloids and thus to exert the amebacidal action of ipecac in the body.

Dosage.—Two to three tablets three times a day, one hour before meals, for a period of four to six days. Prolonged use of these tablets may cause diarrhea.

Manufactured by Eli Lilly & Co., Indianapolis, Ind. U. S. patents Nos. 1,048,711 (Dec. 31, 1912; expires 1929) and 1,048,712 (Dec. 31, 1912; expires 1929). No U. S. trademark.

The adsorption product of ipecac alkaloids which is contained in alcresta ipecac tablets is insoluble in water, alcohol and alcoholic or aqueous acidulated liquids. The compound is decomposed by alkaline fluids with liberation of the free alkaloids.

The basic product, alcresta ipecac, is assayed by the method which follows, and an amount of it used so that each alcresta ipecac tablet shall represent 10 grains of ipecac of standard alkaloidal strength:

Two Gm. of alcresta ipecac are placed in a 250 Cc. flask, 25 Cc. of ether added, the mixture well shaken and 5 Cc. of stronger ammonia water added. The mixture is shaken vigorously for several minutes and the ether then decanted through a filter into a 200 Cc. beaker. The contents of the flask are extracted in the same way with four more 25 Cc. portions of ether, decanting each portion through the filter. The filter is washed with a small amount of ether and the combined ethereal solutions evaporated to dryness on a water bath. The residue is dried for two hours at about 70 C. The alkaloids are dissolved in 20 Cc. of neutral alcohol, and 5 Cc. of tenth-normal sulphuric acid and 50 Cc. of distilled water added. The liquid is then titrated with fiftieth-normal potassium hydroxide using cochineal as indicator. Each cubic centimeter of tenth-normal sulphuric acid consumed represents 0.02384 Gm. of ipecac alkaloids.

LIVER FUNCTION AS INFLUENCED BY DUCTLESS GLANDS

Much has been written of late in regard to the interrelations of the ductless glands. Most of the suggestions advanced are purely hypothetic and serve merely to permit the formulation of definite questions in regard to the possible part played by the internal secretions. The thyroid, pancreas and suprarenal bodies, for example, have been alleged to influence each other in a complex manner, so that either failure or overactivity on the part of any one member of this group might affect the organism by the attendant alteration in the functions of the remaining allied ductless glands. The situation has been further complicated by the assumption that the action exerted by these individual glandular organs may be in the nature both of inhibition and of stimulation.

However vague these ideas may seem, and however much they are unfounded in the actual facts of experience, they embody a new point of view. We are asked to consider whether the deficiency of a specific internal secretion may not affect the organism by an indirect effect which its failure induces in other glandular functions as well as by the direct result of the suppression of its own immediate activities. To cite an illustrative possibility, if it were demonstrated that the thyroid exerts an inhibitory effect on the pancreas or a stimulating influence on the adrenals, then the failure of thyroid function might manifest itself not only in the direct consequences of hypothyroidism, but also in an unrestrained overactivity of the pancreas in the one case or a diminished efficiency of the unstimulated adrenals in the other.

There is a dearth of reliable facts regarding these suggested glandular interrelations. The questions involved are rendered extremely complicated and difficult to solve in the face of so many simultaneously occurring variables. Recent researches from the Hunterian Laboratory of Experimental Pathology at the Johns Hopkins Medical School[1] throw some light in this field. Whipple and his collaborators have shown that valuable information concerning liver function and liver disease can be obtained by the intravenous injection of a solution of phenoltetrachlorphthalein. The drug is excreted through the bile by the activity of the hepatic epithelium and may be extracted from the feces and estimated with considerable accuracy.[2] Under various conditions in which the functional capacity of the liver cells is interfered with, the output of phenoltetrachlorphthalein falls below normal, depending on the extent of the derangement. For example, in passive congestion of the liver there will be periods of decreased output corresponding to the intensity of the stasis or breaks in cardiac activity. When the portal blood is shunted around the liver by an Eck fistula, a distinct depression in the phenoltetrachlorphthalein output is noted as soon as liver atrophy and fatty degeneration set in. With an acute fatal poisoning and a definite liver injury produced by such toxic agents as chloroform and phosphorus, the output in the bile will usually be proportional to the amount of hepatic damage produced and may be completely suppressed.

Inasmuch as it is thus found that definite and known functional derangement of the liver is associated with a definite change in the excretion of phenoltetrachlorphthalein, it seems permissible to assume in turn that a decrease in the phenoltetrachlorphthalein output means a decrease in the functional capacity of the liver. From this point of view the Johns Hopkins pathologists have studied the liver function in the pathologic states brought about by removal of various ductless glands. After complete extirpation of the pancreas there is a steady fall in phenoltetrachlorphthalein excretion which speaks strongly for the idea that pancreatic activity is essential to proper liver function. The same is the case with the adrenals. These facts have a bearing on the theories of diabetes.

Thyroid insufficiency is without apparent effect on the functions here considered. Parathyroid insufficiency with tetany causes no decrease in phenoltetrachlorphthalein output and may even increase the readiness with which it is excreted. The tetany may cause hyperactivity on the part of the liver cells. Hypophysis extirpation produces varying results. Reverting to our opening remarks, therefore, these interesting new experimental studies supply evidence to the effect that the liver is very much concerned in the derangement that follows the removal of the ductless glands. Hence it is not at all improbable, in the opinion of Whipple and Christman, that this disturbance may be an important factor in the general symptom complex of ductless gland insufficiency.

ENDAMEBAS AND PUS POCKETS ABOUT THE TEETH

The recent articles of Barrett,[1] Smith,[2] Bass and Johns,[3] Evans,[4] Middleton and others on the presence of endamebas in pus pockets about the roots of teeth, the relationship of these to other lesions and the use of emetin in treatment, emphasize again the need of cooperation between physician and dentist and better knowledge by each of the field of the other. The dentist has not usually been trained to recognize or appreciate the danger of these chronic suppurations to the general health, and the physician, including perhaps the bacteriologist, has not made a sufficiently close study of the tissues involved in these suppurations to enable him to draw proper conclusions, especially with reference to the complete cure of such cases under the most favorable treatment imaginable. For example, Bass and Johns state that the periosteum of the alveolus is "continuous with that of the surface of the jaw bone, but it also continues up and covers the neck of the tooth." This statement might lead to the belief that the root of the tooth is covered with a periosteum similar to that of bone and subject to the same physiologic and pathologic changes. Such is not the case.

It seems desirable to call attention to the peculiar characteristics of the outer hard tissue of the tooth root—the cementum—since a knowledge of the physiologic functions of this tissue in connection with the changes which take place, as a result of suppuration, presents the key for prognosis. The dentin, which forms the bulk of the root of the tooth, is covered with a layer of cementum, which corresponds in many respects to bone. The periosteum which lines the bone of the alveolar socket and the cementum covering the root are connected by many bundles of fibers of the peridental membrane, the ends of which are embedded in the periosteum and the cementum, respectively. The function of these fibers is to hold the tooth in position and cushion it against the force of mastication. Lying on the surface of the cementum between the ends of these fibers is a layer of cementoblasts, which correspond to the osteoblasts lying on the surface of the periosteum; and their functions are similar. The important difference between the two tissues is that the cementum does not have a blood supply corresponding to that in bone, nor does it have haversian systems.

If we do not fully appreciate this difference, we might naturally expect the same response and the same processes of repair in cementum which occur in bone as a result of periosteal inflammations. If the periosteum is stripped from bone, the bone may become necrosed, in which case the activity of the cells within the bone will separate the necrosed area and exfoliate it. Similar changes cannot take place in the cementum because of the lack of circulation of blood. When the peridental membrane is stripped from the cementum by suppuration, the cementum becomes a dead tissue which cannot be exfoliated, except in its entirety by the removal of the tooth. It is sufficiently porous to become saturated with the products of suppuration, and remains as a constant irritant to the overlying tissue. Therefore, there is established in each of these pockets a condition similar to that caused by a piece of necrosed bone continuously held in position.

All of the investing tissues of the teeth—the peridental membrane with its specialized cells and fibers, and the bone of the alveolar process—must be considered as tooth appendages, since they develop with the tooth and always disappear subsequently to its extraction. Likewise, whenever there is a suppurative detachment of the peridental membrane from the cementum, the fibers of the peridental membrane and the alveolar process corresponding to the area of detachment are absorbed, as has been shown by microscopic examination of the overlying tissue. A careful study of the tissues involved in these chronic suppurations will show that the suppurative process first attacks the tissue at the very surface of the root and strips it off, no soft tissue whatever remaining attached. The involvement of the tissue along the immediate root surface is always in advance of the involvement of the tissue farther removed from the root, and the bone of the alveolar process at any particular level disappears last, apparently by absorption rather than as a direct result of suppuration. This disease should, therefore, be considered a pericementitis, rather than an alveolitis. The bone of the alveolus is practically never laid bare by this disease, but is covered by the soft tissue membrane, which presents a granulating surface to the root. A "gum boil" or a sinus discharging through the gum seldom occurs; generally these result from abscesses occurring at the apex of the root of a tooth following the death of the pulp.

On account of the foregoing conditions, the word "cure" should be used with caution. Evidently some of those who have been studying these cases have considered them "cured" when no more endamebas were demonstrable, apparently without considering the tissue changes and conditions which prevent the closure of the pocket. A case should not be considered cured, when there remains the constant irritant—the denuded cementum—which maintains the harbor for a reinfection. This fact—that such treatment does not result in permanent cure—seems already partially recognized in the present report of Bass and Johns,[5] as they state that reinfection has occurred in about 12 per cent. of cases within four weeks.

It is also stated that a previous injury or inflammation seems necessary "to furnish a kind of a pocket" in order to provide a nidus for the endamebas, and that they "are not known to live on open surfaces." These statements should impress on both dentist and physician the possibilities of greater watchfulness of the gingivae and more careful management of operative procedures to prevent the injury which prepares the pocket for the endamebas. The pus pocket is always preceded by a gingivitis which may be so insidious as scarcely to attract the patient's attention. Most cases may be cured by very simple procedures, if undertaken previous to the detachment of the tissue from the root.

NYSTAGMUS AND VERTIGO

Vertigo and involuntary eye movements are two symptoms whose significance is frequently puzzling to the clinician. The frequency with which they are associated with disturbances of the internal ear suggests that this peripheral sense organ and its nerve offer an experimental basis of attack on the problems.

Wilson and Pike[1] have recently reviewed this subject, and have given a brief résumé of the experimental work they have carried on for several years.

The labyrinth of the ear is a definitely located sense organ supplied by the vestibular branch of the eighth cranial nerve whose function is to give information of change in position of the head, and whose destruction causes important and often lasting alterations in the posture of the animal. Impulses arising in it become effective only after they have reached a central mechanism and have there been transformed and sent out as efferent or motor impulses. Through its central connections there is more close association with the oculomotor muscles than with the skeletal muscles generally. Our conception of our position or change of position in space is due in large measure to the fusion of afferent impulses from the labyrinth and from the retinal and muscular apparatus of the eyes. The lack of agreement of the impulses from these different sources is one cause of vertigo.

Normal stimulation of the labyrinth comes from movements of the head. Despite the general acceptance by physiologists of Mach's view that actual fluid currents in such minute tubes as the semicircular canals are unthinkable, the hypothesis of the stimulation of their ampullary nerve endings by fluid currents has had a wide following among clinicians. This has led to a lack of appreciation of the rôle of pressure in the usual stimulation of the labyrinth, and of the significance of pressure on the central vestibular tract in intracranial disturbances.

Much confusion has existed also with reference to nystagmus. Wilson and Pike have endeavored to clear up this situation by pointing out that, although involuntary oscillatory movements of the eyes may arise from various experimental intracranial or other lesions, the labyrinthine type of nystagmus, consisting of alternate slow movements in one direction and quick in the opposite, is not encountered in any other experimental lesion which does not involve the vestibular tract. These papers furnish additional evidence that "if there is anything definite to say in regard to labyrinthine nystagmus it is that the cause of the slow deviation lies in the labyrinth or the vestibular tract," and that the quick return is a cerebral act indicating disturbance in the oculomotor rather than in the labyrinthine or vestibular mechanism.

A change in the position of the head in space is commonly, but not invariably, associated with a change in position of the eyes. Stimulation of the labyrinth of unusual violence always brings about a change in the position of the eyes unless there is some oculomotor deficiency, and usually also gives rise to a disharmony of the impulses from the eye and ear and other parts of the body. Impulses of ordinary intensity are harmonized or integrated and give rise to a definite orderly motor response which results in the restoration or maintenance of equilibrium. Disharmony of these various afferent impulses is attended by an incoordinated motor response—the objective sign of vertigo. Both the normal motor response and the incoordinated motor response are reflex responses.

From the time of Flourens in 1828, numerous investigators have worked on the labyrinth. Prior to Flourens, Purkinje studied rotation vertigo and laid the foundation for its laws. Later came Hitzig, who studied electrical stimulation and harmonized galvanic vertigo with rotation vertigo. Hitzig, Goltz and Bornhardt noted stimulation of the labyrinth with heat and cold, but it remained for Bárány to show the importance of the caloric test in clinical practice. As a result of these experimental investigations, the fundamental phenomena which accompany stimulation of the labyrinth became well known to physiologists. But it remained to explain which were essentially labyrinthine. Bartels and Wilson and Pike have furnished experimental evidence which leaves little doubt that the slow deviation is the only essential movement of nystagmus which is labyrinthine, and that the quick movement must be regarded as cerebral.

The part played by the cerebellum in labyrinthine nystagmus has long been in doubt. The more recent experiments of Wilson and Pike corroborate what they reported some time ago, that "neither the slow deviation nor the quick return has any necessary pathway or any indispensable center in the cerebellum."

---

[1] Wilson, J. G., and Pike, F. H.: Some Considerations on the Physiology of the Otic Labyrinth, Arch. Int. Med., December, 1914, p. 911; The Mechanism of Labyrinthine Nystagmus ana Its Modifications by Lesions in the Cerebellum and Cerebrum, ibid., January, 1915, p. 31.

Bárány believes that the more complete recovery in man as compared with animals after labyrinthine extirpation is evidence of the retrogression of the vestibular system in man. Wilson and Pike object to this interpretation, and point out that the certainty and the severity of the motor disturbances immediately attending labyrinthine extirpation in the higher mammals is evidence of the persistence of the function of the vestibular mechanism. The more complete recovery in man is not necessarily to be interpreted as evidence of the retrogression of the vestibular system, but is to be regarded as evidence of the much greater degree of adaptability on the part of the highly complex somatic motor system and of the greater capacity for readjustment following certain lesions, inherent in the enormous development of association tracts in the central nervous system.

The modes of stimulation of the labyrinth, and its results, have been fairly well defined and are now available for diagnostic purposes. The deviation of the eyes which is the direct result of the labyrinthine irritation has a definite and now generally acknowledged pathway. Any irritative lesion here will cause labyrinthine symptoms—vertigo, nystagmus, etc.; and a destructive lesion will annul reactions normally produced from the labyrinth.

The quick phase which follows and is dependent on the slow phase has a separate and distinct pathway in the cerebrum. When this pathway is interrupted, they have found experimentally that while the normal slow deviation is present, the quick return movement is altered or suppressed. As this pathway passes through areas of the cerebrum in which lesions are difficult to diagnose, there is here the possibility of great usefulness.

In this issue Wilson and Pike[2] have shown the application of these principles to the diagnosis and treatment of vertigo as a symptom. Their complete study of this condition shows again the great value of scientific research applied to practical medicine.

THE DRINKING OF MINERAL WATERS

The drinking of mineral waters, particularly as it is practiced by thousands of patients who are sent for curative purposes to the numerous mineral spring resorts in all parts of the world, is an established therapeutic custom. The multitudes of persons who indulge in the water drinking at the spas, as well as the large number of physicians who repeatedly advise the treatment as an established routine, make it seem more than probable that the practice is a well-founded one. Yet we venture to believe that few at best of all those who adopt or prescribe the mineral spring therapy could offer a reasonably tenable explanation of precisely what they hope to accomplish thereby, and how they have succeeded. Thus it happens that the cure or the improvement of the patient is obvious; a reason for the satisfactory outcome is wanting. Consequently in some quarters there has arisen the same sort of nihilism in relation to mineral waters that one finds exhibited in respect to the use of drugs. It is the reaction against a blind empiricism.

When an interpretation of the alleged beneficial effects of drinking mineral waters has been indulged in, the answer is sometimes made that the effects are merely those of water drinking per se. Nothing specific is claimed other than a diuresis which has given rise to that overworked expression, "flushing out" the system — whatever it may mean. Again, residence at the mineral spas usually involves the simultaneous regulation of diet and the orderly pursuit of a carefully planned routine of living; also, it means a change of environment, new scenes and elimination of social and business worries. Rest and exercise, food, drink, baths — physical therapy, dietotherapy, balneotherapy, psychotherapy—are combined to create an internal and external hygienic environment of which the individual factors are not easily dissociated. The mineral water thus becomes a mere incident rather than a dominant force in the therapeutic success.

There are, of course, mineral waters which have a determined basis for their use. Strongly alkaline waters of the Vichy type have a rational use. Laxative waters find an explanation of their effects in the presence of known purgative salts. Chalybeate waters and those which contain arsenic may serve as useful means of administering well-known therapeutic agents. But for the majority of waters there exists a sort of chaos of explanation from which refuge is taken in the vague uncertainties of radio-activity or some similar indefinite novelty. For this reason we may welcome any serious attempt at a scientific analysis of the physiologic action of mineral waters, even if it leads us no farther than the domain of suggestive hypothesis.

The Prague pharmacologist, Professor Wiechowski, has based a tentative interpretation of the action of mineral waters on certain facts established by animal experimentation.[1] It is maintained that prolonged use of diets containing inorganic components in unlike proportions may lead to marked changes in the mineral composition of the body. Changes in the interrelations of the cations, for example, can be brought about. What is even more significant, however, is the assertion that organisms thus affected by an alteration of their usual inorganic makeup respond in unusual ways to various stimuli. An illustrative case is found in rabbits fed on an exclusive oat diet (which is especially deficient in calcium). They are exceedingly sensitive to skin irritants, and unduly resistant to fever-producing processes. According to Wiechowski, the mineral waters may bring about an alteration in the cation relations of the organism — a reaction depending in the individual cases on the makeup of the water ingested. These changes in the inorganic environment alter the responses of the organism. It is impossible to foresee at present what changes in all manner of functions this may involve. In any event, the Bohemian investigator believes that it is reasonable to ascribe the essential therapeutic effects of certain mineral waters to these alterations produced by their ingredients. It is not so much a matter of adding more inorganic salts to an organism already well provided with them, as it is a change in the equilibrium between the various ions. It is unnecessary to cite experimental evidence bearing on the point involved, for it is to the hypothesis primarily that we have aimed to call attention.

SOME CONSTITUENTS OF THE BLOOD

It requires little argument to emphasize the great scientific importance of learning as much as possible respecting the chemical composition of the circulating blood. A precise knowledge of the make-up of this fluid would serve to tell a good part of the story of tissue metabolism. Investigators have long realized the inherent difficulties both in detecting and in determining quantitatively various constituents of the blood, owing to the minute amounts in which they are present in a unit volume of the circulating medium at any moment. One hundred c.c. of blood — a large quantity to furnish at once — ordinarily contain not more than 0.1 gm. of sugar. Yet even this small content renewed or discharged from moment to moment in the course of the circulation may represent the exchange of no inconsiderable total amount of carbohydrate in the course of a few hours.

Other constituents are present in even smaller amounts at any given moment, and inasmuch as the methods of analysis hitherto current have involved the examination of single samples of blood, it is not surprising that many substances suspected in this fluid have never really been identified. By employing large quantities of blood obtained from large animals, Abderhalden[1] actually separated from it some of the amino-acids absorbed from the alimentary tract. In other cases progress has depended on the application of special microchemical methods with the uncertainty that goes with them.

Several months ago we referred to a method of removing diffusible substances from the circulating blood of living animals by dialysis. This process, devised by Abel, Rowntree and Turner[2] of the Johns Hopkins Medical School, consists essentially in the continuous passage of the blood from an artery through a system of tubes made of celloidin immersed in a saline solution or artificial serum, and its return to a vein, thus yielding by dialysis certain of its constituents to the fluid surrounding the tubes. The relative proportions of the different non-protein nitrogenous substances in the diffusate do not vary greatly from those in the blood. The latest contribution attributable to this method is the actual separation of two amino-acid derivatives of protein — alanin and valin — in crystalline form.[3] Histidin and creatinin have been shown by reactions to be present. Oxyacids were found in noticeable proportions; lactic and beta-oxybutyric acids in particular have been identified.

Current Comment

HEALTH INSTRUCTION IN AN INDIANA COUNTY

Common sense is an uncommon quality. Those who in their early youth read and enjoyed the William Henry Letters, will recall that this was a refreshing characteristic of that young hero. When sent away to a boarding school, he was told that he would have to take dancing lessons in order to learn how to enter a room. He could not see the need of taking lessons for this purpose. He said, "Just walk right in." One of the most difficult lessons to learn is that the way to do a thing is to do it. The county health commissioner of Union County, Indiana, feels that one of his duties is to teach the people of the county how to keep well. He has accordingly prepared a little seventy-five page pamphlet, made up largely of material published by the various state boards of health. The board of county commissioners made an appropriation to send a complimentary copy to every home in the county. The pamphlet is simply but forcibly written, and contains chapters on the home, contagious diseases and the baby. In the first chapter, the people are told how to keep their homes clean and healthful, how to dispose of their garbage, how to care for their food and how to take care of their bodies. Directions for disinfection and especially directions for various contagious diseases make up the second chapter, while the third and most important contains directions to mothers for the care of themselves and their children. We have been a long time in learning that if the teacher of good health would compete with the patent medicine man, he must meet him on his own ground. Instruction of the people on health topics is a public duty. It should not be left to professional zeal or to philanthropy. The publication and distribution of such pamphlets as the Union

County Health Book are directly and solely for the public good and will yield large dividends in the form of better health and prosperity for the people. If each county in the nation had a health officer as wide awake and a board of commissioners as broad minded as those of Union County, Indiana, the problems of the prevention of disease and the prolongation of life would be immensely simplified.

SCHOLARSHIPS IN MEDICAL EDUCATION, AND THE "POOR BOY"

As various reports on medical education have shown, it is the proprietary or commercially inclined medical schools which have been most avowedly solicitous for the "poor boy" but which do the least for him in return for what he does pay. The cry of "a medical education for the poor boy," therefore, has often meant a poor medical education (dear at any price) at the same or even greater cost than a good one, and this for the boy who is perhaps "poor" in scholarship rather than in purse. There is certainly no reason for encouraging the dullard or the ignoramus, even if he is also indigent, to attempt to practice medicine at the expense of the "poor" public. Yet it would be unfortunate if the career of medicine were indeed to be closed to ambitious and able young men because of lack of means. This danger has been emphasized in recent years by the increased expense connected with the teaching of medicine, which in turn, in some of the medical schools, has led to increased charges for tuition. On the other hand, some of the best medical teaching institutions, particularly the medical departments of state universities, have very low tuition fees, or, in some instances, make no charge except for laboratory fees. Again, in some of our best medical schools having high tuition fees, opportunities exist for determined students to make at least a part of their expenses; but the attempt to earn all expenses, while doing justice to the exacting work of a medical course, means a strain which few constitutions are fitted to endure. The solution of the problem lies in free scholarships to be awarded to good students who cannot afford to pay their own way. A review of the medical college announcements shows there is now a total provision for about 170 scholarships,[1] most of which are granted annually and are reserved for students of ability who are in need of financial aid. Included in the total are several which have been granted in recent years. In 1912, three scholarships were established at the Leland Stanford Junior University, School of Medicine, from "The Alumni Jordan Medical Scholarship Fund." In 1913, the Philadelphia Alumni Society of the University of Pennsylvania Medical Department founded a scholarship in honor of Dr. Roland G. Curtin. In 1914, through the generosity of an anonymous donor, ten free scholarships in the University of Cincinnati College of Medicine were announced. Last month a gift from Mr. James A. Patten of $27,000 was made to the Northwestern University Medical School to provide an endowment for eight free scholarships, and of these, two are to be awarded each year to the students with the highest standing in the College of Liberal Arts who enter the medical school and need such aid. It is to be hoped that these benefactions will serve as suggestions to men who are considering the direction which their philanthropies shall take, and that eventually all our best medical schools may have at their disposal a number of free scholarships sufficient to ensure that no promising student whose talents lie in the direction of medicine need to be prevented by poverty from entering on that work.

THE PROCEEDINGS OF THE NATIONAL ACADEMY OF SCIENCES

Beginning with January, 1915, the National Academy of Sciences has instituted the issue of a monthly journal, the *Proceedings*, which, in addition to being the official organ of publication of the Academy, will serve as a medium for the prompt presentation of brief original papers by members and other American investigators. Its aim will be thus to furnish a comprehensive survey of some of the more important results of the scientific research of this country, and it is intended to supplement, not replace, the papers appearing in special journals. The first number of the *Proceedings* contains, among others, papers on physiology and genetics, including a contribution by Davenport on "Violent Temper and Its Inheritance." This is an attempt to study the hereditary behavior of some of the elements of moral action — to analyze, by the methods of the Eugenics Record Office, the family history of persons who have marked emotional traits. Violent and more or less periodic outbursts of temper occur in families which are characterized by prevalence of epileptic attacks; also in those exhibiting cases of mania, and in others in which "hysteric" attacks are common. The special form of the attacks differs somewhat in these classes of families, but the method of inheritance of the tendency is the same in all, and it seems probable that in each class the simple symptoms of the emotional outburst are modified by the differences in these three classes of the nervous condition. The fact that the tendency to outbursts of temper does not skip a generation, according to the report of 165 family histories of wayward girls in state institutions, indicates that it is a positive or dominant trait. This tends to emphasize that such features have a typical hereditary basis, a statement which many sociologists who hold differences in the "conditions of life" responsible for the differences in men, are quite likely to dispute.

---

[1] The medical schools which provide for scholarships and the number in each are as follows: Leland Stanford Junior University, School of Medicine, 3; University of California, College of Medicine, 1; Northwestern University Medical School, 8; University of Illinois, College of Medicine, 4; Indiana University, School of Medicine, 10; Johns Hopkins University, Medical Department, 7; Boston University, School of Medicine, 5; Harvard University Medical School, 23; Detroit College of Medicine and Surgery, 3; Washington University Medical School, 1; Columbia University, College of Physicians and Surgeons, 31; Syracuse University, College of Medicine, 1; University of North Carolina, School of Medicine, 1; University of Cincinnati, Medical College, 10; Western Reserve University, School of Medicine, 1; Hahnemann Medical College and Hospital, 3; Jefferson Medical College, 2; University of Pennsylvania, School of Medicine, 54; University of Virginia, Department of Medicine, 1.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

New Clinic Opened.—A new tuberculosis clinic is to be opened at Ninth and Wilson Streets, Los Angeles, by Health Commissioner Luther M. Powers.

State Medical Board Appointments.—On January 22, the governor appointed Drs. Arthur M. Smith, Oakland; H. Clifford Loos, San Diego, and Harry V. Brown, Los Angeles, members of the State Board of Medical Examiners for a term of four years. Dr. Smith succeeds Dr. Samuel H. Buteau, Oakland, while the other members were reappointed. ——Dr. Adelaide Brown, San Francisco, has been appointed a member of the State Board of Health to succeed Dr. Oscar Stansbury, Chico; Dr. Frederick F. Gundrum, Sacramento, to succeed Dr. Wallace A. Briggs, Sacramento, and Dr. George F. Bright, San Francisco, to succeed Dr. Martin Regensburger of the same city.

FLORIDA

New Home for Tuberculous Insane.—The board of commissioners of state institutions has made arrangements at the Florida Hospital for the Insane, Tallahassee, for a building especially for the housing and treating of patients of the hospital who are afflicted with tuberculosis.

Model Vital Statistics Ordinance Passed.—The model ordinance for vital statistics has been passed by twenty Florida municipalities in addition to the registration cities. Eight other municipalities are expected to pass the ordinance in the near future, and it is under consideration by eleven other municipalities.

Branch Bacteriologic Laboratories Opened at Miami and Tallahassee.—The State Board of Health has recently opened two bacteriologic laboratories, which will be operated as branches of the central laboratory at Jacksonville. Both will be in charge of assistant bacteriologists of the State Board of Health, the one at Miami in charge of Dr. Iva C. Youmans and the one at Tallahassee in charge of Dr. William A. Claxton.

Hospital News.—A contract for the Morton F. Plant Endowed Hospital, Clearwater, has been awarded for $20,478.——There is at present at least $15,000 available for the construction of a new city hospital, Miami.——The Deland Hospital, located in the Nutt House, Deland, is now open and ready for the reception of patients. The institution at present will accommodate eight patients.——Former Governor Albert W. Gilcrist makes an urgent appeal for the establishment of a state hospital for indigent crippled children to be built in Jacksonville in accordance with a bill passed by the legislature of 1911.——The Emergency Hospital at West Palm Beach was reopened last month.——The mayor of Jacksonville is at the head of a movement to bring about the erection of a hospital for Jacksonville and Duval County and the Poor Farm at the City Prison Farm site. ——Dr. Calvin D. Christ, Orlando, has opened a sanatorium in Orlando in a building constructed especially for hospital purposes.——The East Coast Hospital Association has given notice of its intention to apply for charter. Its purpose is to establish a hospital at St. Augustine.

GEORGIA

Personal.—Dr. Robert C. Woodard has been appointed local surgeon for the G. S. and F. Railway at Adel.——Dr. Leon L. Moye, Vidalia, was operated on recently at Atlanta for peritonitis.

Surgeon Club Symposium.—The Georgia Surgeons' Club, Atlanta, will hold a two-day clinic in that city, February 25 and 26. On the evening of the first day, a symposium on "Surgical Indigestion" will be held.

Physicians Club Organized.—The Physicians' Club of Atlanta was organized, January 19, with an initial membership of more than 100, and the following officers were elected: president, Dr. George P. Huguley; vice-president, Dr. Edgar L. Griffin; secretary, Dr. S. T. Harris, and treasurer, Dr. William A. Arnold.

Work for Eradication of Hookworm.—The State Board of Health has issued a bulletin giving details of the hookworm work carried on in the counties of the second district. In November, 1911, the department of field sanitation of the State Board of Health began to institute free dispensaries in the counties of the second district. Work has been carried on in Early, Mitchell, Colquitt, Decatur, Grady, Thomas, Tift and Worth counties. A successful campaign is now in operation in Miller County and an appropriation for work begun in January has been secured for Baker County. The work must be done by June 30, 1915, because the organization then ceases.——Dodge County on January 21, appropriated $150 to supplement the funds given by the Rockefeller Institute for the campaign against hookworm and for better sanitation.——The work of the Rockefeller Sanitary Commission will come to an end in Georgia, June 30. Meanwhile, the State Board of Health is undertaking work in the various counties, Dr. Floyd D. Rodgers, Columbia, S. C., assistant director of field sanitation, being now engaged in Richmond County, where 66 per cent. of the rural population are said to be infected with the disease.

ILLINOIS

Leper at Club.—Angelo Lunardi, night watchman at the Exmoor Country Club, Highland Park, is suffering from tubercular leprosy and has been placed in isolation pending the decision of the question of his deportation.

College Closed on Account of Scarlet Fever.—McKendree College at Lebanon was closed early in February on account of the reappearance of scarlet fever in the school. Two new cases were found This is the second time within a month that the school has been closed on account of this disease.

Personal.—A committee of medical men from the Winnebago County Medical Society of Rockford presented a petition to the mayor, January 30, signed by practically every member of the society, requesting him not to accept the resignation of Dr. Daniel Lichty, Rockford, from the board of the Tuberculosis Sanatorium.——Dr. Thomas B. Knox, Quincy, has resigned as president of the Adams County Tuberculosis Society.——Dr. William Healy, Winnetka, has passed the examination for director of the Juvenile Psycopathic Institute, Chicago, with the highest average.

Chicago

Hospital Site Selected.—A new hospital to cost about $100,000 and to be known as the Concordia Evangelical-Lutheran Hospital, is to be erected on Hadden Avenue, near Kedzie, where the trustees have acquired a tract 300 by 117 feet.

Ventilation of Street Cars.—Under an amended ordinance the health department now has authority to supervise the ventilation of elevated and surface cars. Recently samples of air were taken from 220 cars. In 150 of these carbon dioxid was found in quantities far in excess of the standard set by the ordinances and suit will be filed on these violations. Suits have also been brought for failure to operate ventilating fans in 128 instances.

Society Incorporated.—The Robert Koch Society for the Study of Tuberculosis, which has been in operation for about two years, has been incorporated with the following charter members: Drs. Theodore B. Sachs, Henry B. Favill, Frank S. Johnson, Ethan A. Gray, John Ritter, Orville W. McMichael and James A. Harvey. One of the prime objects of the organization is the dissemination of information on tuberculosis among medical men at large.

Safeguarding Against Scopolamin Casualties. — The authorities of Michael Reese Hospital announce, as the result of their experience after a series of about forty obstetric cases treated by the scopolamin-morphin anesthesia, the so-called "Twilight Sleep," that they will not use this method in labor except with the express guarantee of the patient that the hospital shall be free from all liability as regards ill results to the mother or the child.

INDIANA

Decrease in Sales of Narcotics.—A report from the State Board of Pharmacy shows that there has been a very marked decrease in the sale of all narcotic drugs during the year 1914. This is thought to be due to the anticocain law which went into effect in 1913.

Sanitary Survey.—A sanitary survey of the schools of Porter County was started February 1 by Surg. Taliaferro Clark, U. S. P. H. S., with five assistants. This survey has been requested by Dr. Simon J. Young, Valparaiso, health commissioner of Porter County.

Free Clinic at Anderson.—St. John's Hospital, Anderson, has offered the clinic committee of the Council of Women of that city, the use of two well lighted rooms in the basement of the new hospital addition for the use of the clinic. The addition will be opened about March 15.

Vaccination Required by Large Industries.—The Union Traction Company of Indiana, it is reported, has issued an order at Muncie that all employees must be vaccinated if not previously thoroughly protected.——City Health Officer Noah D. Berry, Muncie, has also canvassed the large industries of the city asking the managers to secure prompt and effective vaccination of all employees, and it is believed the majority will comply with this request.

Bills Before the Legislature.—One of the most important bills introduced into the Indiana legislature and one which has received wide-spread support from medical men is the bill providing for the registration and quarantining of tuberculosis patients. This bill places tuberculosis in the same class as other contagious diseases. It provides for the complete registration of cases of this disease and report within twenty-four hours after discovery to the local health officer, making this report obligatory not only on physicians but also on nurses, employers, teachers and others; also requiring the complete disinfection of all houses wherein tubercular patients have died.——One of the legislative measures before the present house of representatives, which has received condemnation by members of both parties gives the governor, secretary of state and auditor of state power to appoint the secretary of the State Board of Health. This measure is aimed to remove Dr. John N. Hurty, Indianapolis, state health commissioner, who for nearly twenty years has been at the head of the hygienic, sanitary and medical work in this state.

MARYLAND

St. Luke's Hospital Closed.—Owing to lack of funds, St. Luke's Hospital, Baltimore, has been forced to close.

Brady Institute in Service.—The Brady Urological Institute at Johns Hopkins Hospital has been put into full service. Eight patients have been transferred from the hospital proper to the new rooms of the clinic. Fourteen ward patients have been installed in the last week and the admittance of the room cases put the new building into active service. No ceremonies were held in connection with the inauguration. The formal dedication of the institute is to be held in the spring. The building is entirely complete, with the exception of full equipment for the laboratory work and experiments. Nearly $250,000 has been spent in the venture, the gift of Mr. Brady of New York.

MASSACHUSETTS

Fire at State Infirmary.—Fire in the combination cloth and storage dormitories of the State Infirmary, Tewkesbury, caused damage of $2,000. Panic was avoided by the efforts of the superintendent and attendants.

Health Officers Elected.—At the annual meeting of the Massachusetts Association of Boards of Health, held in Boston, January 28, Dr. Milton J. Rosenau, Boston, was elected president, and Dr. Francis H. Slack, Boston, secretary.

Ambulance Chasers Law.—The first case under this new 1914 law accuses Harry Noonan of soliciting, procuring and attempting to procure the management and control of the claim of Gertrude Lake against the Boston Elevated Railway for an accident which occurred January 11.

Age Limit Raised.—The Massachusetts State Department of Health announces that for the first examination for the position of district health officer, under the regulations prepared by the Public Health Council of the department governing appointments and promotions of district health officers, the age limit has been raised from 32 to 36 years.

Censure of Dr. Cabot.—Publicity is given by the daily press to the fact that the Dorchester Medical Society at a recent meeting passed resolutions censuring Dr. Richard C. Cabot, Boston, for his criticism of the medical profession. Similar resolutions presented at the last meeting of the Norfolk District Branch of the Massachusetts Medical Society, in which district Dorchester lies, were debated and laid on the table.

Personal.—Dr. George B. Magrath, Boston, has been reappointed medical examiner of Suffolk County.——Dr. James L. Wellington, Swansea, the oldest graduate of Harvard Medical School, recently celebrated his ninety-seventh birthday anniversary.——Dr. William L. Richardson, Boston, has been appointed a trustee for the Perkins Institution and the Massachusetts School for the Blind.——Drs. Frederick C. Shattuck, Boston, and Clarence J. Blake, Boston, have been elected members of the board of managers of the Boston Children's Hospital.

MISSOURI

Asks Shifting of Appropriation.—The board of managers of the State Sanatorium for Tuberculosis of Mt. Vernon appeared before the house committee of Jefferson City, January 28, and made a plea for a more advantageous distribution of the appropriation recommended by the legislative committee. The amount appropriated was sufficient, but they asked that more buildings for patients be provided as this is more urgent at present.

Personal.—Dr. Charles R. Woodson, St. Joseph, was assaulted by a man who entered his office presumably to consult him professionally. Dr. Woodson overpowered him but was struck on the head with a pistol, suffering a fracture of the outer plate of the frontal bone. The man was intoxicated and later said he had no recollection of the assault. Dr. Woodson is recovering from the attack.——Dr. Dexter B. Farnsworth, Springfield, was presented with a gold-headed cane by the members of the Greene County Medical Society in recognition of his sixteen years' service as treasurer. He declined reelection.——Dr. Walter S. Wheeler, health commissioner of Kansas City, who underwent an operation last month, is said to be doing well.——Dr. James J. Brien, Oronogo, fractured a rib and sustained cuts and bruises by the overturning of his automobile, between Oronogo and Galesburg, recently.

St. Louis

Asks Appropriation to Fight Tuberculosis.—The St. Louis Society for the Relief and Prevention of Tuberculosis made an appeal at a public hearing with the board of estimate and apportionment for an appropriation of $75,000 to assist in the work against tuberculosis in St. Louis.

Research Department to Be Discontinued.—The board of directors of the Barnard Free Skin and Cancer Hospital took action at their December meeting to discontinue the research department as at present operated, the order to take effect April 1. The present financial situation is responsible for the retrenchment.

NEW YORK

Sanatorium Bonds Purchased.—The Trust and Deposit Company of Onondaga, Syracuse, has purchased the $185,000 bond issue for a tuberculosis sanatorium for Onondaga County, at a premium of $2,645.

Senate Gets Coroner's Bill.—The bill abolishing coroners in New York City and substituting medical examiners has been presented to the legislature with the endorsement of the New York City administration.

New Children's Hospital.—The Rochester Public Health Association has remodeled the third floor and attic of its building on Troup Street, to provide hospital wards for work by the association in its charter as a children's hospital.

Parole of the Insane.—The State Charities Aid Association reports that the reorganization of the parole system in the fourteen state hospitals for the insane has saved the state $87,000 in a year. Under this system many patients are returned to their homes and are frequently examined by medical experts. It is found that frequently the home environment has proved beneficial, and as the cost of maintenance of each patient is $200 per annum, this means a considerable saving to the state. The association advocates a judicious extension of the system.

New York City

Classes for Abnormal Children.—On February 8 there was opened at Speyer School, which is the experimental school of teachers college, a special class for exceptional children under the direction and with the cooperation of specialists in education psychology, elementary education and physical education of the college staff.

Caring for Mental Defectives.—Charity Commissioner Jerome Kingsbury has decided to consider the plan for a clearing house for mental defectives submitted by Dr. Max

WAR NOTES

Red Cross Reenforcements.—The American Red Cross announces that three surgeons will leave for Europe shortly. These are Dr. Earl B. Downer, Lansing, Mich., who is assigned to Hospital Unit No. 1 at Belgrade, Servia, and Drs. James E. Stowers, Kansas City, Mo., and Edgar L. Gilcreest, Gainesville, Tex., who will replace two of the American surgeons in the Red Cross Hospital at Paignton, England.

Fatalities in French Corps.—The first list that has come to hand that makes any pretensions to completeness appears in the *Caducée*, which has just arrived. It gives the names and titles of fifty-two French surgeons who have been killed and of thirty-one wounded. The list of killed includes two undergraduates, Senator Reymond, and Dr. A. Marie, physician in chief of the Villejuif asylum. Their deaths were mentioned in the Paris Letter at the time.

Meningitis Outbreak Traced to Valcartier Camp.—It is stated that the Canadian troops will remain in England until all the meningitis cases at Salisbury Plain have terminated. The outbreak started at Valcartier, the first death taking place at Quebec and the second on arrival at Plymouth. There have been twenty-five deaths and only two recoveries out of twenty-nine cases. Two patients are now in the hospital, regarded as incurable. Five cases have occurred among children at Salisbury. Professor Ashworth of the Lister Institute is studying the outbreak.

Appreciation for Special Gallantry Under Fire.—The French government publishes notices in the official journals calling attention to the special services and gallantry of certain persons, describing each by name and title and the special action in detail. The Austrian government does the same, and these touching tributes often fall to the lot of the members of the medical and nursing staff. The last *Wiener klinische Wochenschrift* gives the names and titles of six surgeons thus singled out for special mention on account of brave and devoted services under fire. (Anbefohlen, dass die kaiserliche belobende Anerkennung bekanntgegeben werde: in Anerkennung tapferen und aufopferungsvollen Verhaltens vor dem Feinde; the name and title follows. The French notice reads: Le gouvernemente porte à la connaissance du pays la belle conduite, etc.) The German authorities decorate with the iron cross for special gallantry under fire or services otherwise; the mere conferring of this decoration is equivalent to calling the attention of the country to the recipient's devoted services.

Aid for Belgian Physicians.—Dr. F. F. Simpson, Jenkins Arcade Building, Pittsburgh, Pa., treasurer of the committee of American physicians for the aid of the Belgian profession, announces for the week ended Feb. 6, 1915, the following contributions:

Dr. Willard Bartlett, St. Louis, Mo.		$ 10.00
Dr. M. Manges, New York, N. Y.		15.00
Dr. G. D. Hale, P. A. Surg., U. S. N., San Francisco, Cal.		10.00
Dr. Alfred Wiener, New York, N. Y.		10.00
Dr. John Woodman, New York, N. Y.		5.00
Dr. Robert T. Frank, New York, N. Y.		10.00
Cash—B, Pittsburgh, Pa.		10.00
Dr. R. O. Raymond, Flagstaff, Ariz.		10.00
Dr. A. Hymanson, New York, N. Y.		5.00
Dr. Mazyck P. Ravenel, Columbia, Mo.		15.00
Oklahoma State Med. Assoc., Muskogee, Okla.		100.00
Dr. H. H. Sherk, Pasadena, Cal.		25.00
Dr. Charles Lee King, Pasadena, Cal.		20.00
Dr. James Williamson, Philadelphia, Pa.		5.00
Dr. J. S. Kauffman, Blue Island, Ill.		5.00
Dr. John P. Treanor, Dorchester, Mass.		10.00
The Clinical Club of Albany, Albany, N. Y.		25.00
Dr. Thomas J. Watkins, Chicago, Ill.		50.00
Dr. H. E. Oesterling, Wheeling, W. Va.		10.00
Dr. Leslie W. Schwab, Chicago, Ill.		2.00
Dr. A. Howard Smith, Marietta, Ohio		5.00
Dr. Woodson H. Taulbee, Maysville, Ky.		5.00
Total		$ 362.00
Previously reported receipts		2,166.00
Grand total		$2,528.00
Previously reported disbursements	$2,090.00	
Disbursements week ending Feb. 6th	440.00	
Total disbursements		$2,530.00
Deficit		*$2.00*

Dr. Lewis S. McMurtry, Louisville, Ky., and Dr. Charles A. L. Reed, Cincinnati, Ohio, have consented to become members of the committee of American physicians for the aid of the Belgian profession. At the request of the treasurer, the executive committee has arranged to have the accounts audited quarterly. The first audit will be about March 20.

LONDON LETTER

London, Jan. 22, 1915.

First Issue of New Journal

In the *Journal of the Royal Naval Medical Service*, a new periodical which made its first appearance in January, Surgeon-General Donald T. Hoskyn, R. N., of the Royal Naval Hospital, Hong Kong, has a note on the use of subcutaneous injections of the salts of emetin. He refers to six cases, of which he reports two; first, one of diarrhea with some constitutional disturbance and stools containing blood and mucus, was successfully treated with subcutaneous injections of emetin hydrochlorid, ⅙ grain, morning and evening. In the second case, in which 1 grain of emetin was administered daily at one dose, amebas were found. The patients who received only 1 grain were cured with an average of 5½ doses in fifteen days, while those who received ⅙ grain twice a day required 16½ doses and forty and one-half days. Thus he concluded that larger doses save time. The author also speaks from experience of the value of the drug in simple colitis, in which only one injection was required to effect a cure. The new journal contains also articles on the British antarctic expedition, 1910-1913, by Staff-Surgeon E. L. Atkinson, R. N.; on the naval action off Heligoland, by Fleet-Surgeon Walter K. Hopkins, R. N.; on the treatment of the wounded at three of the naval base hospitals, by the respective medical officers; a simple method of localizing bullets, by Surgeon S. Bradbury, R. N.; a report by Fleet-Surgeon M. L. S. Rodd, R. N., on the transport and treatment of wounded on the hospital ship *Plassy*; on typhoid and its prevention, by Fleet-Surgeon P. W. Bassett Smith, C. B., R. N., and on the flying service from a medical point of view, by Staff-Surgeon Hardy V. Wells, R. N. The journal is edited by Fleet-Surgeon R. C. Munday, R. N., and Fleet-Surgeon W. L. Martin, R. N.

The War

THE AIR RAID ON THE EAST COAST

After dark one evening, German airships appeared over the unfortified towns of Yarmouth and King's Lynn and dropped bombs. In the former town a shoemaker, aged 53, and a woman aged 72 were killed by the explosion. At King's Lynn a woman, aged 26, and a boy, aged 14, were killed. Arrangements have been made by the police in London, and other places where air raids are likely to take place, for the prompt rendering of first aid to the victims. Dressing stations have been arranged to which physicians have been assigned. A warning has also been issued to all persons to take cover preferably in basements or cellars, in case of aerial attack. It is pointed out that in the streets, danger will be incurred not only from bombs dropped from air craft but also from the falling of missiles from guns directed against them.

THE SHORTAGE OF PHYSICIANS

Women have been admitted to the medical profession in this country for about a generation, but their practice apart from hospitals and even to a certain extent in them has been almost confined to women and children. This is partly due to their own desire and partly to the view of the public as to their sphere. The war has considerably altered the position. At the front, five hospitals are staffed entirely by women. At home, the scarcity of physicians resulting from the needs which are constantly increasing in consequence of the expansion of the army has produced a great demand for women physicians and dispensers to fill the places vacated by men. Another cause of increased demand for women physicians is the national insurance act. Under it five million women are insured and a great number take advantage of the free choice of physician allowed and select a woman. At some hospitals, the difficulties in filling vacancies in the resident staff is so great that it has been found impossible to carry out the rule by which appointments must be held by qualified physicians. Medical students have to be appointed. It is understood that the War Office will require 1,200 more physicians in connection with the new armies. This, of course, will further increase the difficulty.

A MOTOR OPERATING THEATER AND A MOTOR LABORATORY

A motor operating theater has been devised by an Aberdeen surgeon, Mr. G. H. Colt, with the idea of constructing the smallest theater in which an operation can be performed in comfort, and arranging that the contents shall be as light as possible. By using a 3 ton chassis it has been found that the length of the interior of the theater can be increased to 13 feet 4 inches, and the width to 6 feet 6 inches. In addition, a cab can be provided in front 5 feet wide and 3 feet 6 inches from front to back. The design is intended to provide for the continuous use of two operating tables. The scheme has not yet been adopted by the War Office. A fully equipped motor bacteriologic laboratory has been placed at the service of the War Office by an anomymous donor. The main laboratory is 6 feet 6 inches long and 6 feet wide, and is equipped with glass covered bench top, sink, centrifuge, balances, microscope, book shelf, water cistern, reagents, etc. A smaller compartment 2 feet 10 inches in depth by 6 feet wide is separated from the laboratory by sliding doors and contains two incubators, hot air and steam sterilizers, still and condenser, autoclave and water bath. Electric current for general and microscopic illumination is obtained by a dynamo driven from the engine. In association with the laboratory car is a motorcycle with side car attachment which provides a means of fetching pathologic fluids and specimens from points nearer the firing line than the car itself would ordinarily reach. Captain A. C. H. Gray, assistant professor of pathology at the Royal Army Medical College, is in charge of the laboratory.

BRITISH HOSPITALS FOR THE BALKANS

The dispatch from this country of a hospital unit for Serbia has been previously reported in THE JOURNAL. Two more hospital units are now being sent to the Balkans, one to Serbia and the other to Montenegro. The Serbian unit is in charge of Mr. James Berry, the well-known surgeon, and will be transported free of cost by the British Admiralty. A full medical and surgical outfit, as well as clothing, and other comforts for the Serbian people will be taken. Excepting one surgeon and the radiographer, the staff consists almost entirely of women—the house surgeon, dressers, eight nurses and five women orderlies. It is being furnished by the Royal Free Hospital, which is the medical school for women in London, to which Mr. Berry is senior surgeon. The unit for Montenegro is in charge of Dr. F. G. Clemow, and the staff consists of two surgeons, two trained nurses, two voluntary aid detachment women, and four male orderlies.

PARIS LETTER

PARIS, Jan. 21, 1915.

The War

INTERNS OF THE HOSPITALS AND THE WAR

The minister of war has recently decided that medical students who have passed the *concours* for internships in cities where there is a Faculté de médecine, may, so long as the war lasts, be nominated at their request where vacant places exist for the grade of *médecin aide-major* (grade corresponding to that of sub-lieutenant). In order to qualify they must have filled the position of intern for at least a year and have had the four years' work required for the doctor's degree. Professor Landouzy, dean of the Faculté de médecine de Paris, has drawn the attention of the minister of war to the fact that the second condition may deprive the health service of a considerable number of valuable assistants. It frequently happens that the interns, being more devoted to the hospital than to the school, postpone the examinations which permit them to qualify for the doctor's degree. So far as competence goes, however, the years of the internship, lived in contact with patients, are much better guarantees than the years of class-room instruction. As Landouzy says, between the student who has passed all his examinations and the student performing the duties of an intern there is the same difference that there is between a cadet finishing his course in the military school and the soldier who has seen active service. There are interns who, though they have had only three years' class room work, are expert assistants, whose aid would be particularly desirable under present circumstances.

The medical group in parliament in a meeting held under the presidency of Dr. Léon Labbé, senator, has decided to ask the minister of war for the immediate nomination to the grade of assistant physician (corresponding to that of noncommissioned officer) of medical students who have had three years' of medical school work and interns of the hospitals in cities where there is a faculté de médecine.

THE FOOD-SUPPLY OF THE ARMIES IN THE FIELD

At the last session of the Société de pathologie comparée, M. Maurice Piettre, a veterinary officer, presented a long report on this subject. In order to economize the stock of the country, already much depleted by the first five months of the campaign, it would be desirable to have recourse, as has already been proposed, to pork, which is very nutritious and cheap at this time of the year. The real solution of the problem, however, consists, according to M. Piettre, in the liberal use of frozen meats from South America and Australia, the purchase of which, in spite of speculation, should permit an important economy in our home-grown meat. M. Piettre has studied carefully the adaptation of the food-supply to the new conditions of the war—a war of siege with sojourn in trenches where it is almost impossible to supply cooked meats and vegetables. The solution will consist in putting into practicable form the physiologic ration for intensive labor (150 gm. of albuminoids, 100 gm. of fats and 500 gm. of carbohydrates). The problem of albuminoids has already been solved by the regulation 300 gm. can of meat in which, the waste matter having been removed, there is from 50 to 60 gm. of fat. Another class of canned food (vegetables) needs to be devised which shall contain the remainder of the ration of fat, that is, from 100 to 150 gm. of lard or roast pork and 500 gm. of vegetables (carrots, peas, beans, string beans, lentils, etc.) in suitable mixtures and with suitable seasoning. Provisions for marching or for the trenches would thus be reduced to two classes of cans,, one of meat (beef or pork) the other of vegetables with fat, which could be warmed up in a few minutes by the use of solidified alcohol.

The excessive use of meats presents many inconveniences. The need of vegetables and even of cooked fruits (apples and prunes) is keenly felt in the trenches. As the chemist, Armand Gautier, has said, there is danger in drawing more than 60 or 65 per cent. of the food nitrogen from flesh foods. The weight of the protein ought not to exceed one-fourth of that of the ternary substances.

A SIMPLE MEANS OF EXTRACTING FOREIGN BODIES IN WOUNDS OF WAR

In a recent session of the Académie de médecine, Dr. Lacroix called attention to the procedure of injections of hydrogen peroxid in wounds of war in which bones are fractured. The foaming up from the interior of the wound brings the foreign bodies with it. Independently of Dr. Lacroix, other surgeons have experimented with this procedure, and it has given good results when the foreign bodies consisted of fragments of clothing. It is less efficacious when metallic fragments are present, especially if they have become encrusted into the walls of the wound.

PARLIAMENTARY INVESTIGATION INTO THE HEALTH OF THE ARMY

The commission of public hygiene of the Chamber of Deputies has asked the minister of war for an opportunity to collect information with regard to the working of the health services of the army. Three subcommissions of four members each are about to visit the sanitary formations. The first subcommission accompanied by Dr. Chavasse, medical inspector-general, will visit the army zone. During its absence the other subcommissions will investigate the hospitals, etc., in the zone of the interior with a view to suggesting all possible improvements.

BERLIN LETTER

BERLIN, Jan. 12, 1915.

The War

MEDICAL CASUALTIES

According to the latest official list, 132 medical men have so far been killed in the war, 22 wounded, 45 have died and 166 are missing or prisoners. Among the medical victims of the war are, unfortunately, three distinguished scientists. A few days ago, Professor Jochmann, the medical head of the infectious department of the municipal Rudolph Virchow Hospital, succumbed to typhus fever which he acquired in the examination and treatment of Russian prisoners, of whom 800 are ill with typhus. In Jochmann, who was only 40, we have lost one of our most talented young internists, who was endowed with an extraordinary combination of preparatory training in bacteriology and clinical experience in the field of infectious diseases. He laid an especially thorough foundation for the study of disease as a pupil of Professor Strümpell at Breslau and of Lenhartz at Hamburg. In the Virchow Hospital, the infectious department of which is in combination with the Robert Koch Institute for Infectious Diseases, he had a splendid opportunity to extend his clinical experience and place it on a broad bacteriologic basis. He published the results of his investigations in numerous articles and addresses and further in contributions to various treatises. As the most mature fruit of his work a text-book on infectious diseases appeared a few weeks ago. This must be considered both from its contents as well as from its illustrations as the leading work in this field, at least in German literature. It must be regarded as an especial tragic circumstance that Jochmann himself died from an infectious disease, one almost wholly unknown in Germany, but now present in our country as a consequence of the war.

Another victim of the war is Professor Sprengel, the superintendent of the surgical department of the Ducal Hospital in Brunswick. He died from sepsis at the age of 62, having infected himself at an operation on a wounded soldier. Sprengel was an excellent practitioner and had published a large number of excellent monographs, particularly one on appendicitis. He was a collaborator on Deutsche Chirurgie and on the text-book of Kocher and de Quervain.

The Freiburg dermatologist, Professor Jakobi, died in the field as a result of disease. This scientist, who had reached the age of nearly 53, was an assistant of Neisser, and joined the faculty of Breslau in the department of skin diseases in 1890 and in 1895 was appointed professor extraordinary. In addition to numerous single treatises, he published an atlas of skin and venereal diseases and in connection with Neisser was the editor and publisher of *Iconographia dermatologica.*

IRON CROSSES FOR PHYSICIANS

To date, 2,700 physicians and surgeons have received this decoration for valor. It is moreover notable that the efforts of the leaders of the army to make the medical officers equal in rank with the regular army officers have found expression in the bestowal of the iron cross. While in the Franco-German War of 1870-71 the iron cross for physicians was awarded only to be worn on the ribbon provided for a noncombatant, in this war they receive it on a black and white ribbon, such as is given the fighting soldiers as a reward for gallantry.

TRANSPORTATION OF THE WOUNDED

While in the beginning the transportation of the wounded in our army was somewhat imperfect, on account of the extreme demands imposed on the medical service by the great battles of the immense army as well as on account of the preference which was given to the trains for troops and ammunition over the medical service, later and particularly in the last months complaints of such imperfections have ceased. This is essentially due to the better equipment of the hospital trains, which provide for a quicker and more suitable removal of the wounded from the seat of war to the base hospitals and especially to their home districts. In the equipment of the hospital trains, private persons and officials have competed, as in all other fields of social and military benevolence. Many cities and well-to-do persons have placed hospital trains of this sort at the disposal of the government. A few days ago, one of the most comfortable trains, fitted out by a member of the world-renowned banking house, Bleichröder, at an expense of $25,000 (100,000 marks) was placed in service and Professor Israel was put in charge. It is worthy of special recognition that Professor Israel, in spite of his 67 years, should undertake so difficult a service.

THE CONSERVATION OF FOOD SUPPLIES

The measures which the government has now taken to an increased extent to secure economy in the employment of foodstuffs, especially of grains and particularly of wheat are not to be taken as a sign of established need. Our supplies of foodstuffs are sufficient until the next harvest, and the present limitations on their use prescribed by the government may be regarded as a wise provision, a precaution taken at the right time. These precautions have, in fact, the purpose of preventing careless disregard to economy in the matter of nutrition but not to force an insufficient nutrition. On the other hand, it will be of advantage for the health of our people if the excessive consumption of meat, which has grown more and more as a result of our prosperity in the last few years, can be reduced to an intelligent moderation based on hygiene. The same is true, naturally, of the use of alcohol and other luxuries. People will learn how to get along with the restriction in the production of pastry which stands in close relation to the reduction of wheat flour. It appears likely that we shall not need to depend for our nutrition simply on our own agriculture but will be assisted directly or indirectly by the neutral states in spite of blockading (Einkreisungspolitik). Since Russia has raised the embargo on exportation of eggs for Sweden and Bulgaria for beans, cheese, lard and hogs, these foodstuffs no doubt will reach us.

Association News

THE SAN FRANCISCO SESSION

Chairmen of Subcommittees of Local Committee on Arrangements

The local Committee on Arrangements for the San Francisco session has appointed the following as chairmen of its several subcommittees:

Finance: J. Henry Barbat.

Hotels, Headquarters and Information: George B. Somers.

Halls and Section Meetings: W. P. Lucas.

Commercial Exhibits: R. E. Bering.

Entertainments and President's Reception: Emmet Rixford.

Section Entertainments: W. P. Lucas.

Press and Publicity: Sol Hyman.

Scientific Exhibits: William Ophüls.

Communications which naturally fall under one of these divisions should be addressed to the chairman of the appropriate committee at 916 Butler Building, San Francisco.

Additional Special Trains[1]

THE AMERICAN MEDICAL DIRECT ROUTE SPECIAL

This train is routed over the Chicago and Northwestern Railroad, Union Pacific and Southern Pacific, and the schedule noted below is arranged with a view of making the trip between Chicago and San Francisco in as short a time as is practical. The following schedule is announced:

Lv. Chicago	Friday	June 18,	5:30 p. m.	C. & N. W. Ry.
Ar. Omaha	Saturday	June 19,	6:00 a. m.	C. & N. W. Ry.
Lv. Omaha	Saturday	June 19,	6:30 a. m.	U. P. Ry.
Ar. Ogden	Sunday	June 20,	9:10 a. m. (M.T.)	U. P. Ry.
Lv. Ogden	Sunday	June 20,	11:30 a. m. (P. T.)	S. P. Co.
Ar. San Francisco	Monday	June 21,	11:00 a. m.	

Leaving Chicago Friday, June 18, via the Chicago and Northwestern Railway, the line west and northwest of Chicago which, with its connections, the Union Pacific and Southern Pacific, formed the first transcontinental line, the route traverses the northern part of Illinois, crossing the Mississippi River at Clinton, Iowa, and passes through the central portion of Iowa, a region noted for its productive farms and rich dairies. The Missouri River is crossed at Omaha, early on the morning of June 19. From this city, the route closely follows the old overland stage trail to Ogden, Utah, a distance of about 1,000 miles. This historic wagon road was the pioneer overland route before the building of the railway. Following the Platte River Valley, the road gradually reaches a higher altitude. Shortly after leaving Cheyenne, Wyo., the train passes through Sherman, the highest point on the route. Between Sherman and Ogden, the interest of the traveler will be centered on Green River, Rock Springs, Evanston, Echo and Weber Canyons. The train is scheduled to arrive at Ogden at 9:10 a. m., Sunday, June 20, Mountain Time, and will leave at 11:30 a. m. Pacific Time, by way of the Southern Pacific. The roadway is directly across the Great Salt Lake over the "Great Salt Lake Cut-Off," so that travelers enjoy the novelty of "going to sea by rail," since for 30 miles the train crosses the lake.

Through Nevada and California, the train passes such historic places as Donner Lake, Emigrant Gap, Blue Canyon, American River, Sacramento and Benicia, and is scheduled to reach San Francisco on Monday morning, June 21, at 11:30.

This Direct Route Special train is scheduled to make the run between Chicago and San Francisco in sixty-five and one-half hours.

THE AMERICAN MEDICAL GRAND CANYON ROUTE SPECIAL

The American Medical Grand Canyon Route Special is scheduled to leave Chicago, June 13, via the Santa Fe, and to permit visits to the Grand Canyon and the Panama California Exposition at San Diego en route. The entire day of June 16 will be spent at Grand Canyon, Arizona, and the day of June 18 at San Diego, arriving in San Francisco Monday morning, June 21, at 9:40. An additional fare of $7.50 is charged for the Grand Canyon side trip. The Pullman rates for lower berth are $5 more than the rate for direct routes without stopover.

---

[1] Other special trains to San Francisco were announced in The Journal, Feb. 6, 1915, p. 527; rates in the issue for Jan. 30, 1915, p. 457.

Following is the schedule:

June 13—Leave	Chicago	8:05 p. m.
June 14—Arrive	Kansas City	8:45 a. m.
June 14—Leave	Kansas City	9:00 a. m.
June 14—Arrive	La Junta	10:45 p. m.
June 15—Arrive	Albuquerque	11:00 a. m.
June 16—Arrive	Grand Canyon	6:50 a. m.
June 16—Leave	Grand Canyon	7:40 p. m.
June 17—Arrive	Los Angeles	2:40 p. m.
June 17—Arrive	San Diego	6:30 p. m.
June 19—Leave	San Diego	8:40 a. m.
June 19—Arrive	Los Angeles	12:50 p. m.
June 20—Leave	Los Angeles	5:00 p. m.
June 21—Arrive	San Francisco	9:40 a. m.

The route followed is along the historic old Santa Fe trail. As will be noted, the train leaves Chicago at night, reaching Kansas City early the next morning. The next day the train passes through Kansas, late in the afternoon of June 14 reaching Colorado, and then through Trinidad and across Raton Pass during the night. Early the next morning, June 15, it will be in the adobe land, the territory of the Mexican and Pueblo Indians. It is interesting to note the development of the country which has resulted from the conservation of the water supply, and similar agricultural developments. The Glorieta Range is crossed at an elevation of 7,453 feet. Here, Starvation Peak, and the old Pecos Church are of interest. Further south is Albuquerque on the Rio Grande, which point should be reached at 11 in the morning of June 15. Here, a stop of half an hour will be made, permitting a visit to the Indian museum on the station grounds. Immediately after leaving Albuquerque, the uphill climb to the Continental Divide begins, and the Indian village Isleta is passed. This settlement was an old one when Coronado visited it in 1540. During the afternoon the train passes through the black lava flows and huge red cliffs. The morning of June 16 will find the train parked on the brink of the Grand Canyon of the Colorado. The entire day will be available for trips along the rim of the Canyon, or for going down the Bright Angel Trail. The train leaves Grand Canyon at 7:40 p. m. From this point, it is practically down hill all the way to the eastern boundary of California, where the Colorado River is crossed at Needles. By daylight on June 17, the train will be in the Mojave Desert. About noon, it will pass down the slopes of Cajon Pass across fertile acres of fruits and flowers, and is due to reach Los Angeles at 2:40 in the afternoon. The special will not stop at Los Angeles but will go through to San Diego. The journey from Los Angeles to San Diego is through orange, olive and walnut groves, passing beautiful little cities and the San Juan Capistrano Mission, perhaps the most picturesque of all the old missions. Then for many miles the road skirts the Pacific, and the train should reach San Diego at 6:30 in the evening. The famous Hotel del Coronado is just across the bay. The entire day, June 18, is given to seeing San Diego and the Panama California Exposition. Leaving San Diego at 8:40 a. m., June 19, the train will return to Los Angeles, reaching that city at 12:50 p. m. Here the train will be parked at the Santa Fe station until 5 o'clock of the afternoon of June 20, when the special will leave for San Francisco, arriving at 9:40 Monday morning, June 21.

Morbidity Reports.—Morbidity reports when recorded over a period of time and properly compiled become a record of the past occurrence of disease. They show the relative prevalence of disease from year to year and under varying conditions. They show the effect of the introduction of public health measures and of sanitary works. They give a history of disease not obtainable in their absence.—John W. Trask, Supplement No. 12, Public Health Reports, April 3, 1914.

Marriages

Amy Bell Rohrer, M.D., and Rev. August Frederick Albert Neudoerffer, at Rajahmundry, Madras Presidency, India, Dec. 3, 1914.

Philip Newton, M.D., Washington, D. C., to Princess Helene Schaholfskaya of Kiev, Russia, at Petrograd, Russia, recently.

Captain Ernest Robert Gentry, M. C., U. S. A., to Miss Lydia Fuller, at Fort Leavenworth, Kan., February 6.

Mark Delimon Stevenson, M.D., Akron, Ohio, to Miss Martha von Norelly of Vienna, Austria, January 29.

Leonard Pratt Daws, M.D., Juneau, Alaska, to Miss Effie Lenore Buzard of Albany, Mo., Dec. 30, 1914.

Rachel Buchanan McMaster, M.D., and Rev. Samuel Hutson Hay, at Winnsboro, S. C., Dec. 29, 1914.

Ray Samuel Friedby, M.D., Akron, Ohio, to Miss Mary Emily Thomas of Delaware, Ohio, Dec. 31, 1914.

William Albert Dearman, M.D., to Miss Stella Wright Gates, both of Long Beach, Miss., Oct. 28, 1914.

Robert Holbrook Smith, M.D., Akron, Ohio, to Miss Anna Robinson Finley of Oak Park, Ill., January 25.

August Herman Meise, M.D., to Miss Alice Grace O'Hara, both of New York City, Oct. 27, 1914.

James Samson, M.D., to Miss Lillian Baines, both of Detroit, Dec. 5, 1914.

Deaths

Surgeon Carl DeWolf Brownell, M.D., Lieutenant Commander, U. S. Navy (retired). New York University, New York City, 1888; a Fellow of the American Medical Association and a member of the Association of Military Surgeons of the United States; who was placed on the retired list, Jan. 20, 1914, on account of disability resulting from an incident of the service; died at his home in Providence, R. I., January 28, aged 48.

William P. Keasby, M.D. New York University, New York City, 1888; formerly of Perth Amboy, N. J.; later a druggist in Hollywood, Cal., and a resident of Los Angeles; a patient in the California Hospital of that city; died in that institution, January 20, as the result of an incised wound of both arms, self-inflicted, it is believed, with suicidal intent while despondent on account of ill health.

Aaron Ivins Comfort, M.D. University of Pennsylvania, Philadelphia, 1860; surgeon of volunteers during the Civil War; a Fellow of the American Medical Association; for twenty-three years surgeon at the National Soldiers' Home, National Home, near Milwaukee, Wis.; died in that institution, January 31, four days after a fall, in which he sustained a fracture of the hip, aged 89.

Daniel C. Noble, M.D. New York Homeopathic Medical College, 1892; of Middlebury, Vt.; for ten years health officer of that city and for a long time a member of the board of trustees of the Vermont Sanatorium, Pittsford; from 1908 to 1910 surgeon-general of Vermont; died in the Hayes Sanatorium, Burlington, Vt., January 18, aged 52.

Robert S. Bennett, M.D. Kansas City (Mo.) Medical College, 1877; a Fellow of the American Medical Association; formerly surgeon of the Kansas City Southern Railway, at Drexel, Mo., but for the last four months under medical treatment in Kansas City; died in his apartment in Kansas City, January 24, aged 53.

Albert Bledsoe Wayland, M.D. University of Virginia, Charlottesville, 1897; a Fellow of the American Medical Association and a well-known practitioner of Albemarle County, Va., but for a year a resident of San Antonio, Tex., on account of his health; died at his home in Crozet, Va., January 25, aged 40.

D. Morris Thurston, M.D. Cincinnati College of Medicine and Surgery, 1875; a member of the State Medical Association of Texas; surgeon at Beeville, Tex., for the San Antonio and Aransas Pass and Southern Pacific systems; died in a sanatorium in San Antonio, Tex., January 25, aged 62.

George W. Gray (license, Minnesota Exemption Certificate, 1883), a member of the Minnesota State Medical Association; formerly of Brownsdale and Austin, Minn.; died recently at his home in Minneapolis, aged 61.

Silas Hall, M.D. Physio-Medical Institute, Cincinnati, 1875; Columbus (Ohio) Medical College, 1891; formerly a member of the Indiana State Medical Association and a practitioner of Vincennes; died in the Woodmere Hospital, Evansville, Ind., Oct. 29, 1914, from nephritis, aged 65.

Ernest Wesley Russell, M.D. University of Vermont, Burlington, 1879; a Fellow of the American Medical Association and a member of the surgical staff of St. Mary's General Hospital, Lewiston, Maine; died at his home in that city, January 27, from cerebral hemorrhage, aged 56.

Thomas F. Keen, M.D. University of Maryland, Baltimore, 1881; formerly a member of the Medical Society of Virginia; president of the Hamilton (Va.) Bank; one of the most widely known practitioners of northern Virginia; died at his home in Hamilton, January 24, aged 57.

William Layton, M.D. University of Louisville, 1868; of St. Louis; first assistant physician at the Eastern Kentucky State Hospital, Lexington, for several years; died in Webster Groves, Mo., Dec. 9, 1914, from the effects of an accidental fall from a second story window, aged 78.

George S. Courtright, M.D. Medical College of Ohio, Cincinnati, 1862; Miami Medical College, Cincinnati, 1868; a Fellow of the American Medical Association; surgeon of volunteers during the Civil War; died at his home in Lithopolis, Ohio, January 19, aged 74.

Harry Clifton Boutelle, M.D. Harvard Medical School, 1899; a Fellow of the American Medical Association; a member of the Board of Health of Danvers, Mass., and physician to the public schools of that city; died at his home, January 26, from pneumonia, aged 39.

Isham Henry Clayton Cook, M.D. Louisville (Ky.) Medical College, 1875; formerly a member of the Mississippi State Medical Association and vice-president of the Forrest County Medical Society; died at his home in Hattiesburg, Miss., January 22, aged 61.

Arthur Field Hinman, M.D. Syracuse (N. Y.) University, 1910; later intern in the St. Joseph Hospital, Syracuse, and thereafter a practitioner of Auburn, N. Y.; died at the home of his parents in Clyde, N. Y., from carcinoma of the intestines, aged 31.

Adolphus E. Chamberlain, M.D. Hahnemann Medical College, Chicago, 1881; of Yuma, Mich.; died at his home in that place, January 9, from the effects of a gunshot wound of the head, self-inflicted, it is believed, with suicidal intent, aged 56.

Aurelius Martin, M.D. University of Louisville, Ky., 1881; a member of the Mississippi State Medical Association and once president of the Granada County Medical Society; died at his home in Hardy Station, Miss., January 23, aged 56.

Francis Marion Flinn, M.D. St. Louis College of Physicians and Surgeons, 1895; formerly a medical officer of the Montana National Guard, and later of Deeth, Nev.; died at his home in Molta, Mont., January 15, from nephritis, aged 53.

George Grosline Rutledge, M.D. Starling Medical College, Columbus, Ohio, 1886; of Owensville, Ohio; a member of the Ohio State Medical Association; died suddenly, January 22, from heart disease, while making a professional call, aged 52.

James Rea Crawford, M.D. University of Pennsylvania, Philadelphia, 1899; a member of the staff of the Polyclinic Hospital, Philadelphia; died suddenly from heart disease in his room in that institution, January 15, aged 40.

Samuel W. Gibson (license, Virginia), surgeon in the Confederate Service during the Civil War and for more than forty years a practitioner of Russell County, Va.; died at his home in Castlewood, Va., January 17, aged 89.

Théophile Gonaux, M.D. Tulane University, New Orleans, 1885; for several years physician to the French Society, New Orleans; died at his home in that city, January 15, aged 64.

Malcolm James Farrish, M.D. Trinity Medical College, Toronto, Ont., 1891; died at his home in Sherburn, Minn., January 22, from tuberculosis, aged 50.

Harrison V. Appley, M.D. Philadelphia University of Medicine and Surgery, 1877; died at his home in Grand Rapids, Mich., January 21, aged 62.

Cornelius F. Yeager, M.D. College of Physicians and Surgeons, Baltimore, 1884; died at his home in Mineral Wells, Tex., January 19, aged 67.

John Weir Wiestling, M.D. University of Pennsylvania, Philadelphia, 1866; died at his home in Vandalia, Ill., January 19, from dropsy, aged 72.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

CELERINA, ALETRIS CORDIAL AND KENNEDY'S PINUS CANADENSIS, LIGHT AND DARK

Report of the Council on Pharmacy and Chemistry

The following reports on products of the Rio Chemical Company have been submitted by a referee. The Council recommends that they be published, as the preparations discussed are glaring instances of nostrums exploited through physicians on unscientific claims and false representations.

W. A. Puckner, Secretary.

Celerina

Celerina belongs to what Samuel Hopkins Adams calls the "bracer" type of nostrum. According to the label it contains 42 per cent. alcohol (whisky contains about 50 per cent.). The other ingredients of Celerina are declared to be as follows:

> "Each fluidounce represents Forty grains each Kola, Viburnum, Forty-eight grains Celery, Twenty grains Cypripedium, Sixteen grains Xanthoxylum and Aromatics.
>
> "Dose—1 or 2 teaspoonfuls 3 times a day."

Kola contains a very small percentage each of caffein and theobromin. It is impossible for the infinitesimal amounts of these alkaloids in an ordinary dose of Celerina to produce any physiologic effect.

Viburnum has been called a "uterine sedative," whatever that may be. Its only real activity is the psychic one due to its taste and odor.

Celery at one time was credited with being both an antispasmodic and a nerve stimulant—a remarkable combination of opposing qualities! Scientific investigation has failed to show that celery has any physiologic or therapeutic activities. If it had the slightest medicinal value, the rational course would be to prescribe it in its fresh and natural state. The small dose contained in a teaspoonful of Celerina is inappreciable and not even equivalent to that contained in a stalk of celery.

Ladyslipper, more imposing under the Latin name of "cypripedium," is a flowering plant with a legendary reputation as an "antispasmodic and nerve stimulant." It has been in the therapeutic scrap-heap for years. It contains a little tannic acid, gallic acid and a volatile oil. Even a tannic acid action cannot be expected from a teaspoonful of a preparation containing 20 grains of ladyslipper to the ounce.

Prickly ash (xanthoxylum) has never been shown to have any activity other than that of a local irritant, especially to mucous membranes. The slight "bite" from this drug would be entirely covered up by the alcohol in Celerina. Any stimulating effect which this drug may have on the stomach is greatly inferior to that produced by a very small glass of ordinary ginger ale.

In short, there is no ingredient in Celerina, except the alcohol, that has any recognizable activity; and the alcohol content is nearly as great as that of ordinary whisky. Some of the claims and recommendations for this nostrum are:

> "Celerina (Nerve Tonic), for Nervousness, Hysteria, Insomnia, Nervous Indigestion, Languid and Debilitated Conditions, Recovery from Alcoholic Excess."

Think of prescribing an alcoholic nostrum four times a day to promote recovery from alcoholic excess!

> "NEURASTHENIA: The bane of the general practitioner; the puzzle of the neurologist; the juicy fruit of the quack and faddist; the opportunity of the intelligent therapist. . . . For the medical treatment CELERINA is the preparation of wide utility."

The *sang froid* with which the exploiters of this nostrum refer to other "quacks and faddists" as reaping "juicy fruit" from neurasthenics would command admiration were it not so pitiful.

> "Celerina has substantial endorsement in nervous disorders characterized by Aphonia (nervous)."

Of course, the disappearance of nervous aphonia might follow the application of any treatment whatever, be it Eddyism, Chiropractic, Peruna or Celerina.

> "CLIMACTERIC (the Menopause) flattering results have been reported from a combination of equal parts Celerina and Aletris Cordial Rio."
>
> "Teaspoonful doses after meals and upon retiring have proven efficacious [in "dyspepsia"] when other remedies have failed."

Here is a good example of proprietary-house therapeutics: Such widely different conditions as digestive trouble and the climacteric are to be treated with a combination of alcohol, simple bitters and aromatics! Why not order a cocktail under its own name? It would be equally efficacious, less mysterious and its dangers might be better realized!

> "*A teaspoonful or two in three tablespoonfuls of boiling hot water [for insomnia] upon retiring.*"

Any other hot toddy at bedtime (and it need *not* cost a dollar a bottle) might give relief; but the intelligent physician to-day recognizes the danger of prescribing alcohol in such conditions.

> "In the case of brain workers who suffer from *nervous excitability* and mental fatigue, the administration of Celerina in teaspoonful doses, three times a day and at bedtime, rapidly controls the condition and increases *mental* capacity."

And the same effect follows its use:

> "In cases involving worry, anxiety, overwork, and excesses of *various* kinds. . . ."

Moreover:

> "*Celerina* is the most prompt and efficient of remedies for devitalized or broken-down *constitutions*—doses four times a day."

The statement made by its manufacturers that this preparation is free from narcotics or habit-forming drugs is not true. Alcohol is both a narcotic and a habit-forming drug.

As in the case of other nostrums containing no potent drugs but alcohol, Celerina is recommended for various diseased conditions in combination with a familiar form of treatment by drugs of more or less value. The physician who thoughtlessly prescribes one of these combinations will without doubt unthinkingly attribute any subsequent improvement to the Celerina. Thus, for malaria, a prescription of quinin and Celerina is advised; for chorea in children, arsenic with Celerina; in "Convalescence from La Grippe," strychnin sulphate, Fowler's solution, and Celerina; for impotence, nux vomica, dilute phosphoric acid and Celerina. In none of these conditions would Celerina affect favorably anything except the pockets of the exploiters; in some, as in the chorea of children, the alcohol would be positively detrimental. Of course, the value of such prescriptions (so far as they have any apart from the fictitious value lent by the alcohol) resides altogether in the standard drugs prescribed with Celerina.

There is no possible excuse for writing a prescription for Celerina, either in original package or mixed with well-known or valuable drugs. The sooner it is realized that this preparation has no place in medicine, should never be prescribed by physicians and is essentially nothing but alcohol and bitters exploited under a fancy name, the better for the public health and the science of medicine. The continued sale and use of Celerina is a disgrace to the medical profession.

Aletris Cordial

Aletris Cordial is a nostrum containing therapeutically worthless drugs in alcohol (28 per cent.).

The "formula" on the label reads:

> "Each fluidounce represents ten grains Aletris, thirty grains Helonias and thirty grains Scrophularia."

At one time these drugs had some vogue, chiefly as domestic remedies. They have been discarded as valueless by modern scientific medicine.

Aletris, or unicorn root (Aletris farinosa), contains a bitter principle and starch. The remarkable uterine tonic properties formerly ascribed to it have not been confirmed by reliable observers. It is practically worthless.

Helonias, or false unicorn (Chamaelirium luteum), is asserted to be a hemostatic and uterine tonic. No trustworthy evidence has ever been offered in support of the claims made for this drug; reliable medical literature contains no reference to it; it has no valid claim on the attention of physicians.

Scrophularia, or figwort (Scrophularia marilandica), contains a principle which has a digitalis-like action on the heart. Its activity is so slight in comparison with that of digitalis, however, that there was nothing to be gained by studying it. The drug is consequently little known and is not mentioned in critical works on pharmacology. If the drug were therapeutically active in the quantities used, another danger would be added to that of the alcohol content of Aletris Cordial. Since the recommended dose (a teaspoonful) contains, if the formula be correct, only about 4 grains of figwort, this drug too may be regarded as practically inert in this preparation.

Not one of these drugs has been deemed worthy of mention in the Pharmacopeia. The Council has previously discussed them and declared them valueless (Reports Council Pharm. and Chem., 1909, p. 146; 1910, p. 10; 1912, p. 42).

In Aletris Cordial, then, there is no ingredient capable of producing any other effect than the alcohol stimulation and such psychic effect as may be due to the bitter taste. Yet physicians are asked to believe that

> "Probably no remedy is so uniformly successful in the prevention of threatened miscarriage as ALETRIS CORDIAL Rio."
>
> "HABITUAL MISCARRIAGE can be effectually overcome by the systematic use of *Aletris Cordial Rio.*"
>
> ". . . regulates the local *circulation* and imparts normal tone and strength to the uterine muscle."
>
> "The use of Aletris Cordial Rio throughout pregnancy goes far to assure normal, uncomplicated labor."

Such claims as these, when made for a mixture containing no therapeutically active constituent except alcohol, are absolutely preposterous. It should be noted that the declared alcohol content of Aletris Cordial is much higher than that of the strongest wines, and, in the light of medical experience, quite high enough to promote the formation of the alcohol habit in a steady user. The following recommendation, taken from the company's "Budding into Womanhood" circular, therefore, is outrageous:

> "Many medical practitioners recommend to mothers the use of Aletris Cordial Rio for their growing daughters, ranging in age from twelve to eighteen years. . . ."

It is to be hoped that no medical practitioner is so heedless of consequences as to prescribe for adolescent girls a worthless nostrum capable of creating a craving for alcohol. The temperance societies might with profit take steps to inform laymen, especially women, concerning the worthlessness of this nostrum, the risk involved in taking it, and the outrageous character of the recommendations made for it by the manufacturers.

Kennedy's Pinus Canadensis, Light and Dark (Abican and Darpin)

Kennedy's Pinus Canadensis, Light (recently renamed "Abican") and Dark (renamed "Darpin") are also exploited by the Rio Chemical Company. Although they have been on the market some thirty or forty years they appear to have achieved no marked degree of commercial success. Yet they have been imitated by most of the pharmaceutic houses. They are of interest chiefly through the barefaced fraud involved in their exploitation.

COMPOSITION CLAIMED

Apparently the dark preparation ("Darpin") was first put on the market; then the light one ("Abican") was offered, to be used only "as an injection and externally." The reason for the existence of the light preparation evidently was the objectionable property of the dark, which stained linen. The two preparations are both said to be extracts of Pinus Canadensis or hemlock bark. A circular issued some years ago contained the following statement:

> "Pinus Can. (Ken.)—*Dark*—A non-alcoholic extract of Pinus Canadensis, to each fluidounce of which is added 0.48 grains Thymol.
> "Pinus Can. (Ken.)—*Light*—A non-alcoholic extract of Pinus Canadensis, to each fluidounce of which is added 24 grains each of pure Alum Potash and Sulphate of Zinc and 0.48 grains of Thymol."

The labels on the packages of the light and dark preparations sent out to-day bear, respectively, only the following references to composition, the first on the dark and the second on the light:

> "Each fluidounce also contains 0.48 grains Thymol."
> "A non-alcoholic preparation of Pinus Canadensis, to which is added twenty-four grains each pure alum potash and sulphate of zinc and 0.48 grains thymol to the fluidounce."

ACTUAL COMPOSITION

"Darpin" or Kennedy's Pinus Canadensis, Dark, does contain tannin, but, as the simplest of chemical tests demonstrate, Pinus Canadensis, Light, does not contain tannin. It might as truthfully be called maple syrup or beef tea.

It is almost a work of supererogation to discuss the therapeutic claims made for preparations sold under false pretenses as to composition. It is enough to mention that Kennedy's Pinus Canadensis, Dark or Light, is recommended in

ALBUMINURIA
DIARRHEA-DYSENTERY
FETID PERSPIRATION
ENDOMETRITIS
FISSURES
FISTULA
GONORRHEA
HEMORRHAGE FROM THE NOSE
UTERINE HEMORRHAGE
LEUCORRHEA
NASAL AND PHARYNGEAL CATARRH
PILES
SORE THROAT
ULCERATION OF THE CERVIX

The intelligent physician of to-day knows that his forefathers in the days of the stage-coach employed tannic acid in its crude form and treated intestinal disease in a very unsatisfactory manner; he knows, further, that advances in our knowledge of pathology have rendered the use of tannic acid in gastro-intestinal therapeutics largely unnecessary and that when it is used it should be in some form that will pass the stomach unchanged. So far as its use as local application is concerned, he knows, without need of instruction from the Rio Chemical Company, when tannin is indicated, and the Pharmacopeia furnishes a suitable preparation for the physician so that he need not resort to an unscientific nostrum like Darpin.

The physician who is competent to treat a case of gonorrhea does not need to be told that alum and zinc sulphate may be useful in such conditions, and he does not want them palmed off on him for something else under the name of Pinus Canadensis, Light, Abican or what not. Also, he prefers to use them when they are needed singly and in strength suited to the conditions of the individual case.

[EDITORIAL COMMENT.—Celerina, Aletris Cordial and Kennedy's Pinus Canadensis, Light and Dark, appear to be the entire output of the Rio Chemical Company, which was one of the earliest of the various companies organized by James J. Lawrence of *Medical Brief* fame. The business was moved from St. Louis to New York City in 1901. According to what we believe to be reliable information, the Rio Chemical Company is now composed of James P. Dawson, president; William W. Conley, vice-president and treasurer; and E. D. Pinkerton, secretary. These also constitute the directors. It appears that James P. Dawson is a member of the law firm of Dawson and Garven, St. Louis; E. D. Pinkerton is said to be Miss Effie D. Pinkerton, stenographer for Dawson and Garven. We know little concerning William W. Conley except that he appears to be in charge of the establishment in New York. We find no evidence that he is either a chemist or a pharmacist; his name does not appear in the membership list of the American Chemical Society or of the American Pharmaceutical Association, nor can we discover that he has published anything in the way of chemistry or pharmacy. As a matter of fact, the Rio Chemical Company is another of the pseudo-chemical companies created to exploit one or more proprietaries—in this instance Celerina, Aletris Cordial and Pinus Canadensis. The following medical journals carry advertisements of the Rio products, (or did late in 1914): *American Journal of Surgery, American Medicine, Denver Medical Times and Utah Medical Journal, Eclectic Medical Journal, International Journal of Surgery, Interstate Medical Journal, Massachusetts Medical Journal, Medical Brief, Medical Century, Medical Council, Medical Review of Reviews, Medical Sentinel, Medical Standard, Texas Medical Journal* and *Woman's Medical Journal*.]

Correspondence

U. S. Public Health Service Report on a Tuberculosis Treatment

To the Editor:—In reply to your editorial (THE JOURNAL, Jan. 23, 1915, p. 347), I wish to discuss the experimental work of my methods, as recorded in Dr. Stimson's report, in almost every paragraph of which I find serious misstatements, important omissions and disregards of specific instructions which, when corrected, will show the justice of my general objection that the report is unfair and misleading and that the investigation itself was conducted in such a manner that the failure of the experiments was inevitable. I wish to state that I am prepared to supply documentary and other evidence for every assertion I shall make.

1. Dr. Stimson stated to me on his first arrival that he had no practical experience in the work contemplated. He never even suggested to conduct his work independently or without my general supervision; on the contrary, he stated that his object and purpose would be attained if he were given an opportunity to make the infections and autopsies on animals which I considered resistant, and with serums which I considered germicidal, regardless of whether or not he succeeded in applying certain tests which served me as guides for the purpose of avoiding failures. On or about Oct. 4, 1913, Dr. Stimson changed his attitude and proposed "independent" work in the sense that this was to be secret, by excluding me from all knowledge of its conduct. This I promptly refused, not because I lacked confidence in my methods but because I had reason, under the circumstances, to lack confidence in the investigator.

2. Dr. Stimson's statement that he used an entirely fresh preparation of my vaccine in his experiments is not in accordance with his personal knowledge or with that of his superior officers.

The facts are that the vaccine which he used was supplied by me for comparative chemical studies, together with a letter to Dr. Anderson, expressly forbidding its official use, for reasons stated, namely, that it was not entirely fresh and had not been tested for its efficiency. I withdrew my consent to its use for any purpose whatever, a few days later, in a letter to Surgeon-General Blue, for good and sufficient reasons.

No vaccine or serum was supplied by me thereafter until May, 1914. The vaccine which I supplied then, we sent on the condition (because likewise not entirely fresh) that no report should be made on results obtained with it, provided that I supplied an entirely fresh and, in my opinion, superior preparation as soon as this could be finished, namely, within six months from April 24, 1914. This agreement was sanctioned by Assistant Secretary of the Treasury Hon. Byron R. Newton, and is in my possession bearing his signature.

I did supply the entirely fresh specimen of vaccine within the time stated. Neither this nor the specimen of May, 1914, was used, and the report was made prematurely and in violation of the agreement.

3. According to printed directions supplied by me for the use of the partly fresh vaccine, the animals treated with the older specimen of October, 1913, were insufficiently treated, and were infected with ten times the prescribed quantity of virulent tubercle bacilli.

4. The serums used by Dr. Stimson prior to May 15, 1914, were neither supplied nor tested by me. They were apparently removed, secretly and without my knowledge and consent, from my laboratory.

5. The serums used by Dr. Stimson on May 15 were six days old on that date. My directions conditioned the need of entirely fresh serums and the content of certain maximal amounts of specific antibodies, which were not found in sufficient quantities when we made our own tests. Dr. Anderson was promptly informed of this and, to give him the opportunity of making experiments with fresh serums, I offered to have persons living in Washington, who had been vaccinated by us, call at the Hygienic Laboratory to be bled. He did not avail himself of this offer. Numerous other specimens of serums, some of them closely approximating the necessary content of specific antibodies, were afterward sent, but were not used in the experiments on which Dr. Stimson reports.

Without further comment I submit the foregoing facts as bearing directly on the experiments on which Dr. Stimson formulated his conclusions.

As to the reference, at the end of the editorial article, to the suspicions which Dr. Stimson directs against our personal integrity and honesty, these would have been ignored entirely by me, as a matter beneath my dignity to defend; but, since they impressed the editor, I will state that the correctness of certain records was a matter of dispute between the chief of my laboratory and Dr. Stimson. The latter having called my attention to them (which, by the way, did not in any manner concern him), I made a personal examination, accepted the records as correct, and myself directed the entry in the record book on the day following, to complete the records, from memoranda and personal statements by the chief of the laboratory, after his being fully corroborated by an assistant who had aided in the work. Dr. Stimson's objections were based on inferences only.

The following papers now in course of preparation, and bearing on the subject, will appear in the near future: "A Critical Examination of Dr. Stimson's Report," "Further Experimental and Other Studies on Prophylactic and Therapeutic Immunization in Tuberculosis," "The Results of a Collective Inquiry on the Practical Use of My Vaccine, by Several Hundred Independent Observers," "Pseudo-Tuberculosis in Guinea Pigs, and Its Relation to Failures in Tuberculosis Experiments." We also expect reprints on the experimental results obtained with the vaccine and with serums from vaccinated persons, in the laboratory of Sir Almroth E. Wright, as soon as the report has been published in London. To any physician interested and requesting it, one or all of them will be mailed.

Karl von Ruck, M.D., Asheville, N. C.

[The foregoing letter was referred to the Surgeon-General of the U. S. Public Health Service. The following is the reply:]

Washington, Feb. 2, 1915.

To the Editor:—Your letter to Surgeon-General Blue, U. S. Public Health Service, enclosing one from Dr. von Ruck which is to be published in The Journal, has been referred to me for comment. Dr. von Ruck's letter contains serious charges against me, and I appreciate your courtesy in permitting an opportunity for reply. I am under a disadvantage in two particulars: first, that my report[1] on the von Ruck methods had only the limited distribution of a Senate document and is not available to most of those who will read the criticism of it, and second, that in this limited space I shall have difficulty in presenting adequately all the facts concerning von Ruck. The service has on file letters from him which, if they could be published *in toto*, would show to any reader the unscientific attitude of Dr. von Ruck, and trace his evasions and contradictions, and the obstacles which he threw in the way of the investigation, dating from the time when he ascertained that it was to be a sincere and impartial effort to ascertain the truth, and not a mere admiring inspection, as it were, over his shoulder.

Taking up his letter in detail, I deny first of all that there are any misstatements or important omissions in the report. The only "disregards" of specific instructions were of his instructions which were given with a view of frustrating the investigation, or of delaying it until the same influence which brought about the investigation could be importuned to abolish it. I had no motive for animosity toward Dr. von Ruck, and should have been only too glad to have assisted in indorsing his methods, which, if his claims had been true, would have been of undoubted value to mankind. Unfortunately he was unable to substantiate his claims, and I should have failed in my duty as a public servant, had I not made this clear in my report. I shall now refer to his criticisms seriatim.

1. My statement to Dr. von Ruck regarding my lack of experience in the line of work contemplated has been abbreviated by him so as to give the impression that I had admitted my incompetence to undertake the investigation. I told him that I was familiar with the theory and practice of procedures in serology, which he had applied by methods of his own (in reality of his assistant's) devising, to the study of tuberculosis, but that I was naturally unversed in his application of them. So is every one else outside of his laboratory. His methods are peculiarly his own, and peculiarly unreliable.

Never from the beginning of the investigation did I contemplate anything but an independent investigation, and if I failed to make this clear at the outset, it was because I assumed that he was a scientist and would ask for no other kind. His phrase "a sympathetic investigation" was not then familiar to me. I outlined my proposed course to him as follows: to remain at his laboratory long enough to acquire familiarity with his methods and results, and then to transfer the work to Washington, where the facilities were incomparably better. When he had been forced by concrete examples to the confession that his serologic methods were defective, I agreed that, after all, the outcome of virulent inoculation constituted the supreme test of whether an animal was immune to tuberculosis or not. Obviously I welcomed his offer to certify on the basis of his tests that a given animal was immune, and then turn the animal over to me for the final test of immunity. This offer he has never made good in spite of repeated requests. He later stated that he did not wish to do this because he wanted to have the opportunity of seeing the inoculations made, of knowing what cultures and amounts were used, and of seeing the results and autopsies. This attitude of unwillingness to permit a single detail of the investigation to transpire without his personal supervision he vigorously maintained at a conference with Dr. Anderson and myself, and I leave this fact to the judgment of scientific workers, for appraisal as to its bearing on his scientific standing. Later, when the demands of the service for some tangible evidence of the immunizing properties of his vaccine became more peremptory, he pleaded his inability to comply because all the animals he was able to obtain suffered from tuberculosis or pseudotuberculosis, which rendered them insusceptible of immunization. How then will he presume to immunize human beings, who are mostly infected at some period with tuberculosis? He calls on us to assume parallelism between the action of the vaccine in persons and guinea pigs. I excluded Dr. von Ruck and his assistants from all knowledge of my work (as far as I was able) only after it became clear to me that there were persons in his staff who were capable of falsifying records of his alleged scientific experiments.

2. The vaccine referred to by me as "an entirely new batch" I had observed in various stages of its manufacture. It was represented to me as such, and Dr. von Ruck refers to it in a letter of Oct. 11, 1914, as follows: "I am sending you 50 c.c. of the old vaccine made in 1911, and 50 c.c. of the new vaccine made last month." He used this vaccine in the treatment of human beings. I still believe it to have been a completely new batch of vaccine, and that Dr. von Ruck's objections are but a subterfuge to excuse an inefficient

---

[1] This report is contained in Senate Document 641, 63rd Congress, 3rd Session. It may be obtained by applying to the Chairman, Senate Committee on Public Health and Quarantine.

preparation. At any rate it was the best he was able to prepare and was therefore the legitimate subject of investigation. His attempted limitation of this product to chemical studies was made by letter after the vaccine had been turned over to us for animal experimentation. The central question of this investigation is whether or not the preparations used by him on patients at the time of it conform to his claims, and not whether in the course of many attempts covering months or years he may be able to produce one which will do so.

We did not attempt to immunize animals with the vaccine sent us in May, 1914, because Dr. von Ruck had finally agreed to send us animals which he himself was to immunize with it. To overcome his difficulty with diseased animals, we sent him a shipment of guinea-pigs from our own healthy stock, which, however, he reported later had by accident been mixed with other animals, and found subsequently to be diseased.

That Dr. von Ruck could have no just basis for his claim of superiority for the vaccine supplied Oct. 24, 1914, is shown by his own words under date of October 3, "There is now no chance of finishing a satisfactory preparation of vaccine in the near future, and certainly not by the 23d of this month, the date when the limit of six months, set by the Hon. Mr. Newton, Assistant Secretary of the Treasury, expires." Nevertheless he did furnish vaccine by that date which he stated he believed to be superior to the vaccine previously supplied to the department. Since testing a vaccine by Dr. von Ruck's methods requires months of animal experimentation before its assumed potency can be determined, he could not possibly have such data for a vaccine just prepared. The assistant secretary therefore decided that this new vaccine was not properly the subject of investigation. Accordingly I was instructed to make no tests on it.

3. The printed directions regarding dosage for immunization were published six months after the experiments were begun. Dr. von Ruck's oral instructions, however, were faithfully followed. The dose of virulent bacilli, he told me, varied from 0.01 to 0.1 mg., according to virulence. My strain not being highly virulent, the larger amount was used. The average duration of life in control animals with this amount was ninety-six days, including a number of animals dying prematurely from complications. The printed directions recommend a strain causing death in about sixty days, so that my infecting dose was a reasonable one.

4. The serums used by me prior to May 15, 1914, were both supplied and tested by Dr. von Ruck, who personally sent for previously vaccinated persons to be brought to his laboratory, in order that I might obtain blood from them for examination. I never made surreptitious collections of serum, although I did not communicate my results after having reason to distrust the scientific honesty of his staff.

5. Serums sent from Asheville were carefully kept cold, and used as promptly as possible. I do not believe that deterioration accounts for the lack of antibodies in these serums, as good complement fixation has been repeatedly secured with serums sent from New Mexico. No specimen was intentionally omitted from examination and report.

The specific details of the shortcomings of Dr. von Ruck's records which I published in the Senate report show that my objections were based not on inference but on observation.

As far as I am aware, Dr. von Ruck never makes serologic tests himself. He relies on his assistants, although he occasionally inspects results. The following quotations from one of his letters to Dr. Anderson, explaining the inconsistency of his results, justify my belief that much of the work done at his laboratory was unscientific and unreliable. Referring to a former assistant who had performed tests for demonstration purposes during the visit of a certain government official, Dr. von Ruck says that in response to query as to the use of serum controls "he wrote confidentially that he made serum controls only when 'he wanted to show off' [*sic*] and that one of the occasions was the one referred to." Referring to one of his assistants who was at the laboratory at the time of the investigation, he says, "I cannot but believe that he purposely and wilfully deceived me, and persists in telling me what he knows is not true, namely, that he always used serum controls, unless in specimens received from a distance, and in which the amount of available serum was not enough." Again, "my inference that——[the same assistant] for some reason best known to himself deceived me, is I believe justified, until the contrary is proved. I find further, that the more precaution I demand, and the more I personally control the work, the more frequent are the failures, and that the 'uniformity' of successful work can had [*sic*] no foundation in fact. . . . I had the same troubles in London; we had but few 'clean cut' results, and am thus convinced, that the uniformity, shown by——prior to August, 1912, had no existence in fact and that if he had used serum controls as he persists in assuring me, he could not possibly have missed a like experience as is before me since that time."

The composition and use of the von Ruck vaccine are based to a great extent on complement fixation tests. Such tests without full controls are valueless.

If then, Dr. von Ruck has had such experiences with the tests and with his assistants, the validity of his results and of his records may well be questioned.

This investigation was undertaken without prejudice, and continued impartially. It is a matter of regret that in accordance with the facts, an adverse opinion had to be rendered.

A. M. Stimson, M.D., Washington, D. C.
Assistant Director, Hygienic Laboratory.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. *Every letter must contain the writer's name and address, but these will be omitted, on request.*

METOL DERMATITIS

To the Editor:—1. What is Metol developer used by photographers?
2. What are the symptoms and end result of Metol poisoning?
3. What is the best treatment?

E. M. Stansbury, M.D., Vermilion, S. Dak.

Answer.—1. Metol is the trade name for methyl-para-amino-phenol sulphate.

2. It produces a dermatitis accompanied by ulceration which may result in fissures and cracks which are slow to heal.

3. There have been various recommendations for prophylaxis and treatment. Coating the hands with petrolatum before beginning development is a useful precaution. L. A. Freeman (*British Journal of Photography,* June 5, 1914) recommends that 2 drops of pure phenol (carbolic acid) be added to a quart of cold water. Immerse the hands in it after the use of Metol, and warm gently over a gas flame until the heat is no longer tolerable. Then wash thoroughly with carbolic soap, and dry well.

Before the skin is broken N. T. Beers (*New York Med. Jour.,* Sept. 10, 1908; abstr. The Journal, A. M. A., Sept. 26, 1908, p. 1107) recommends soothing applications such as lead lotion. After the skin is broken, care must be taken to protect the parts thoroughly and to use the blandest of applications. Zinc stearate with 1 or 2 per cent. of phenol or salicylic acid makes a useful dusting powder. In the later stages more stimulating applications may be used, such as small amounts of oil of cade or of resorcin or ichthyol.

The following ointment has been advised: ichthyol, resorcinol, glycerin, of each, 1 ounce; zinc oxid, ½ ounce; white petrolatum, 6 ounces (*Brit. Jour. Photog.,* Nov. 7, 1913, p. 860).

DIET IN TYPHOID FEVER

To the Editor:—Please give me a list of recent articles relative to the treatment of typhoid fever, with special reference to diet.

O. F. Wellenreiter, M.D., Gessie, Ind.

Answer.—The following is a list of articles on this subject:

Barker, L. F.: Diet in Typhoid Fever, *The Journal,* Sept. 12, 1914, p. 929.

Coleman, W.: *Effects of Food on* Metabolism in Typhoid Fever, The Journal, Sept. 12, 1914, p. 932.

Kenefick, M. J.: Increased Diet in Typhoid: Arguments for and Against, *Iowa State Med. Soc. Jour.*, April, 1913.
Graves, M. L.: Some Clinical Experiments in Treatment of Typhoid with Calorie Food Values, *Texas State Jour. Med.*, May, 1913; abstr., The Journal, May 24, 1913, p. 1668.
Cornwall, E. E.: Rational Diet for Typhoid, *Med. Rec.*, Oct. 3, 1914; abstr., The Journal, Oct. 17, 1914, p. 1425.
Bodenstab, W. H.: Typhoid Feeding, with Special Reference to High-Calory Diet, *Journal-Lancet*, Jan. 15, 1914.
Sicard, M. H.: High Calory Diet in Typhoid, *Med. Rec.*, March 22, 1913; abstr., The Journal, April 5, 1913, p. 1107.

APPARATUS FOR MOISTENING THE AIR—EFFECT OF DRY AIR ON RESPIRATORY DISEASES

To the Editor:—In the issue of January 2, you recommend for the prevention of colds that we should see that the air contains the proper amount of moisture.

1. Please inform me how the air in steam-heated rooms can best be moistened.

2. What is the best instrument to use to detect changes in humidity in rooms? What is its price, and where can it be purchased?

3. Please give references to the effects of dry air on the spread of respiratory disease.

M. M.

Answer.—1. There are many types of humidifying apparatus. It is difficult to recommend any specific form unless the conditions of operation are precisely known. A very simple and often effective means of adding moisture in steam-heated rooms is to let some of the steam from the radiator pass directly into the room atmosphere.

2. The Committee of the American Public Health Association on Standard Methods for the Examination of Air (*Am. Jour. Pub. Hyg.*, 1910, xx, 346) recommends the sling psychrometer, used by the United States Weather Bureau. This apparatus consists of two mercurial thermometers fixed to an aluminum back and mounted by a handle, by which they can be whirled. Full directions for its use are printed in Bulletin 235 of the United States Weather Bureau. The instrument may be obtained from Schneider Brothers of New York or from Queen and Company.

3. Much less is known about the problem of humidity in ventilation than about that of temperature. A sound physiologic foundation for artificial humidification is still lacking. Experiments being carried out by the New York Ventilation Commission may throw some light on this matter. A paper by Clark and Gage, dealing with certain features of this subject and entitled "A Study of the Hygienic Condition of the Air in Certain Textile Mills with Reference to the Influence of Artificial Humidification" appeared in the *American Journal of Public Health*, 1913, iii, 1176.

THE HARRISON ANTINARCOTIC LAW

To the Editor:—1. May a physician without formally registering with the Collector of Internal Revenue, dispense a cough mixture containing more than ⅛ gr. of heroin to the ounce after March 1 next?

2. If registered as above is it necessary to keep a formal record of same more than his regular office memorandum?

3. May a physician who has not formally registered, write a prescription for above?

4. Is it necessary to keep a formal record of such prescription?

F. R. F.

Answer.—1. Section 6 of the law provides that the provisions of the act shall not be construed to apply to the sale, distribution, giving away, dispensing or possession of preparations which do not contain more than . . . ⅛ of a grain of heroin in one fluidounce, etc. Obviously any mixture containing more than ⅛ of a grain of heroin to the fluidounce would not be exempt. A prescription for such a preparation must therefore be signed by a physician "registered under the act."

2. The second question is ambiguous. Registered physicians are required to keep a record only of preparations which they dispense. They are not required to keep a record of prescriptions.

3. Unregistered physicians could write prescriptions for a cough mixture containing more than ⅛ grain of heroin, but a druggist could not fill it.

4. Physicians are not required to keep a record of prescriptions but only of preparations which they dispense. Druggists must keep record of prescriptions subject to inspection.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Connecticut: New Haven, March 8-9. Sec., Dr. Charles A. Tuttle, 196 York St., New Haven. Homeopathic; New Haven, March 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Eclectic: New Haven, March 9. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

Maine: Portland, March 9-10. Sec., Dr. F. W. Searle, 776 Congress Street.

Massachusetts: Boston, March 9-11. Sec., Dr. Walter P. Bowers, Room 501, No. 1 Beacon St., Boston.

Missouri: St. Louis, March 22-24. Sec., Dr. J. A. B. Adcock, State House, Jefferson City.

Missouri September Report

Dr. J. A. B. Adcock, secretary of the Missouri State Board of Health, reports the oral and written examination held at Kansas City, Sept. 28-30, 1914. The total number of subjects examined in was 14; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 41, of whom 35 passed and 6 failed. The following colleges were represented:

College	Year Grad.	Total No. Examined
PASSED		
Bennett Medical College	(1914)	1
Chicago College of Medicine and Surgery	(1914)	2

Book Notices

Symptomatology, Psychognosis and Diagnosis of Psychopathic Diseases. By Boris Sidis, A.M., Ph.D., M.D., Medical Director of the Sidis Psychotherapeutic Institute. Cloth. Price, $2.50 net. Pp. 448. Boston: Richard C. Badger, 1914.

To the various new procedures in the study of the psychology of abnormal mental states is undoubtedly due the large amount of recent literature concerning this subject. Medical colleges are beginning to awaken to the new interest in psychiatry, and in general the courses, which previously were hardly up to the standard of other departments, have begun to broaden out in such a manner as really to cover psychopathic diseases. "To one case of insanity," says Sidis, "there are thousands of cases of functional neurosis and psychopathic affections which have absolutely nothing to do with insanity, affections which the psychiatrist, from the very nature of his training, is neither in a condition to grasp nor able to deal with." In the introduction Sidis discusses the recent intense interest in psychanalysis, and attacks fiercely the Freudian school. He says, "The sight of some medical dignitaries taking a regular bath in sexual filth, possibly as a matter of redemption and expiation, would be ludicrous, if it were not so pathetic. . . . Psychoanalysis is a form of medical bacchanalia. . . . Psychoanalysis is a sheer humbug." The book is divided into three parts, one including subconscious states and borderland phenomena, the second, psychopathic diseases, and the third psychognosis and diagnosis. By psychognosis the author means the complete detailed study which will enable the observer to obtain a working knowledge of the patient's soul. This embodies the use of all the available best methods. The sanatorium treatment is evidently included, for he says, "It is best to live with the patient. . . ." A few of the chapters have appeared previously in periodical publications. There is a wealth of information and a thorough discussion of dissociation and hypnoidal states, on which Sidis' views are authoritative. In a number of appendixes are given methods of examination for the various disease states considered, "The Hypnoidal State" of Sidis discussed by T. W. Mitchell, and two other interesting essays somewhat apart. The work is interesting and worthy of thorough consideration by those who are attempting to keep abreast in this rapidly advancing field.

The Vaccination Question in the Light of Modern Experience. An Appeal for Reconsideration. By C. Killick Millard, M.D., D.Sc., Medical Officer of Health for Leicester. Cloth. Price, 6 shillings net. Pp. 243, with 10 illustrations. London: H. K. Lewis, 1914.

The author makes a serious effort to review the vaccination situation in England in the light of experience gained in recent years, and to determine whether or not compulsory vaccination, especially compulsory infantile vaccination, is necessary or advisable under present conditions. He believes absolutely in vaccination for the protection of the individual against small-pox, especially in those exposed to infection. He questions the value "to the community" under present-day conditions of infantile vaccination, holding that sanitation has played a much more important part in the prevention of small-pox in the last forty years than has infantile vaccination. He declares that the dangers of infantile vaccination and the injuries to health caused by it are not sufficiently appreciated by physicians, and that there is definite evidence that small-pox is disappearing in spite of the increasing neglect of vaccination. He asserts that the greatest difficulty in controlling small-pox to-day is the mild unrecognized cases found chiefly (?) among persons vaccinated in infancy, and because they were so vaccinated. From this basis he argues that infantile vaccination has a distinct tendency to encourage the spread of small-pox. His arguments, which really bear only on conditions in England, are based on an analysis of the mortality records of England for the past 150 years, and on his own experience as health officer in Leicester.

Negligence and the Use of Unsterilized Instruments

(Rogers vs. Tegarden Packing Co. (Mo.), 170 S. W. R., 675)

The Springfield (Mo.) Court of Appeals, in discussing the nature of negligence, says that the latter has been defined as being the failure to exercise that degree of care which ordinarily prudent persons are accustomed to exercise under like circumstances. Negligence is purely a relative term, and depends on the facts of the particular case. A certain act is to be done, and two ways are open for performance, one as much at hand and within the grasp of the actor as the other. One way, by the very nature of the circumstances, is more hazardous and dangerous than the other. By voluntarily following one method an injury may be reasonably and naturally anticipated. By using the other method the act can be performed in safety. In such a case, a court would be called on to say which method reason and prudence and ordinary care would dictate. As an illustration: A surgeon is called to attend an injured man, and an immediate operation is imperative. The only instrument at hand is one that shows it has not been sterilized, from which fact he must know that to use it may infect the patient and cause blood poisoning. He must use it in that condition or not at all. He does use it and blood poisoning follows. His course is questioned. To determine whether he was negligent in using such an instrument, it must be ascertained whether, under the circumstances, he used such care as a reasonably careful surgeon would have exercised, or whether the apparent condition of the instrument rendered its use so dangerous that no prudent surgeon would have taken the chances of operating with it. Now, suppose there were at his hand not only this instrument, but another which showed that it was properly sterilized, and the surgeon had the choice between them, and chose the unsterilized instrument. His conduct would then be measured by a determination of which instrument an ordinarily prudent surgeon would have used. While it cannot be laid down as a set rule that ordinary prudence requires every act to be done in the safest way, yet in determining whether the way it was done meets the requirement as to the exercise of ordinary care, either as a question of law or one of fact, there must be taken into consideration the circumstances surrounding the occurrence of an injury sustained in doing the act.

Power of Local Bodies to Require Vaccination of Schoolchildren

(Zucht vs. San Antonio School Board (Tex.), 170 S. W. R., 840)

The Court of Civil Appeals of Texas affirms a judgment in favor of the defendant in this suit to compel it to permit the plaintiff's children to attend the public schools of the district without vaccination. The court says that the power of local bodies to require the vaccination of schoolchildren as a condition to their admission to public schools, in the absence of express authority, is dependent on the conditions existing in the community with reference to small-pox. When an epidemic exists, or is imminent, there can be no doubt that the power may be exercised. It has also been held that such regulations may be adopted and enforced when small-pox exists in a community, and by some courts the expression is used that such regulations may be adopted when an epidemic is reasonably apprehended. In this case it was found that no epidemic existed or was imminent, but that the existing conditions with reference to small-pox constituted a menace to the public health. The court concludes from its investigation of the authorities that it is not necessary for an epidemic to exist or be imminent in order for the school board to be justified in adopting and enforcing the regulation complained of, because, if the conditions are such that they constitute a menace to the public health, it cannot be said that the board's action was unreasonable and that the want of necessity for the measures has been shown to be clear, manifest and undoubted. If existing conditions constitute a menace to the public health, an epidemic is threatened, and it cannot be said that it did not reasonably appear to the board to be necessary to adopt the regulation.

The court cannot agree with the contention that, as the regulation in question did not provide when it was to expire, it was permanent and to be enforced whether or not conditions justified it, and that it was therefore void. Ordinances and regulations which are valid when measured by existing conditions become unenforceable when such conditions cease. They need not provide the time when they shall cease to be in effect or that they shall expire when certain conditions change.

Nor was the regulation unreasonable and void because it provided that a child or teacher who brought a certificate from a physician to the effect that the health of the teacher or child was such that vaccination should not be done, could be admitted for sixty days without vaccination if the school physician so recommended, and should the child at the end of said time produce another such certificate, then that the question be referred to the board of health of the city together with the school physician to determine whether and how long the child might attend the schools without vaccination. This was attacked on the ground that the question of admission was first left to the arbitrary discretion of the school physician, and ultimately to said physician and the board of health of the city. But the court will not assume that the power will be exercised arbitrarily, nor should the regulation be construed as authorizing such an exercise thereof, for it is apparent that all decisions with respect to the matter are to be based on the physical condition of the child, and the power is placed in the hands of persons competent to investigate and make a decision which will not be arbitrary.

If the school board can keep out children afflicted with contagious diseases and those who have been exposed to the contagion, without coming into conflict with the state constitution and statutes, it also has the power to keep out those who fail to comply with other regulations reasonably necessary to protect the health of those attending the schools.

Society Proceedings

NEW YORK ACADEMY OF MEDICINE

Meeting held Dec. 17, 1914

The President, DR. WILLIAM M. POLK, in the Chair

Blood Transfusion

DRS. R. OTTENBERG and E. LIBMAN: We have studied 212 transfusions in 189 cases at the Mount Sinai Hospital. Of these, eighty-five cases, or 45 per cent., were successful in that the condition of the patient was greatly improved, and forty-two of these, or 20 per cent. of the whole number, were actually life-saving.

Successful Cases (85): 1. Cases in which prognosis was extremely bad, and transfusion saved life (42): (*a*) cases which subsequently completely recovered (29); (*b*) cases in which the original underlying disease continued (13). 2. Cases with recovery, in which prognosis before transfusion was not desperate (43).

Unsuccessful Cases (104): 1. Cases in which there was temporary improvement following transfusion, with death later from continuation of the original disease. 2. Cases with death from some disease necessarily fatal and in which transfusion could not have been expected to do much good. 3. Cases in which transfusion did little or no good, although from the nature of the disease a good result might have been possible.

The most interesting cases were those in which the transfusion was life-saving. These were almost all cases of hemorrhage either from operation, disease or hemorrhagic diathesis. Some of them were cases of grave chronic anemia or poisoning.

Indications for transfusion: 1. Transfusion for simple hemorrhage: (*a*) gastric and duodenal ulcer; (*b*) dysentery; (*c*) typhoid hemorrhage; (*d*) ectopic pregnancy.

2. Transfusions in connection with surgical operations: (*a*) preliminary to operation; (*b*) for postoperative hemorrhage; (*c*) for shock.

3. Transfusions for the cure of hemorrhagic conditions: (*a*) purpura hemorrhagica; (*b*) hemophilia; (*c*) hemorrhages secondary to: (1) blood diseases; (2) severe infectious disease; (3) jaundice (cholemia).

4. Transfusions for blood diseases: (*a*) pernicious anemia; (*b*) leukemia.

5. Transfusions for infections: (*a*) infections with pyogenic organisms; (*b*) infective endocarditis.

6. Transfusions for intoxications: (*a*) acute poisoning; (*b*) diabetic coma.

7. Transfusions for debilitated conditions: (*a*) cancer; (*b*) malnutrition; (*c*) simple anemia.

In the cases of hemorrhage from gastric or duodenal ulcer the results were exceedingly good; although all of the patients were in a desperate condition at the time of the transfusion, twelve of the fourteen recovered. In dysentery, on the other hand, the results were rather poor. In typhoid fever the results were exceedingly encouraging. Among seven transfusions, four were successful in relieving the immediate symptoms of hemorrhage. In the three cases of ectopic pregnancy, transfusion was life-saving. Among the most satisfactory transfusions in the whole series were some done preliminary to operation in patients whose condition would otherwise have contra-indicated any other operation. There were twenty-three such preoperative transfusions, and in thirteen of them the result was decisive and the patients recovered. In shock the results were very disappointing. We believe, however, that if shock could have been foreseen, so that the transfusion could have been done immediately instead of after several hour's delay in obtaining a donor, the results might have been better. The best results in all the series of cases were those in the group of hemorrhagic conditions. Of the nine patients with purpura hemorrhagica, six recovered completely and one left the hospital improved. In five of the six cases of hemophilia treated, the hemorrhage stopped promptly, and the coagulating property of the blood became practically normal. We suggest as a prophylactic treatment for hemophilia that every individual known to have hemophilia ought to have at his command several persons whose blood, by previous tests, is known to be compatible with his own. Whenever serious hemorrhage occurs, prompt transfusion should be done. In almost all of the thirty-five cases which had been transfused for hemorrhagic disease, the serum treatment had been tried out thoroughly before the transfusion and had had no effect; we believe, however, that the serum treatment deserves a further trial. In cholemic hemorrhage the results were rather disappointing; only one of the seven patients recovered. In regard to pernicious anemia, and our study embraced twenty-four cases, transfusion is the best remedy, and though it never cures, it leads to remission in about half the cases. If the first transfusion fails to bring about remission, one should be tried from a different donor. Splenectomy in pernicious anemia has about the same effect as transfusion. This should be reserved as a final method of producing remission when transfusion will no longer do so. In myelogenous leukemia and acute lymphatic leukemia, transfusion was without effect, but in four of the five cases of chronic lymphatic leukemia, transfusion was followed by a remarkable remission in which the blood picture returned temporarily to the normal. The ultimate outcome of course was not affected. In bacterial infections, transfusion is of value only in so far as it restores the general resistance of the patient. In gas poisoning, transfusion is almost a specific treatment and should be accompanied by phlebotomy. In diabetic coma it is useless.

Treatment of Pernicious Anemia by Transfusion

DR. E. LINDEMAN: The results of transfusion are often brilliant, sometimes only temporary, and sometimes indifferent and even poor; in my opinion, this variable response is due in part to the extent and seat of the pathologic invasion and, in some cases, to the incompatibility of the blood introduced. Splenectomy in pernicious anemia was not an accidental thought, but was arrived at through laborious study and logical reasoning. About thirty-five cases of splenectomy have been reported. I have had under observation six cases of splenectomy with transfusion for pernicious anemia. From a close study of these and about thirty other cases I conclude as follows: 1. Splenectomy plays an important part in the course of events in this disease. 2. The removal of the spleen reduces the blood destruction. 3. The extreme blood crises do not occur after splenectomy. 4. Splenectomy does not cure the disease; the patients still maintain the blood picture of a primary anemia, though clinically normal. 5. Considering the course of the disease, the procedure is entirely justifiable. 6. Cases should be selected carefully, and those showing petechiae, hemorrhage, mental disturbances and marked cord disturbances should be considered unfavorable to this procedure. Cases in which the vital staining cannot be demonstrated belong to the unfavorable group. 7. The patient should be transfused before splenectomy, and he must not be allowed to make the blood himself. In many cases he cannot; but even if he can, he should not be permitted to do so. By blood transfusion, the bone-marrow function is conserved for the vital need of the patient in the future.

DR. MORRIS MANGES: Five or six years hence the field for transfusion will be larger. The failures which have been reported so candidly are small when compared with the striking results obtained by transfusion. I have never seen a case in which transfusion was done as in one case of typhoid fever in which the primary attack lasted seventy-eight days. Without the transfusion, this case would have been shorter and fatal. The first transfusion was done on the thirty-eighth day, when the patient had a third hemorrhage and was in a desperate condition. The transfusion checked the hemorrhage, and the patient went on with the disease. On the sixty-sixth day the blood culture showed that typhoid bacilli were still present, and the condition of the patient was as bad as could be conceived, and petechiae were abundant. A second transfusion was done, and within six days the patient was convalescent.

DR. WILLY MEYER: I have performed transfusion in two cases of pernicious anemia with marked temporary improvement. Perhaps the lives of both patients might have been saved had splenectomy been added and the transfusion continued. I wish to say a good word for the subcutaneous injection of human blood serum in hemophiliacs and in patients suffering from chronic jaundice. In both, the secondary parenchymatous hemorrhage can often be well overcome by prophylactic and repeated injections of the serum. I wish to emphasize the necessity of the injections before operation. This kind of preparation is simpler than transfusion. However, transfusion is preferable in case the patient is also rather anemic.

DR. EUGENE H. POOL: I have adopted this method in ten cases without much difficulty. The method is valuable in cases of hemorrhage with jaundice; in this condition it might be well to use it as a prophylactic measure. It is also of value as an anteoperative procedure in cases of extreme anemia.

DR. WILLIAM A. DOWNES: In regard to splenectomy plus transfusion in pernicious anemia, five of the patients whose histories were given were transfused by Dr. Lindeman and later splenectomized by me. Two were of the type in which there were marked cerebral symptoms, and they should not have been operated on. There was a continuation of the symptoms, and death in both cases in from two to three weeks. The other three have done remarkably well, and while a cure could not be claimed, it did seem that splenectomy with transfusion both before and after operation offered more in this disease than any treatment yet proposed.

DR. LOUIS HAUSWIRTH: Remissions in this disease are just as long after transfusion in pernicious anemia as after splenectomy.

1. **Endocrine Functions of Gonads in Males.**—More and more, Barker says, are we forced to realize that the general form and the external appearance of the human body depend to a large extent on the functioning, during the early developmental period (and later) of the endocrine glands. Our stature, the kinds of faces we have, the length of our arms and legs, the shape of the pelvis, the color and consistency of our integument, the quantity and regional location of our subcutaneous fat, the amount and distribution of hair on our bodies, the tonicity of our muscles, the sound of the voice and the size of the larynx, the emotions to which our *extérieur* gives expression — all are to a certain extent conditioned by the productivity of our hormonopoietic glands. We are simultaneously, in a sense, the beneficiaries and the victims of the chemical correlations of our endocrine organs. More than ever before, is the minute examination of the external appearance of the body—the habitus—of significance for the practicing physician who desires to make accurate diagnoses.

2. **Syphilitic Nephritis.**—The clinical significance of the appearance of doubly refractile lipoids in the urine, and especially their possible relation to a syphilitic nephritis, led Stengel and Austin to examine the urine fifty-eight times in forty-six cases, with a polarizing microscope. Of these 46 cases, 23 patients showed nephritis with an abundance of albumin and casts in the urine. Of these 23, 6 had positive Wassermann, 3 had strong presumptive evidence of syphilis but not positive Wassermann, 14 had not the slightest evidence of syphilis. The 6 patients with positive Wassermann all showed lipoids in the urine, whereas of the 14 nonsyphilitic cases only 5 patients showed lipoids in the urine. The rest of the 46 cases studied were made up in part of cases of nephritis of the interstitial or arteriosclerotic types, with only traces of albumin in the urine and a few hyaline and granular casts, in some cases in which syphilis was present and in some in which it was not, in part, of syphilitic cases in which there was no nephritis and, in part, of control cases showing neither syphilis nor nephritis. None of these cases showed lipoids in the urine. One of the 6 syphilitic patients with nephritis showing lipoids in the urine, had not received any mercury.

Stengel and Austin believe that the evidence suggests that there exists a parenchymatous type of nephritis due to syphilis, characterized by an abundant albuminuria, with many hyaline, granular, and occasionally epithelial casts, with a tendency to produce edema of renal distribution. This is associated, as a rule, with a moderate reduction of phenolsulphonephthalein output and exhibits an almost constant tendency to the presence of doubly refractile lipoid globules varying in size from that of an erythrocyte to globules three or four times this diameter, seen sometimes floating free in the urine but not rarely as a constituent of a compound granular cell or possibly on an epithelial cast. On the other hand, similar lipoid globules may be found in severe acute or chronic parenchymatous nephritis of other etiology, but in only a minority of cases. Of further interest is the fact that in 66 out of the last 84 cases of nephritis, there could be recognized from the histories, such possible etiologic influence as infections, lead, alcohol, excessive work, exposure, senility, etc.; but in 18 cases no such factors could be determined. Of these 18 cases, there existed in 8 either an unquestionable history of syphilis or a positive Wassermann or both; in 6 more of these cases no Wassermann had been secured; while in 4 syphilis was definitely excluded.

4. **Damage Done by Pyelography.**—Experiments on dogs made by Keyes and Mohan showed that momentary gentle distention of the normal pelvis of the kidney doubtless causes no more damage than a congestion of the organ, doubtless of brief duration; but if the distention persists for a few minutes the injected fluid is absorbed into the blood-vessels and lymph-spaces about the kidney pelvis. Although, like Strassmann, the authors have been unable to detect any collargol forced into the collecting tubules, they found collargol in the glomeruli and in the convoluted tubules. As there was much less collargol within the glomeruli and tubules than in the lymph-spaces and vessels, they conclude that the appearance of the collargol within the glomeruli and tubules is a secretory phenomenon.

In actual practice a secondary infiltration due to renal retention following the examination must be considered. The secondary distention is of far greater importance than the primary retention at the time of injection. It is the cause of most of the deaths that have been reported from pyelography. The cause of infiltration in these cases is ureteral obstruction. Hence, it may occur when there has been no primary distention. Alarming symptoms following pyelography are to be relieved by immediate drainage of the kidney or nephrectomy. The presence of collargol in the kidney parenchyma should not be a cause of apprehension, though it shows that the injection has been made with too much force. The collargol may enter the general circulation and be distributed to the other kidney and elsewhere, in some instances at least, and yet no great harm results.

8. **Aconite as Vasodilator.**—After an experience of years in its use for this purpose, Thomson regards aconite as the most efficacious vasodilator when given systematically in full doses. Aconite thus administered at once reduces blood pressure, produces a full and compressible pulse, and greatly increases the percentage of the elimination of urea in interstitial nephritis.

10. **Eczematoid Ring-Worm.**—Hartzell has found the ointment suggested by Whitfield, which contains 3 per cent. of salicylic acid with 5 per cent. of benzoic acid, most effective; but, he says, it cannot be used, as Whitfield has pointed out, without some degree of caution in markedly inflammatory cases, as it occasionally produces considerable irritation.

11. **Aortic Aneurysm With Recurrent Fever.**—Five or six weeks before entering the hospital, McPhedran's patient, a woman 36 years of age, of bad habits, is said to have been kicked below the right scapula. She complained of pain in this part, and she was troubled with nausea and vomiting. Over the part there was dulness, and the breathing sounds were weak. There were 13,500 leukocytes per centimeter, the increase being in the polymorphonuclear cells. Her temperature was 104 F. She did not appear seriously ill; with the fall of temperature the leukocytes returned to normal and remained so even in the recurrent attacks of fever. The signs in the chest grew gradually less marked and the pain ceased. In the general examination of the chest signs of dilated aorta were found. The Wassermann test gave a marked reaction.

She was kept five weeks under observation in order to note the natural course of the fever—it showed little if any improvement. Then mercurial inunctions were used and potassium iodid given. There was only one sharp rise of temperature after that, but slight, somewhat irregular fever persisted, and six weeks later salvarsan was resorted to. A first intravenous injection of 0.3 gm. was given. There was no reaction. Eight days later 0.6 gm. was given, still without reaction. A similar dose was given eight days later, followed by a slight short reaction, the temperature rising to 100 F., but falling to normal and remaining so. A fourth dose was given after ten days, and the reaction was rather sharp, the temperature reached 102.5 F., but again fell and remained normal. Thirteen days later the last injection was given; the reaction was less; temperature, 101.5 F. After that the temperature remained normal while in the hospital—six weeks—and her general health improved very much, but there was no change apparent in the state of the aorta or the aneurysm, and the Wassermann reaction was quite as marked.

18. **Roentgen Diagnosis of Stomach and Duodenum Lesions.**—The interpretation of the roentgenograms and the diagnosis of the 27 consecutive cases described in this communication are the result of a study of about 20,000 roentgenograms in 700 cases. The 27 cases reported include all cases examined roentgenographically by Cole and subsequently operated on by Brewer. Each case was referred to Cole with the simple statement that an organic lesion of the stomach or duodenum was suspected; no history or data obtained by physical examination or gastric analysis being furnished. As a result of the roentgenographic examination, a typewritten report was returned, giving the exact findings and an opinion regarding the presence or absence of a gastric or duodenal lesion, its location, extent and probable cause. In several cases a lesion of some other portion of the gastro-intestinal tract was diagnosticated. Later each case was explored, and the findings at operation were recorded.

Of the 22 cases in which a definite diagnosis was made by the Roentgen method subsequent operation proved that in 20 instances this diagnosis was correct, and in 2 it was incorrect. In 11 of these cases the diagnosis was negative as to the presence of a gastric or duodenal lesion, although the clinical history so strongly suggested ulcer or carcinoma as to justify exploratory operation. In not one of these cases was an organic lesion found to exist. In the five instances in which the roentgenologic diagnosis was not definitely stated, owing to incomplete observation or unusual findings which could not be definitely interpreted, and concerning which only an opinion was expressed as to the probable lesion present, the opinion proved to be correct in four instances and incorrect in one instance. In other words, in this particular series, a correct diagnosis was made by serial roentgenography in 89 per cent. of the cases.

22. **Keloid Formation in Negro.**—Brenizer states that the negro is much more susceptible to all connective-tissue tumors than the white man, about 2 to 1. The negro at birth shows many gross congenital malformations and, on the dissecting table, many anomalies of blood vessels and nerve

formations confuse the student as he follows his text-book guide. These perverted structural conditions point to an instability in the equilibrium of growth. There must be some disturbance of an inhibitory influence which holds the growth of the cells in check and prevents their growth at random. If the abnormal growth of cells is due to an injury of an inhibitory substance, this substance must be injured before the cells can grow. This inhibitory substance is then more sensitive than the cells themselves. If we possess evidence of a much greater preponderance of abnormalities of growth and tumor formation in the negro than in the white man, we may know that this inhibitory substance is weaker and more unstable than in the white man. Therefore, irritation which might pass without a demonstrable effect in the white man, might so injure this inhibitory substance in the negro as to allow an overgrowth of the dermal connective-tissue cells and the formation of a fibroma, a keloid.

24. **Tendon Fixation for Deformity.**—In the case cited by Gallie, that of a boy, 5 years of age, the calf muscle seemed to have about one-quarter of the normal power, the tibialis posticus no power at all, and the peronei, tibialis anticus, dorsi flexors and plantar flexors of the toes about normal power. The result was a moderate calcaneovalgus, the patient walking entirely on the heel and with considerable valgus, apparently making no use of the power still persisting in the calf. The following operation was done: A vertical incision 5 inches long was made along the outer side of the tendo achillis, down to the posterior extremity of the os calcis. The sheath of the tendo achillis was split throughout the length of the incision and the tendon exposed. The tendon was then split into an anterior and a posterior half from the upper end of the incision down to the os calcis. At the upper end of this incision the anterior half of the tendon was then cut free from the muscle. Close to the insertion of the tendon a small opening was made in the anterior portion of its sheath and the cut end of the half tendon drawn through it so that it was now entirely anterior to the sheath. The posterior surface of the tibia was then exposed by retraction of the flexor longus hallucis and the periosteum divided vertically for 3 inches, down to the lower end of the bone. After reflecting the periosteum sufficiently, a piece of bone, 3 inches long and of the thickness of the half tendon, was removed with a gouge and the tendon laid in the trough thus prepared. When this tendon had been drawn sufficiently taut to produce a slight equinus, it was sewn solidly in place with kangaroo tendon and catgut and completely covered with periosteum. Thus, passive or active dorsiflexion of the foot beyond a slight obtuse angle was made impossible.

The peronei tendons were then transplanted into the os calcis and, finally, a fixation was done on the tibialis posticus tendon to prevent the valgus deformity, the tendon being buried in the internal malleolus. After two months the fixations were quite solid and the peroneal transplantation successful. The part of the tendo achillis still attached to the muscle had regained its normal thickness so far as one could tell. The point of greatest interest, however, was that while dorsiflexion beyond a slight obtuse angle was impossible the patient was able to plantar-flex the foot strongly by the combined action of the calf muscle and the transplanted peronei. Thus the deformity and disability were overcome without interference with the power present. With the assistance of a Whitman plate the patient walks nearly normally.

43. **Lymphatic Leukemia in Acute Infection After Removal of Spleen.**—Jackson and Smith cite the case of a young man who, a few weeks after removal of the spleen in 1909, showed an essentially normal blood picture. In 1913 he developed what seemed clinically an acute tonsillar infection; this was quickly followed by marked enlargement of the glands of the neck and moderate general glandular enlargement involving axillary, inguinal and epitrochlear glands. This situation was accompanied by a blood picture so typical of lymphatic leukemia that no other diagnosis seemed possible. After a week of sore-throat, general malaise and moderate elevation of temperature the symptoms abated and a normal convalescence as from an acute infection ensued. Blood examinations done from time to time showed a gradual diminution in the white count and a change in the blood picture from that of a typical lymphatic leukemia on June 3, 1913, to an approximately normal picture on Aug. 23, 1913, and a normal picture on April 15, 1914.

45. **Injection of Alcohol Into Gasserian Ganglion for Relief of Trigeminal Neuralgia.**—Byrnes' clinical (in fourteen cases) and experimental (on dogs) observations have convinced him that in the treatment of trigeminal neuralgia, a single successful injection of alcohol into the gasserian ganglion is followed by immediate relief of pain and all the symptoms indicative of its complete physiologic destruction. Although a general anesthetic is not administered, the painfulness of the injection is not unbearable or greater than that experienced in making deep intraneural injections. In experienced hands, this form of treatment is without serious risk, and no fatalities have been recorded as a direct result of the injection. Byrnes asserts that in spite of the contentions of Alexander and Unger, injections in man by exposure of the ganglion appear to be unwarranted and lacking in judgment, except in rare cases in which this slight saving of time may determine the immediate result during exposure of the ganglion. If the ganglion is in view or accessible, direct injection might be practiced; otherwise the original

operation for removal or avulsion of the root should be employed. If deep neural injections have been unsuccessful, and repeated attempts to inject the ganglion by the subcutaneous method have failed, Byrnes agrees that an effort might be made to inject through the exposed foramen ovale before resorting to the subtemporal operation for removal.

It has been demonstrated, by fractional injection, that the extent of destruction may be, in a measure, limited to that portion of the ganglion from which the affected nerve-trunk originates; and that not infrequently the corneal fibers can be spread. From the distribution of corneal anesthesia, following partial injections of the gasserian ganglion, it appears that the upper and lower halves of the cornea receive separate innervation. In cases of bilateral trigeminal neuralgia, injection of the ganglion possesses distinct advantages over other methods of radical treatment. Since anatomic continuity is not actually destroyed and the motor nucleus is not directly affected, conditions are most favorable for recovery of motor function; while sensation should be permanently lost if the ganglion is completely destroyed. Thus, by allowing sufficient time for regeneration in the motor root, bilateral ganglionolysis might be safely practiced. Experimental studies appear to indicate that it is not probable that the ganglion can be completely destroyed by a single injection of alcohol. It is Byrnes' opinion, however, that by repeated injections of the ganglion its complete destruction may finally be accomplished. Byrnes has treated fourteen patients. A little more than eighteen months have elapsed since the earliest injection. During this period, six patients who were treated more than a year ago are still free from pain—the longest period of relief being eighteen months. Four patients, treated within the last twelve months of this period have had no return of pain. Three patients in whom only partial injections were obtained, returned for further treatment.

47. **Tuberculin Hypersensitiveness in Pulmonary Tuberculosis.**—The application of the intracutaneous test of Mendel to the study of the course of tuberculin hypersensitiveness in tuberculous human beings is the basis of Holmes' paper. The eight patients examined were all under institutional treatment. The treatment was essentially the same in each case—hygienic and dietetic. All the cases had been diagnosed as actively tuberculous; the conjunctival test had been employed in many. Each patient was carefully examined from time to time, the more frequently when there was reason to believe some change might be present. All were under Holmes' immediate supervision. A record of the temperature of each patient was available at all times, and a chart containing his subjective sensations, as recorded by himself, was available in most cases. The tests were made at intervals of fourteen days. Three injections were usually given at a distance of from 3 to 4 cm. from each other; first the control solution distally, then the tuberculin dilutions in order of strength, the weaker nearer the control. In subsequent tests, an effort was made to avoid the site of earlier application, lest local hypersensitiveness should be induced.

Each individual was tested first for reaction to 1/100,000 mg., or at least to a dilution weaker than that to which it was likely he would react. Subsequent tests were made to include the dilution to which the patient had previously reacted, and one weaker dilution, or one stronger dilution, or both, according to the peculiarities of the case, as shown in previous reactions. Reactions were read after forty-eight hours; the traumatic (control) reaction had faded away by this time, whereas the tuberculin reaction was then at its height. These studies showed that individuals suffering from pulmonary tuberculosis present marked tuberculin hypersensitiveness soon after the clinical onset of the disease. This hypersensitiveness diminishes if they improve and fluctuates or remains stationary, if they do not improve. More advanced cases, in time of exacerbation, present this elevated hypersensitiveness again; it rises or falls, following more or less closely the clinical course of the disease. Toward death, it may rise much higher, and then fall until it fails entirely.

48. **Relation of Sensory Nerves to Inflammation.**—The relation of the sensory nerves to inflammation is an unsettled question. It is generally believed that an area deprived of its sensory nerve-supply is more susceptible to injury, but recent observations tend to show that the inflammatory reaction in such an area is beneficially modified. The definite results of Bruce and Januschka indicating an amelioration of the inflammatory reaction, as contrasted with the generally accepted idea that there is an increased susceptibility to injury in parts deprived of their sensory nerve-supply, led the authors to repeat in part their experiments. With the sensory nerve-endings eliminated by degeneration an inflammatory reaction was produced by Stevenson and Reid with mustard-seed oil, which was identical with that shown in the control while it lasted, but which subsided more rapidly than in the control and returned more quickly to normal. Cantharides plaster produced inflammation in anesthetic areas in which the sensory nerve-endings had degenerated. This reaction was identical with that observed in the control areas. In areas in which local anesthesia was produced, a definite inflammatory reaction was produced by mustard-seed oil. Morphin and chloral modified the inflammatory reaction to mustard-seed oil in the eye, but probably not through their action on the sensory nerve-endings.

49. **Bacterium Welchii in Dejecta of Children.**—In 18 children suffering from minor ailments but without marked derangement of the intestinal tract, *Bacillus aerogenes capsulatus* was isolated by Knox and Ford on the first examination, in nine cases. The original milk tubes showed characteristic reactions, the rabbits revealed gaseous edema on inoculation and positive cultures were obtained from the organs and tissues. In nine other cases the organism was not obtained on the first trial, but subsequent examination revealed it in all instances. In some of the cases the majority of the milk tubes inoculated had a characteristic appearance at the end of twenty-four to forty-eight hours. In two cases the first examination was negative, but material was not available for a second trial. In 7 breast-fed infants from the obstetric ward the dejecta from 6 were negative for the "gas-bacillus" reaction, although 15 to 20 tubes were inoculated with material from each case. In one instance, however, one milk tube in the series inoculated gave positive results. In this case the possibility of contamination can be excluded. It is evident to the authors, from the results of their inquiry, that *B. aerogenes capsulatus* must be regarded as a normal and constant inhabitant of the intestinal tract in children except in breast-fed infants.

53. **Congenital Dislocation of Hip.**—Starr claims that about 75 per cent. of the cases under 8 years of age coming under his observation can be reduced by manipulation, and a perfect anatomic and functional result obtained. In possibly a small percentage of cases the head is not retained in the acetabulum but slips forward as an anterior transposition, giving what may be called a functional cure but not an anatomic one, the chief defect being a small amount of shortening which necessarily remains. In some 5 per cent. of cases it has been found necessary to make the reduction by operative means. The chief hindrances to the reposition of the head as found in such operation, has been the thickened and contracted condition of the capsule. By making a free crucial incision through the anterior portion of the capsule,

a grooved instrument, similar in character to a shoe spoon, may be introduced, the end of the instrument reaching the margin of the acetabulum, and the head of the femur may be "skidded" along this hollow into the socket.

71 *Germicidal Activity of Chrysarobin and Other Medicaments Used in Psoriasis. J. F. Schamberg, J. A. Kolmer and G. W. Raiziss, Philadelphia.
72 Primary Epithelioma of Hand. H. Fox, New York.
73 *Metabolism Study of Case of Chronic Urticaria. J. Rosenbloom and M. C. Cameron, Pittsburgh.

71. **Germicidal Activity of Chrysarobin.**—The authors summarize the results of their investigations as follows: Chrysarobin, as regards its influence on the *Staphylococcus pyogenes albus,* in the test-tube and in the bodies of animals fails to exert any appreciable germicidal effect. Sodium chrysophanate possesses no germicidal action in the test-tube on the said staphylococcus in saturated aqueous solution within a period of fifteen minutes. Intravenous injections of considerable doses exert no restraining influence on the formation of abscesses in the viscera when simultaneous intravenous injections of the *Staphylococcus aureus* are given. Sodium chrysophanate, when administered intravenously to white rats previously infected with the *Trypanosoma lewisi,* exerts no perceptible influence on the motility or viability of the trypanosomes.

Pyrogallic acid fails to inhibit the *Staphylococcus albus* except when the concentration is greater than 1 in 10 or 10 per cent. In doses of 1 to 10 c.c. of a 1 per cent. solution it fails to prevent pyemic abscesses in the viscera when injected with a bouillon culture of *Staphylococcus aureus.* Pyrogallol in increasing doses of 0.5 per cent. solution, given intravenously in white rats, fails to exert an appreciable influence on the motility of trypanosomes. Arsenic, Fowler's solution, in 1 per cent. aqueous solution, possesses no germicidal effect in the test-tube on the *Staphylococcus pyogenes albus,* after fifteen minutes' exposure. Sodium arsenate, in 20 per cent. aqueous solution, likewise has no germicidal effect on this organism, after fifteen minutes' exposure. Fowler's solution (representing 1 per cent. arsenious acid, in quantities of 0.2 to 0.4 c.c. in 5 c.c. of a sterile neutral bouillon), will inhibit 0.1 c.c. of a twenty-four-hour culture of *Staphylococcus aureus* after forty-eight hours' duration. Smaller quantities fail to inhibit. The intravenous administration of six times the average dosage per kilogram of body-weight, of an arsenious-acid solution, does not prevent staphylococci from producing abscesses in the kidneys.

Arsenic appears to exert an inhibitive effect on the number and motility of trypanosomes in the blood of white rats, but the dose required is a relatively large one.

Calomel, in quantities of 0.0005 to 0.001 gm. (1/120 to 1/60 grain) is absolutely germicidal to the cocci contained in 0.1 c.c. of a twenty-four hour broth-culture of *Staphylococcus aureus.* Calomel in 1 per cent. suspension is capable of destroying the cocci of the skin, both on normal skin and psoriatic patches. Chrysarobin under identical conditions fails to exert any appreciable germicidal effect.

73. **Metabolism in Chronic Urticaria.**—The diet given by Rosenbloom and Cameron consisted of 100 gm. protein, 110 gm. fat, 200 gm. carbohydrate and 16 gm. nitrogen, yielding to a total caloric value of 2,225, or 35 calories per kilogram of body-weight of the patient. In three days there was a nitrogen retention of 5.08 gm. The urea nitrogen in relation to the total nitrogen is very low. It should be about 80 to 86 per cent. of the total nitrogen. This low urea nitrogen is no doubt due to some loss of function of the liver. The ammonia-nitrogen, uric acid, acidity and ratio of uric acid nitrogen to the total nitrogen are normal. There was a marked disturbance in the absorption of nitrogen, as the fecal nitrogen in a certain percentage of the total nitrogen intake was about three times the normal. There was no diarrhea, therefore the patient showed a poor ability to absorb nitrogen, no doubt due to some intestinal condition.

The urinary sulphur partition was normal with the exception of the large amounts of neutral sulphur excreted on the first and second days. On the third day, when the neutral sulphur was normal, the ethereal sulphates showed an increased amount. The high neutral sulphur was indicative of a lessened oxidative capacity while the ethereal sulphate is an evidence of increased intestinal putrefaction. The amount of fat in the stool is above normal, showing an inability to absorb the usual amount. This is, also, no doubt indicative of some intestinal condition. The relation between the neutral fat, fatty acids, and soaps of the feces shows a poor ability to digest fats as shown by the high proportion of neutral fat. In the three days there was a loss of 0.04 gm. of calcium oxid and 0.01 gm. of magnesium oxid, which is perfectly normal. The proportion of calcium and magnesium oxids excreted in the urine and feces is also normal.

85. **Simplified Method of Blood Transfusion.**—The technic used by Lewisohn is the following: Allow the blood to run through an ordinary cannula into a glass jar, containing 5 c.c. of 10 per cent. sodium citrate solution. While the blood runs into the jar it is stirred with a glass rod to effect a good mixture of blood and citrate solution. The blood is then poured into an ordinary glass funnel, which is connected with the other cannula by a piece of rubber tubing. The whole procedure takes five minutes. Lewisohn has used the method on two patients (transfusions of 300 c.c. and 500 c.c., respectively) without any untoward symptoms.

90. **Senile Paraplegia.**—The condition described by Starr, he says, may occur in anyone after the age of 65, depending on his general strength and vitality. The individual becomes gradually more and more feeble, and notices first an increasing disability in walking, in going up stairs, or in standing for any length of time. This undue weariness goes on to an actual feebleness of movement, no longer compensated for by the use of canes or help, and finally results in a partial paralysis of movement, so that it is with difficulty that the patient moves from room to room or chair to chair, and finally becomes bedridden. In some cases the weakness is attended by a marked ataxia, the incoordination being more extreme than the actual weakness. In some cases pain is a very prominent symptom, felt either on motion only, or on standing, although it may occur spontaneously, and is particularly severe after exertion and toward night. The pain is not infrequently attended by sensations of numbness and tingling, and is always attended by coldness of the feet and legs, and an objective coldness of the surface. Occasionally, however, burning pain has been complained of, even though the surface was felt to be cold.

An atrophic condition of the muscles is very often quite pronounced and is attended by a loss of the mechanical excitability of the muscles to percussion and by loss of the tendon reflexes. The limbs, as a rule, are flabby, cold and blue, showing that the vasomotor condition is below normal, and the circulation sluggish; not infrequently edema occurs when the patient is out of bed. Occasionally a loss of control of the sphincters occurs late in the course of the case. Pain in the back and around the loins, is a frequent accompaniment of senile paraplegia, and gives rise to much discomfort and distress, particularly at night, when it is liable to lead to insomnia. It seems possible to distinguish between certain groups. First, those in which the primary disease lies in the muscles alone. Secondly, in another group of cases, it is evident that there is an active degenerative neuritis present. Thirdly, there are cases in which it is evident that the spinal cord is the seat of the disease.

103 Hemorrhagic Disease of New-Born. J. M. Brady, St. Louis.

97. **Surgery of Heart.**—Regarding the treatment of wounds of the heart Kirchner concludes as follows: Wounds of the heart, especially when accompanied by hemorrhage, should be sutured. When the hemorrhage is confined in the pericardium (hemopericardium) and the pulse is irregular and slow, prompt drainage of the pericardial sac is demanded. An early diagnosis is important, and in case of doubt exploratory pericardiotomy should be performed. The choice of the anesthetic and the manner of administration is important, and in no case should the anesthesia be profound. If the heart, when exposed, stops beating, gentle massage of the organ should be practiced. Unless the opportunity for infection were great, it is better not to establish primary drainage of the pleural cavity. The approach to the heart should be well planned, so that the operation may be performed as quickly as possible.

102. **Bronchial Asthma.**—It is Brown's belief that the symptom complex known as bronchial asthma is due, in the main, at least in many cases, to the following factors: bronchitis; chronic cough; overworked right heart; dilatation of bronchial capillaries, lymph vessels; reflex conditions. On one occasion, when a patient was suffering acutely, Brown gave 1/20 grain of strychnin, and waited for perhaps ten minutes, and there was little or no relief. Then he gave ¼ grain morphin, and much to his relief as well as that of the patient, the breathing almost immediately became easy. A few hours later another attack came on and he gave the morphin first, and there was little or no relief until the strychnin followed. Brown tried these agents repeatedly, sometimes giving one first then the other, but always the results were the same. If the two were given together the relief was prompt, and all but instantaneous. Later he used the drugs by mouth to avert the attacks.

107. **Auscultoplectrum.**—The auscultoplectrum designed by Kolipinski is constructed as follows: The funnel end consists of an Otis urethroscope, size 25 or 26 French scale, with the obturator removed, heavily gold plated; 41 inches or 104 cm. of red or black rubber tubing, 5 m.m. in diameter; an ear piece, a small, acorn-shaped piece of hard rubber, such as is used in a phonendoscope or binaural stethoscope. The length of the whole instrument is 45 inches. A cork is the pleximeter with its narrower end applied to the body. The base of the cork is tapped with the plectrum. This is held by the fingers at its insertion into the rubber tubing, so that the metal tube is allowed a free elastic swing; the hand not being in direct contact with it. When percussing, the rubber tubing is hung about the neck.

130. **Theories as to Origin of Jackson's Veil.**—Against the theory of the inflammatory origin of these membranes, Lynch says, are the regularity of situation of the blood vessels, which usually run about a centimeter apart, and the serous surfaces moving one over the other with a fluid between. If due to inflammation, adhesions would take place between the two serous surfaces, as in pleurisy. His conclusions are: 1. The membrane described by Jackson is of embryonal origin, but it may be so altered by inflammation as to appear like an ordinary adhesion. 2. There are unquestionably adhesions of inflammatory origin, due to perityphlitis and pericolitis; these membranes should not be mistaken for those of Jackson, as there are many points of difference. 3. Kinking or malformations are due to improper fixation or rotation; and the length of the mesentery has a great deal to do with the kinking of the ileum.

136. **New Method of Examining Stools for Eggs.**—Fauntleroy and Hayden's method consists essentially of staining the fecal matter with anilin gentian violet. This solution stains everything on the slide except the eggs. It does not penetrate the membrane about the eggs and they are therefore left in a natural state. None of the other ordinary colored stains will do this. The entire slide with the exception of the real eggs is stained violet. This method of examination has been used in the examination of over a thousand stools with uniform success. All eggs, hook-worm and others, stand out very clearly and beautifully. About 2 gm. of the fecal material are thoroughly mixed with 5 c.c. of a 2 per cent. aqueous solution of compound solution of cresol in a centrifuge tube. The specimens are centrifugalized at high speed for one minute, the supernatant liquid is then decanted and fresh compound cresol solution added and mixed with the sediment in the tubes. This operation is repeated three times. On completion of the centrifugalization process a small portion of the bottom sediment is removed with a clean pipette and placed on a clean slide, a small drop of anilin gentian violet mixed with the sediment, and a clean cover-glass placed on it.

1. **Early Pulmonary Tuberculosis in Childhood.**—Fraser's communication is based on an analysis of the results of an investigation, clinical and otherwise, into certain important points in connection with 296 cases of pulmonary tuberculosis (mostly incipient) among schoolchildren attending elementary schools. Fraser found that the commencement of school life has a prejudicial effect on children predisposed to pulmonary tuberculosis. Inadequate increase of weight is very suspicious, and that weight and nutrition should not be considered independently. Defective nutrition is probably the earliest indication of a tuberculous infection, before any recognizable physical signs are present. Night sweating is only significant when the sweats are heavy and characteristic. It was present in 55.8 per cent. of the cases, being heavy in 10.2 per cent. A persistent hard, dry cough is the most suspicious type of cough. It was present in 134, or 45.3 per cent., of the cases. In nearly every case one or other apex is affected, and the right apex is most often the first clinically recognizable focus. In only one case (0.3 per cent.) was neither apex involved; the apices of both lungs were affected (with or without some other part or one or other lung) in 221 cases (76.8 per cent.).

Dulness is almost invariably present over the affected lung (95.3 per cent.). Inequality of the breath sounds is a very early indication of trouble; the duration of this is short, and it is usually succeeded by bronchial breathing, which is nearly always present and which remains indefinitely. Friction and fine crepitations are the most significant accompaniments; and all accompaniments when persistent, and especially if localized, are suspicious. Spontaneous improvement is more common in girls than in boys; from the sixth year the tendency to spontaneous improvement increases year by year; and children in rural areas show a very much greater tendency to spontaneous improvement than children in urban areas.

13. **Effect of Daylight and Drying on Tubercle Bacilli.**—It is stated by Findlay and Martin that the bovine type is distinctly more susceptible to the prejudicial effect of ordinary atmospheric influences (daylight and drying) than is the human type of tubercle bacillus. This difference between the types may in part explain why aerial infection with the bovine type is so infrequent in human beings.

20. Peripheral Blood in Kala-Azar Patients.—Patton has no difficulty in finding the parasite of kala-azar in films of the peripheral blood. The technic employed aims at collecting as *many* of the leukocytes at the end and the sides of the blood film as possible. The film is then deeply stained with Romanowsky's stain and examined, either with a dry objective, or if time is of no particular consequence, the film may be searched with an oil immersion lens. The parasite was found in the first *blood film examined in* 42 of the cases, in the second film in 13 cases, in the third film in 12 cases, in the fourth film in 5 cases, and in the fifth film in 2 cases, in the sixth film in 4 cases, in the seventh film in 1 case, in the eighth film in 1 case, in the ninth film in 2 cases, in the seventeenth film in 1 case, and in the twentieth film in 1 case. Many of the patients were clearly in the early stages of the disease.

22. Bodies Found in Feces of Kala-Azar Patients.—Especial attention has been paid by Mackie to the feces as one of the possible routes by which the specific parasite might escape. On several occasions he has found one, two, or sometimes a small group of bodies which, in size and general morphology, were indistinguishable from leishmania, with such modifications as one might reasonably expect these bodies to assume in feces. In these few isolated cases, the suspicious bodies were generally lying in or on a small mass of mucus, in which, it may be, they were protected from the action of bacteria. Eighty-two cases of kala-azar have been subjected to examination; eight were found to contain the bodies in question in considerable numbers, eight contained a few, and sixty-six were negative. When the fecal material is kept diluted with water, these bodies generally survive the other cellular elements, and in some cases have been seen to persist *with little* change for ten, twelve and even eighteen days. In 9 cases in which "bodies" were found, the patients were diagnosed as "clinically typical" of kala-azar in 5 they were returned as "clinically probable," and in 2 clinical state was "suspicious."

The feces of 26 healthy persons did not show the bodies in question, either in freshly passed mucus or in the dilutions which were examined daily for *six days*. In size they vary from about 2 microns to 4.5 microns, rarely larger, and almost invariably possess one large uniformly-staining nucleus and often a small nodule of azurphil substance generally placed close to the margin. There is always a defined cell wall which is generally seen as a clear margin, but sometimes it is dense enough to give a double contour on focussing. The cytoplasm is either hyalin or contains certain small chromatin-like dots or is marbled or finely vacuolated. In some specimens which resisted decomposition in water for some days, the nuclear network was seen to be very irregular and the internal structure highly complex and pleomorphic. Some bodies appeared in small clumps and were quite round, with a strong double contour and a basophilic nucleus almost completely filling up the cell. These resembled groups of moniliform spores.

28. Estimation of Quantity of Organisms in Suspension.—The methods employed by Harvey and Acton were: (1) Count against red blood corpuscles. (2) Colony production on Conradi-Drigalski plates. (3) Exhaustion of content of suspension by dilution. (4) Inoculation into animals. They conclude that the area of bacterial growth on solid nutrient medium may, other things being equal, be taken as a fair measure of quantity—at all events for the dysentery bacillus. Enumeration against red blood corpuscles and colony production give fairly consistent results when used for the enumeration of bacteria, such as the bacillus of dysentery, in suspension. The estimate obtained by the method of colony production is lower than that given by enumeration against red blood corpuscles. Enumeration by exhaustion gives low counts but the method is useful as a check on other methods. Interval between inoculation and death as a measure of toxicity or of quantity did not, under the conditions of experiment, yield any satisfactory results.

32 *Treatment of Suppuration by Pus Inoculations, and Treatment of Pneumonia by Subcutaneous Injections of Patient's Own Blood. V. Nesfield.

32. Treatment of Suppuration by Pus Inoculations.—It is pointed out by Nesfield that the logical vaccine treatment for a suppurating wound, compound fracture, boil, carbuncle or inoperable surface cancer, is to inject the issuing pus when rendered innocuous, as this contains the true toxins derived by the living organism in the living host. At first Nesfield heated the pus, now he treats it for twenty-four hours with 1 per cent. phenol and camphor. Neither camphor, nor weak phenol damage toxins or *antibodies*, nor do they coagulate nor, as far as is known, form compounds with tissue juices. Such a vaccine (pus) contains not only the identical infecting organisms, but also active ferments, antibodies and true toxins. The *organisms even in* a twenty-four hour culture are many generations removed from the original infecting organism and have probably developed very different chemical substances *and toxins* and hence are not truly similar to those in the lesion. Nesfield has injected such pus over 1,000 times and has never found an abscess to result. The dose: First day 2 minims, second day 3 minims, third day 4 minims and so on, daily till 17 minim doses have been given. If required 10 minim doses can be given after this on alternate days. Prophylactic dose, 5 minims. The reaction: It is quite ordinary to get *induration* at the site of injection, and for the temperature to rise 1 or 2 degrees. This should not be feared.

40 *Effect of Calcium Chlorid on Hemolysis Occurring in Vivo. W. W. C. Topley and S. G. Platts.

35. Treatment of Frost-Bite.—Mayo-Robson emphasizes that in the treatment of frost-bite it is of the utmost importance to save as much of the injured extremities as possible, and as it is impossible to say how much of the damaged tissues will survive, immediate or early amputation is absolutely contra-indicated. The best treatment at first is friction with snow or cold water in a cold room, the changes to a warmer atmosphere being gradually brought about. Frictions with turpentine and oil or with spirit and soap liniment are useful remedies in the early stage, and after the friction the limbs should be raised on pillows and swathed in cotton-wool, which can be held in position by bandages applied loosely so as to avoid any danger of constriction. If blisters form, or discoloration of the toes or other parts shows that gangrene is probable, the whole foot should be sterilized by rubbing with oil of turpentine to cleanse the skin or with spirit containing 1 in 500 biniodid of mercury, after which strips of sterilized double cyanid gauze should be applied between the toes and the same gauze made to cover the whole foot, which is then enveloped in sterilized cotton-wool. Any blisters—which will be found to contain dark blood stained fluid—should be snipped and carefully dried and dressed with the spirit and biniodid lotion. Painting the foot with tincture of iodin would probably be quite as effectual, as an antiseptic, as the spirit and biniodid solution.

Every effort should be made to keep the parts dry and sterile, and if gangrene occurs the surgeon should on no account make too great haste to amputate, as the tissues adjoining the line of demarcation become more and more healthy and the line of granulation tissue between the dead and living tissues, if kept aseptic, gives rise to little discharge and can be kept aseptic by a daily dressing with the spirit solution. Ultimately, when it is seen what flaps of skin are available, the dry, shrivelled gangrenous parts can be removed and the bones severed at such points as will allow the flaps to be conveniently applied to make a good cover to the stump. Cases in which the gangrenous process has only involved the superficial layers of the skin, the separation of the necrosed part should be left to Nature and afterward skin grafting will be found useful. If as the result of neglect or the use of wet dressings the gangrene has assumed the moist variety and the wounds are infected, the spirit dressings will still be useful, and the foot should be well dusted with equal parts of zinc oxid and boric acid, so as to make every effort to convert the moist into dry necrosis, and thus to avoid general septic complications and the danger of the gangrene spreading.

40. **Effect of Calcium Chlorid on Hemolysis.**—The experiments described by Topley and Platts afford no evidence of any protective influence being exerted by calcium chlorid on the red cells of animals subjected to the action of a specific hemolytic serum, though this salt serves to inhibit the lysis of the same cells by the same serum in test-tube experiments. Conclusions as to the therapeutic value of this and similar salts based on in vitro experiments must therefore be held to be invalid.

44. **Passive Ischemia as Means to Overcome Fatigue.**—De Fleury's experience with the troops has confirmed the remarkable relaxation and relief that follow the simple measure suggested by Jacquet. He calls it the biokinetic method of resting; it aims to expel the blood from the legs by raising them. The men take off their shoes and lie on the ground close to a wall or tree and raise their legs against the wall to a right angle with the body. In this attitude the toes, ankles and knees are worked. If the shoes are not taken off, the benefit is less, but even then the refreshing influence of this transient ischemia is notable. The head should be raised as on a pillow. A body of men apparently entirely exhausted recuperate their energies with five, ten or fifteen minutes' exercise of this kind, the rest and the flood of blood which pours into the tissues as they get up.

45. **Heart Disease Among the Troops at the Front.**—Fiessinger has twelve patients with chronic heart disease who volunteered to go to the front, and who keep themselves in good condition with very small doses of digitalis three days in the week as a preventive measure, and for ten days at a time, with four-day intervals, when compensation is failing. Six with a mitral affection have thus kept up with the campaign to date. One young man with aortic insufficiency forgot to take his digitalis and had to be sent home. Another with aortic insufficiency serves in the aeroplane corps, and there has been no aggravation of the valvular trouble although he had one severe fall, dislocating his shoulder. (See also Paris Letter, page 524.)

Briand relates that numbers of young women have cc
treatment for drug addiction since the war began, as th
from whom they used to buy their morphin or cocain
gone to the front and they are unable to find others to s
them or they have no money to buy the drugs now tha
short supply has raised the price. In many cases fri
have persuaded the drug addicts that now is the chance
them to take a course of treatment; in other cases the
turbance from lack of the drug has been such as to
them in the hospital. In analyzing the cases he finds sev
in which the habit was started by a physician's prescrip
or by a nurse against the physician's orders. Briand
tells of drug addicts among the troops whose enthusia
under the colors has tided them along through the first sta
after deprivation of their accustomed drug and they are
well on the way to a complete cure of their addiction. O
man, an alien, enlisted while under the influence of morph
and now demands to be dismissed as he was not responsibl
at the time.

52. **Epinephrin in Typhoid.**—Sergent has long proclaimed the important part played by the suprarenals in typhoid fever; they seem to be affected early and suffer severely from the typhoid toxin, as is manifest in the prostration and low blood pressure which form such a dangerous element in the typhoid syndrome. The cardiovascular derangement is often the direct cause of death; it can be best combated by supplying systematically the active principle of the suprarenals. It should be given early without waiting for serious symptoms to develop; he gives it twice a day in small doses and thinks that it would prove a great aid also for the severely wounded, tiding them past the first tendency to collapse.

53. **Hygiene and Medical Care for Infants.**—This lecture opened the newly organized course on this subject at the Paris medical school, the authorities now realizing the importance of caring for the generation that is to replace the losses in war. Marfan remarked that he has no *chef de clinique*, no *chef de laboratoire* and that the laboratory is scarcely working at all, while he has numerous military duties to perform, but with the aid of four women physicians he enters confidently on this new work at the Hôpital des Enfants-Malades with its affiliated day nurseries and "infant consultations." His guiding principle is always that nearly

all of the affections which prove fatal among young infants are avoidable. Even pneumonia is much less fatal in infants who are not debilitated by preceding digestive disturbance or constitutional weakness. The four great enemies with which we have to contend are congenital debility, inherited syphilis, digestive disturbance and improper feeding. The first two should be warded off by appropriate measures before the child is born or even conceived; the last two by breast feeding. The medical profession thus shows the way not only for practical eugenics but for reducing infant mortality to the minimum. It is the physician's task to keep pointing the way, striving in each individual case to keep as close to the ideal as possible. No one can take the place here of the practiced physician, no devotion on the part of the laity can compensate for medical guidance in each case, correcting errors, overcoming prejudices, etc., teaching hygiene based on the knowledge of the pathology of the infant. Many young physicians, he added, are graduated without proper knowledge in this line although every facility is offered them in the curriculum but the courses in obstetrics and pediatrics are elective and hence are too often neglected by the students.

Hygiene and pathology are closely united at this age; the slightest infraction of the laws of hygiene brings an upset, while the adult often apparently escapes the penalty. The intensity of the reaction to infection and the tendency for it to become generalized are peculiarly marked in infants, especially the tendency to spread by way of the lymphatics. The lymphatics are exceptionally permeable but the lymph glands are unusually well fitted to arrest the invading process. Another special feature of the pathology of the infant is that any local disturbance upsets the general health more completely than in adults.

54. **Early Diagnosis of Typhoid.**—Orticoni comments on the extreme importance of prompt differentiation of typhoid fever in the trenches, remarking that in his corps every case of acute febrile bronchitis yet encountered proved to be typhoid fever. In one case the syndrome simulated appendicitis, in two others cerebrospinal meningitis. In a number of other cases typhoid seemed certain but there was no agglutination and inoculation of animals was negative. The prompt recovery of the men confirmed the harmless character of their transient sickness.

57 The Cell Count in the Cerebrospinal Fluid. (Procédés de numération des éléments cellulaires du liquide céphalo-rachidien.) E. Cottin.

55. **Partial Fusion of Radius and Ulna.**—Du Pan found by chance this congenital anomaly in three children of 8 and 13, but, as the functional disturbance was slight, no attempt to correct it was made. Study of the literature confirmed the wisdom of abstention as in the five instances in which operative treatment was applied the results were not permanent, the bones growing together again afterward. The muscles, tendons and the joints have adapted their growth to the congenital synostosis, and hence mere separation of the long bones is far from restoring normal conditions.

56. **Enucleation of the Eyeball.**—In Gonin's hospital practice this operation is required for fully 5 per cent. of the eye patients, but the proportion is less in his private practice, as severe injury of the eyes from foreign bodies, explosions and goring accidents is comparatively rare among the well-to-do. The retina had separated in fully 70 per cent. of the 500 cases, but other factors had contributed to the blindness in most of them. He has had all the enucleated eyeballs preserved in gelatin-glycerin for teaching purposes, arranged in sets according to the character and seat of the lesion. He reaffirms from his experience the relative harmlessness of even a considerable loss of the vitreous body when there is no adhesion to the retina; also the frequency of a diffuse retinitis rarely perceptible with the ophthalmoscope; the varying importance of injury of the sclera in regard to detachment of the retina according as the injury is near or remote from the equator of the eye; and, finally, the hitherto unsuspected frequency of detachment of the vitreous body and detachment of the choroid.

59. **Physiology of the Appendix.**—Heile's experiments with dogs having a fistula into the appendix, or studying the functioning of the appendix in other ways, have demonstrated, he asserts, that the musculature of the region, including the appendix, forms a single whole in its muscular action, each element having its share in effectual peristalsis. Besides this muscular action, the walls of the appendix secrete ferments that split albumin and carbohydrates. The cells of the appendix secrete further a hormone.

65. **Operations on the Arch of the Aorta.**—Jeger performed operations on dogs aiming to induce conditions like those necessary in operating on an aneurysm at this point in the human aorta. The technical outcome was fine but the animals so far have succumbed to complications.

71. **Postoperative Paralysis of Stomach and Intestines.**—Peiser cites a recent compilation of 142 cases of acute paralysis of the stomach after an operation, with 52 per cent. mortality. This shows that postoperative paralysis is more common than used to be suspected; in many cases it probably subsides spontaneously. The tendency to it must be greater when the stomach is weak from congenital or acquired causes, and this should be ascertained as a routine measure before operations. A tendency to an unstable nervous system also affords a predisposition. In his experience the working classes are less liable to it than the well-to-do. Deep general anesthesia magnifies any preexisting predisposition and reflex inhibition as the peritoneum is incised. All these factors may cooperate, and extreme thirst after a laparotomy should warn of trouble. Thorough rinsing out of the stomach is the best remedy, possibly supplemented by turning the patient into the prone or knee-elbow position. He reports a case in which the bowel as well as the stomach developed paralysis after a laparotomy for disturbance from adhesions. He believes that a hard purge before the operation invites paralysis later, and urges abundant use of superheated air as a means to promote peristalsis after operations, but never in the form of the hot-air box. This makes too great demands on the heart. The electric hot pad answers the purpose fully without affecting the general condition.

75. **Hydronephrosis and Infection.**—Harttung's long article is profusely illustrated in connection with experiments on sixty-two rabbits in which he threw a ligature around one

ureter. The conditions thus induced invited suppuration in the kidney. When the infection was of ascending origin, the kidney pelvis was involved first and predominantly. With blood-borne infection the cortex suffered most.

76. **Treatment of Abdominal Pain.**—Grober emphasizes anew that the necessity for immediate treatment of emergency conditions should never mislead the physician into being content with superficial action. From the way in which his measures act, he may be able as he supervises the case to guess at the underlying cause which it is his task to seek and root out. Abdominal pain, in particular, may be set up by the most diverse causes; most common, perhaps, is acute catarrhal trouble in the stomach and upper bowel from an error in diet. A gastric ulcer was responsible in a case in a young woman, and sudden invagination or volvulus of the bowel in a boy of 8. In another case the abdominal pain was traced to gall-stones, but tuberculous lesions, ulcerations, typhoid, dysentery, hernia and appendicitis may all set in with abdominal pain as the first symptom to attract attention, likewise female trouble and acute disease of the gall-bladder, pancreas or kidney region. Moist or dry heat to the abdomen and opiates will relieve the pains, probably by the afflux of fresh blood or by its diversion to the skin. A warm sitz-bath and removal of pressure in the abdomen by evacuating the stomach, intestines and bladder aid in relieving the pain. A tendency to nausea can be combated by placing scraps of ice in the mouth, turning the head so the water will run out of the mouth. A few drops of lemon juice on the ice may help. Sherbet and ices in general may be useful in combating nausea, and they deserve more extended use, he says, in the diet for the sick. In giving opiates to relieve the pain, we must not be misled, by the subsidence of the pain under them, to think that the trouble is at an end. With a subcutaneous injection of 0.01 gm. morphin, repeated at need after twelve hours, there is not much danger of masking the true clinical picture. Opium is liable to cause cardiovascular disturbance, the heart beat growing faster and the pulse weaker, with disagreeable sensations in the heart region.

77. **Childbearing and Nervous Disease.**—Meyer presents data which reaffirm that marriage, conception and pregnancy should be strictly warned against in all forms of nervous affections, not only in the interests of eugenics but to save the woman further harm. The hope that marriage and pregnancy may bring about a turn for the better in epilepsy, hysteria, exophthalmic goiter, etc., is very seldom realized; if improvement occurs it is scarcely ever permanent. As a rule, it soon yields to an aggravation of the original trouble. It must be remembered also that dementia praecox may develop at first as merely mild and apparently harmless nervousness, and under the stress of conception may flare up into a serious form. The least harmful from the standpoint of childbearing seem to be the symptomatic psychoses, amentia and the like, but even here an inherited taint should suggest possibility of recurrence under the stress of childbearing.

78. **Scarlet Fever.**—Barasch restricts treatment of scarlet fever to efforts to keep the patient's strength up and spare it all extra tasks, sustaining the body thus in its task of antibody production. Among 1,438 cases at the Urban Hospital at Berlin, 16.1 per cent. developed nephritis; 13.8 per cent. developed otitis; 1.3 per cent. endocarditis, and 5.9 per cent. rheumatism; there was sepsis in 9.1 per cent.; late involvement of the glands in the neck in 33.4 per cent., and in 16.4 per cent. of the total there was complicating diphtheria. The mortality was 15 per cent., but only 6.6 per cent. died later than the first three days after entering. Over half of the deaths were in children under 4. As a rule the hospital gets *only* the severer cases in an epidemic, and consequently the above figures must be regarded as favorable, testifying to the importance of the principles followed. The patients are dismissed at the end of six weeks, and return cases are sometimes encountered. About 150 patients were kept constantly in red light, but no benefit from this was apparent. In the 481 cases of swollen glands in the neck, 14.1 per cent. suppurated.

The sore throat was treated merely with an ice-bag or wet bandage to the neck and gargling with a mild antiseptic. Children too young to gargle had their throats merely wiped out several times a day; this relieved them so much that they generally made no objections after the first. After the first day the children are given a tepid bath every day and adults every second day. To ward off kidney complications, the diet is restricted to saltless food, mostly milk and gruel with apple sauce and raspberry juice. If the children are very hungry, rolls or zwieback with unsalted butter or crackers may be allowed. When there is a distaste for milk, it is given in the form of cocoa. If the kidneys show no signs of trouble by the nineteenth day, one egg is allowed. If this is borne without disturbance, a light mixed diet can be gradually resumed, with constant supervision of the urine. If nephritis develops and there is much blood in the urine, nothing but milk is allowed, or possibly with gruels. If there is not much blood, the milk-gruel diet can be resumed. It is kept up until the urine is free from albumin. The patients are kept always as warm as possible, to ward off nephritis, and are not allowed to leave the bed until the twenty-fifth day after subsidence of the fever, and not even then if there are complications.

81. **Naphthalin to Ward Off Vermin.**—Blaschko advises rubbing the body with 5 per cent. naphthalin-petrolatum to keep body lice away. Or half a teaspoonful of pulverized naphthalin can be shaken into the collar around the neck. It works down from here over the body, or it can be worn in a gauze bag. A little scattered in the bed will drive lice away. Head lice can be combated best by cutting the hair close. These measures against vermin are very important in prophylaxis of typhus, as the transmission of this disease by lice is a well established fact, and they may be concerned in the transmission of other diseases.

82. **Danger of Plague in Europe.**—Martini quotes Gottschlich's statement that he found virulent plague bacilli in the sputum of a man in Egypt the seventy-sixth day after an attack of secondary pneumonic plague. A chronic form of plague persisting for weeks with foci in the lungs has been found in rats on ships. These facts show that plague bacilli may reach Europe notwithstanding the long journey. Pneumonic plague seems to be a winter disease, contagion occurring more readily among the housed, and the bacilli acquiring greater virulence in passing from lung to lung. Fully 50,000 died during the epidemic in Manchuria in 1910 to 1911. When an acute lung disease develops in a robust young man and runs a fatal course in two days, pneumonic plague should be suspected. The sputum is thinner and sprays more readily than with other lung affections. All who have been exposed should be passively immunized; physicians and attendants require active immunization (*Pfeiffer method*). Both are harmless, he declares; he never witnessed any disturbances to mention after subcutaneous injection of a whole, killed, agar culture of Manchurian pneumonic plague bacilli. This was done on a large number of persons. He took the injection himself on two occasions, once with the Haffkine method, and he had considerable disturbance after this.

91 *Proportional Leukocyte and Platelet Count. (Klinische Untersuchungen über das gegenseitige Verhältnis der Leukocyten- und Blutplättchenzahlen.) E. Maixner and A. v. Decastello.

85. **Abdominal Wounds.**—Rotter has been making a special study of gunshot wounds of the abdomen, 59 having been encountered in four field hospitals along the Aisne among a total of 1,218 wounded. The corpses found of men dying on the spot from abdominal wounds showed that the mortality from such injuries was fully 90 per cent., and among those living to reach the field hospital it was still 80 per cent. In the clearing hospital it was 40 or 50 per cent., and zero in the hospital in the home zone. The difference between the mortality of abdominal wounds in peace and in war thus is not so great as usually stated. His experience indicates that a spontaneous cure of a bullet wound of the bowel is possible only when the perforation is small, without prolapse of mucosa, or, with prolapse, only when adjacent tissue sticks to the spot and thus serves as a plug to the perforation. The perforation also must be solitary; there is little chance of this plugging process occurring at several points. Another and indispensable condition is that the bowel must be empty at the time it is perforated. In nine operative cases and necropsy of two there was only one case without several holes in the bowel and in this one case the man succumbed to diffuse peritonitis. In none of the other cases could spontaneous recovery have occurred, and consequently treatment should be the same for abdominal wounds under all circumstances, namely, early operative treatment if the case is seen in the first twelve hours after the injury. Later than this, the results of surgical treatment average no better than with conservative measures. Collapse alone need not deter from operating. Conditions as to asepsis, etc., are so good, he says, in the German field hospitals that no one need hesitate on this account. The advantages of operative treatment were illustrated particularly in one case; seven holes in the small intestine were sutured eight hours after the injury; in one place the gut had been severed almost completely. The man made a smooth recovery. In all the nine operative cases two or more holes were found in the bowel, the smallest large enough to insert the finger or thumb. The injury was found beyond repair in three cases, and 5 others succumbed to peritonitis or never rallied from the collapse. Of those given conservative treatment, 20 per cent. recovered, and the course of the cases showed that the bowel wall had not been perforated in most of these.

87. **Treatment of Wounds.**—Hammer emphasizes that the aim in dressing a wound should be to keep away further irritation from without, and keep the part at rest. The germs that have got into the wound require, like all vegetable bodies, a certain length of time to adapt themselves to their new environment; transplanting a plant always checks its growth for a time. The tissues have certain defensive powers which aid in impeding the proliferation of the germs at first. He says that Nature shows us in the scab the ideal to aim for in a dressing.

89. **Emergency Treatment of Prolapse of the Brain.**—Orth has found it of great advantage to close the gap in the skull at once with a periosteum-bone flap, suturing it in place with silk. Even if it is cast off later, it serves its purpose in warding off infection and injury of the brain until the defect can be permanently corrected.

91. **Relations Between the Leukocytes and the Blood Platelets.**—Maixner and Decastello conclude from their clinical and experimental experiences that the number of leukocytes and platelets rise and fall together. No connection with the numbers of red corpuscles was apparent.

103 Snow Blindness. (Schneeblindheit.) Gross.

92. **Pneumococcus Tonsillitis.**—Leschke reports a few cases to show how the pneumococcus may induce what seems to be an ordinary tonsillitis with or without general disturbance, pains in the limbs and depression, suggesting influenza. There is also a type with sepsis. All of these run a longer or more rebellious course than ordinary follicular tonsillitis. The *Diplococcus lanceolatus* is found on the tonsils.

95. **Verrucous Endocarditis.**—In Reye's 23 cases of verrucous endocarditis there was a history of recent acute articular rheumatism in 4 cases; chronic heart disease with articular rheumatism in the past in 5 cases; chronic tuberculosis in 7; chronic nephritis in 2; cancer in 3, and syphilis or pneumonia once each. His bacteriologic examination and inoculation of animals have apparently established that Schottmüller's endocarditis lenta is the later, severer stage of verrucous endocarditis. Both are the work of the *Streptococcus viridans* but only comparatively rarely does it progress to the severe form of the typical "slow endocarditis."

99. **Jet of Air in Prophylaxis of Tetanus.**—Heisler urges the playing of a jet of air on a wound liable to develop tetanus. Hot air is best as it hastens healing, but even a jet of room air from a bicycle pump or electric fan or bellows checks the development of the anaerobic tetanus bacillus.

100. **Agglutination After Antityphoid Vaccination.**—Kellermann has found that the serum of men vaccinated against typhoid gives a positive agglutination reaction; in three cases it was 1 to 200. Hence this test has no differential value in the diagnosis of typhoid under these circumstances.

101. **Hydrogen Dioxid in Treatment of Tetanus.**—Kellermann injected 10 c.c. of hydrogen dioxid directly into the wound following the path of the bullet and the man rapidly recovered under this and serotherapy. As the injection was painful he gave a little morphin beforehand.

106 *Exclusive Radiotherapy of Operable Cancer of Uterine Cervix. M. Hofmeier.
107 Woman as a Factor in the Strength of the Nation. (Volkskraft und Frauenkraft.) H. Sellheim.

106. **Radiotherapy Versus Operative Treatment of Incipient Cancer.**—Hofmeier calls attention to the tragic case of a woman of 29 with a small ulceration on the posterior lip of

the cervix of the uterus. The first symptom had been a little bleeding four weeks before the discovery of the cancer. It was so small and accessible that it was treated with radium and the Roentgen rays alone, and the cancer cells seemed to have been destroyed by the course of radiotherapy which lasted seventeen days. When the patient returned two or three weeks later it was found that the cancer was still growing in the depths of the tissues, and the whole was excised, but within four weeks there was recurrence in the pelvic connective tissue. The wasting of five or six weeks on the radiotherapy was of tragic moment for the woman's fate.

Zentralblatt für innere Medizin, Leipzig

January 2, XXXVI, No. 1, pp. 1-16

108 Advantages of the Continuous Bath in Treating Large Open Ulcerations. (Dekubitus und Dauerbad.) R. von Jaksch.

Gazzetta degli Ospedali e delle Cliniche, Milan

December 27, XXXV, No. 138, pp. 3033-3048

109 *Diphtheria of the Skin. (Sulla difterite cutanea.) G. Bertelli.

January 3, XXXVI, No. 1, pp. 1-16

110 *Aleukemic Myelosis. (Le mielosi aleucemiche eritroblastiche dal punto di vista clinico.) G. Ghedini.

109. **Primary Diphtheria of the Skin.**—Bertelli's patient was a physician who had been treating a case of ordinary diphtheria. He had at the time a pimple near the lip and this developed into a true diphtheric lesion from which diphtheria bacilli were cultivated with disturbance of the general health. The throat did not become involved until several days later. Under antitoxin the general symptoms and the involvement of the mucosa retrogressed but the skin lesion did not seem to be affected by it until it was applied locally. Then the false membranes were cast off and recovery was soon complete. Bertelli compares this case with the few cases of cutaneous diphtheria on record.

110. **Aleukemic Myelosis.**—Ghedini describes eight different types and cites from the literature specimens of each.

111 Insufficiency of the Ductless Glands Common with Inherited Syphilis. (*Insufficienza glandolare endocrina ed eredosifilide.*) R. Vaglio.
112 Case of Achondroplasia. E. Palmegiani.
113 *Serotherapy of Epidemic Cerebrospinal Meningitis. G. Rutelli.
114 Skin Tuberculin Reaction in Diagnosis of Tuberculosis in 601 Children. G. Salvetti.

113. **Serotherapy of Meningitis.**—Rutelli declares that serotherapy is the only rational method in treatment of epidemic cerebrospinal meningitis in children. The serum should be injected directly into the spinal canal or cerebral ventricles, and in generous and repeated doses. In case no benefit is apparent, he advises giving a trial to antiparameningococcus serum. In the 18 cases he reports, all in children, all recovered but 3. He made from two to ten injections in the course of one to four weeks. The total amount injected was from 20 to 270 c.c. He calls special attention to 2 cases in which the children recovered under the serotherapy although it was not commenced until the ninetieth day of the disease and the children were extremely debilitated. Also in 5 cases in which the disease was at the fifteenth day when the first injections were made. In 2 others the serotherapy was commenced in three or four days but the children died. He injects about 10 or 20 c.c. of serum for an infant and 30 c.c. for a child 2 years old. In older children he injects a quantity about equal to the amount of cerebrospinal fluid withdrawn.

120 *Effectual Treatment of Purulent Pleurisy; Two Cases. (Trattamento della pleurite purulenta, col metodo Kawahara.) T. Silvestri.

120. **Purulent Pleurisy.**—Silvestri has long treated cases of purulent pleurisy by clearing out the pus and rinsing the cavity with air. The procedure is so simple that it is within reach of every practitioner. The instrument used has two openings and air flows in as the fluid is drawn out, so there is no sudden change in pressure inside the chest. The air bubbling through the pus in the chest renders it less viscid and it can thus be drawn out more readily, without necessity for diluting it with fluids introduced from without. Silvestri has been using this method since 1896, but an account of it was published first by another, so it goes by the name of Kawahara's method. He describes here two typical cases, one in a boy and one in a man of 49, to illustrate the advantages of the method. He uses the Potain apparatus, pumping in more air at need to soften up and loosen the pus in the cavity.

Grèce Médicale, Athens

XLVII, Internal Medicine Nos. 1-4. J. G. Edgren Festschrift

Edgren Festschrift.—The sixty-fifth birthday of the professor of internal medicine at the University of Stockholm was celebrated by the presentation of this special and bulky volume of the *Archiv*. The title page states that it represents Nos. 1 to 4 of the 1914 issue of the medical section and Nos. 1 and 2 of the 1915 volume. It contains thirty-three articles by his friends and former pupils. All of them are either written in German or accompanied by a long German summary, with the exception of one article in French and one in English.

133 *The Red Corpuscles in Advanced Pulmonary Tuberculosis, Especially in Regard to Amyloid Degeneration. A. Gullbring.
134 Aneurysm of the Aorta Simulating Spinal Tumor. F. Kaijser.
135 Deformity of All the Finger Nails and Toe Nails, Developing Age of 17. (Onychogryphosis.) J. Strandberg.
136 Spinal Cord Tumor. (Rückenmarkstumor.) G. D. Wilkens.
137 Paratyphoid B Epidemic. A. C. Nilsson.
138 *Segmental Innervation of the Abdominal Muscles. (Quelle est l'innervation radiculaire des muscles abdominaux?) G. Söderbergh.
139 Alcohol and Epilepsy. C. Sebardt.
140 Traumatic Neuroses. J. Billstrom.

141 Purpura with Hemorrhagic Vesicles in Boy of 10. H. Lindvall.
142 *Variations in Growth and Virulence of Cholera Virus. P. G. Olsson.
143 Contribution to the Question of the Teratomata: Case of Epignathus. C. F. Heijl.
144 Shape of the Posterior Surface of the Human Cornea. (Form der hinteren Hornhautfläche.) W. Nordenson.
145 The Nitric Acid Test for Albumin. (Heller's Albuminprobe.) C. Cronquist.
146 Plague at Stockholm about the Seventeenth Century. (Pest während der Jahre 1657 und 1710.) K. Linroth.
147 *Examination of the Lungs. (Einige Hauptzüge der gewöhnlichen Lungenuntersuchung.) C. E. Waller.
148 *Acute Intoxication with Veronal. K. Mattisson.
149 Mixed Tumors in the Mediastinum. (Mediastinala blandningssvulsterna.) F. Lindstedt.
150 Content of Blood not Always an Index of Absorption of Sugar. (Zuckerresorption und Blutzuckerspiegel.) G. Bergmark.
151 *Treatment of Dangerous Hematemesis. (Om behandlingen af lifsfarliga magblödningar.) H. Lindberg.
The Changes in the Cortex of the Brain with General Paresis. (Om forändringarna i störa hjärnans bark vid paralysie générale.) H. Marcus.
153 *Treatment of Abscesses in the Lungs. (Behandlung eitriger Lungenaffektionen.) H. C. Jakobæus.
154 Congenital Stridor. (Der infantile Larynxstridor.) W. Wernstedt.
155 Case of Associated Splenomegaly, Anemia and Infantilism. L. Wolff.
156 Symmetrical Cyanosis of the Hands and Feet; Cure under Thyroid Treatment. (Acrocyanosis — Schilddrüsentherapie—Genesung.) A. Josefson.
157 Vital Staining of the Red Corpuscles. (Om vitalfärgning af röda blodkroppar.) O. Lindborn.
158 *Diagnosis and Treatment of Sagging Stomach. (Gastroptosens diagnos og behandling.) A. Troell.
159 Salvarsan in Treatment of Mercurial Stomatitis. J. Almkvist.
160 Free Thrombus in the Heart as Cause of Sudden Death. (Freie Herzthromben, speziell im linken Vorhof, als Ursache plötzlichen Todes.) J. Tillgren.
161 The Blood Findings in Case of Dementia Praecox with Periodical Fluctuations. (Blodundersökningar vid ett fall af dementia praecox.) G. Kahlmeter.
162 Test for Elastic Tissue in the Sputum. (Einfache Methode zum Nachweis von elastischem Gewebe im Sputum.) I. Hedenius.
163 Chondrectomy for Emphysema of the Lung. (Fall von nach Freund operiertem Lungenemphysem.) E. O. Hultgren and E. Key.
4 Diabetes Mellitus Following Contusion of the Liver Region. E. Salen.
5 The Metabolism, Especially the Metabolism of Minerals, in Two Boys. (Zur Kenntnis des Stoffwechsels und bes. des Mineralstoffwechsels im Knabenalter.) I. Jundell.

133. **The Red Corpuscles in Advanced Tuberculosis.**—ullbring tabulates the findings in 131 patients in the third tage of pulmonary tuberculosis. The largest numbers of eds were in the cases with symptoms suggesting amyloid egeneration. The signs of amyloid degeneration are the ard palpable liver and the changes in the nails known as 'watch-glass nails." Holmgren called attention in 1913 to his amyloid syndrome as he called it; he had found it ronounced in 85 per cent. of the cases of amyloid degeneration; in 88 per cent. of the patients with nails showing these changes there were unmistakable signs of amyloid degeneration. At necropsy in 32 cases Gullbring found pronounced amyloid degeneration in every case in which during life the liver could be felt large and hard and the nails were of this *Uhrglas* type. He excluded from the 131 cases listed here all those with hemorrhage, diarrhea or noticeable dyspnea or fever. The only American work cited by Gullbring is Swan's in The Journal, 1904, xlii, page 696.

138. **Innervation of Abdominal Muscles.**—Söderbergh compares what others have written on this subject with his own findings. He has noticed signs of paresis in certain muscles with tumors compressing certain roots, and thinks that analysis of such cases would supply data enabling us to locate a spinal tumor long before the symptoms usually depended n for the topical diagnosis have developed.

riations in Cholera Virus.—Olsson's report of his ultivation and study of cholera germ-cultures fills nd is accompanied by five full-page plates.

amination of the Lungs.—Waller mentions a num- inor points he has found useful. such as asking in det after the health of the father, the mother, the brothers, th sisters and children, instead of merely inquiring whether there is tuberculosis in the family. A negative general repl- is usually given while inquiring separately after the va members of the family revealed tuberculosis in near tives in 70 or 80 per cent. of all his sanatorium cases. inquiring as to the spitting of blood, other causes f than tuberculosis must always be borne in mind. monary tuberculosis does not always entail coughing, at f Ask the patient whether he has occasion to hawk at ti and if he brings up anything; also if he cannot sleep fortably in certain positions; many of the tuberculous treated for rheumatism alone.

148. **Acute Veronal Poisoning.**—Mattisson reports cases with the elimination of the drug in the urine const supervised. Fully 90 per cent. of the drug was cast o this way but the elimination proceeded very slowly, tinuing up to the eighth, tenth and twelfth days in his c

151. **Dangerous Hemorrhages from Gastric Ulcers.**—l berg tabulates the details of 68 cases of gastric ulcer *hemorrhage so severe as to raise the question of an em*ency operation; 5 died. These 68 cases were encountered at Faber's clinic at Copenhagen among 550 patients with ulceration in the stomach. All the 68 patients were given conservative treatment alone and in the 5 fatal cases necropsy showed that conditions could not have been remedied by operative measures. Comparison of all this material with the operative cases on record from other clinics has convinced Lindberg that surgical measures are never indicated in case of an acute hemorrhage from the stomach or adjacent bowel. On the other hand, recurring hemorrhages, especially when the anemia keeps up during the intervals, require operative treatment and it should not be delayed too long. Stimulants and saline infusion increase the tendency to hemorrhage. The foot of the bed can be raised, but morphin should not be given, not even when there is painful spasm of the pylorus. A subcutaneous injection of 400 c.c. of a 10 per cent. solution of gelatin can be given daily, and Lindberg has been very favorably impressed with the efficacy of rinsing out the stomach with a 1 per cent. solution of ferric chlorid. He pours 100 gm. of this into the stomach through a soft stomach tube and then pumps it out again after a few minutes. This is repeated until the fluid comes away clear, which is generally the case after four or five rinsings. Along with this he injects the gelatin.

153. **Abscess in the Lung.**—Jacobæus applied artificial pneumothorax after evacuation of the acute abscess in 3 cases and with marked benefit in 2; the other patient is still under treatment. In 2 cases of old foreign-body abscess he improved conditions materially by keeping the patient in bed for a week or so with the foot of the bed raised 30 cm. and the patient lying on the sound side. All this improved conditions for drainage so that the disturbances subsided. Afterward he slept nights in this position and when the disturbances returned again a few months later they were improved again by a course in bed as before. The hope has not yet been given up that the scrap of fir in the lung may still be coughed up.

In another foreign-body abscess there was no trace of anything wrong in the bronchi; the abscess was in the left hilus and what seemed to be a scrap of bone was finally coughed up. The absence of any lesion in the bronchi and of any history of a foreign body render plausible the assumption of a concrement developing in the lung. In 2 other cases there was a chronic abscess; one was opened up and cured. The other was of fourteen years' standing and an unsuccessful attempt to apply pneumothorax treatment did not avert the fatal outcome and possibly hastened it. In 2 cases of acquired bilateral bronchiectasia of ten years' standing, the phrenic nerve was severed on one side, followed by resection of part of the chest wall. The benefit from the phrenicotomy seemed to be marked, but the second patient did not survive the operation on the all.

158. **Diagno ent of Gastroptosis.**—Troell devotes 50 eight cases given operative treatm His conclusions are that to at is pathologic in

- *Tumors in the Sympathetic Nervous System and Suprarenals. (Om svulster i det sympatiske nervesystem og i binyrernes medullaris—og særlig om de maligne neuroblastomer.) F. Harbitz.
- *Injury from Competitive Athletics; Seven Cases. (Varig skade paa helbreden forvoldt ved idrætsøvelse.) P. Torgersen.
- Improved Technic for Determination of the Reaction of the Urine. H. F. Høst.
- *Chronic Intestinal Stasis. S. Widerøe.

66. **Tumors in the Sympathetic Nervous System and rarenals.**—Harbitz refers in particular to the tumors inating in the sympathetic nervous system and medulla the suprarenals; they are made up of undifferentiated ryonal nerve tissue and are of extremely malignant vth. In order to understand their development, the ryology of the sympathetic nerve must be comprehended, e explains in detail, illustrating his remarks with four cases from his own experience: a boy of 3 who did not survive the removal of the large neuroblastoma on the front of the sacrum; a six-months' infant apparently healthy until at five months he developed obstinate diarrhea and the abdomen protruded as the liver became much enlarged. Necropsy revealed a primary cystic tumor in the suprarenal medulla with metastases in the liver. In the third case the neuroblastoma in the sacral region was as large as the trunk of the four-months' fetus. The fourth was a fetus weighing 1,150 gm., the teratoma in the sacral region weighing 490 gm.

There are nearly fifty cases of true neuromas on record, he says, and almost all were in the sympathetic nervous system. This form of tumor does not generally incline to infiltration or metastasis. The malignant type of ganglioneuroma occurs only in children, as a rule, such tumors seeming to be less malignant in adults. The third type of tumors belonging in the category under discussion are the so-called paragangliomas or chromaffin tumors, located in the medulla of the suprarenals or carotid gland, of which from twelve to fifteen cases have been published. They are typical epithelial tumors on the borderline between benign and malignant growths. Sometimes they are merely diffuse hyperplasia and they may develop in persons with a tendency to multiple neurofibromatosis. The cases of this type on record are analyzed, including four cases of tumor in the carotid, all in adults, and all were removed without much difficulty. In conclusion Harbitz reports the case of a man of 47 with a large hypernephroma in the left kidney with numerous metastases, a cystic adenoma in the pancreas, a chromaffin tumor in the suprarenal region and another in advanced degeneration in the right kidney region. Most of these numerous tumors were of widely diverse structure. Thirteen illustrations accompany the article.

167. **Injury of the Previously Sound from Competitive Athletics.**—Torgersen comments on his experience that patients seldom or never connect any morbid manifestations later in life with athletic strain during their younger days, and the physician rarely inquires in regard to such antecedents. This is his explanation of the scanty literature in the Scandinavian countries on permanent injury from overstrenuous exercise. In the previously healthy the injury soon rights itself, as a rule, but that this is not always the case he shows by seven instances which he cites from a much larger experience, and is convinced that if physicians will bear this possibility in mind, many more such cases will

exceptionally strong and robust man of 20 after one we of training took part in a rowing match and was exhaust at the close, pale, trembling and vomiting, and for yea afterward complained of recurring pains in the heart regi and difficulty in breathing even after slight exertion. T trainer was a good executive and instructor but he lack the fundamental knowledge of physiology which wou have prevented his consenting to a man's entering the ra with only one week's training. In some of the other cas also the training was crowded into a few days and the m afterward proved unfit for military service; one develop chronic neurasthenia, blasting his career. Another you man after a good course of training had slight tonsilli the morning of the big race, but felt well, and temperatu and pulse were normal. He collapsed within 300 feet of t goal with signs of heart weakness and during the since then he often complains of shortness of breath and sensation of oppression. Valvular disease developed three others after training for ski work or for all-rou athletics; one student of 20 collapsed during a race, t others collapsed while keeping up vigorous gymnasiu exercise and working at a fatiguing business during the da

169. **Chronic Intestinal Stasis.**—Widerøe reviews his exp rience with 23 cases of this nature in his service since 191 The ages of the patients ranged from 17 to 71 and all b 5 were women. An operation was deemed necessary only 3 cases, and in these the appendix and the genital orga were found normal but the cecum was very large and loos with adhesions. In 16 cases the family physician had se the patient to the hospital urging an immediate operatio but in all the cases the trouble was merely chronic intesti stasis. Widerøe reviews the various disturbances whic stagnation of the feces is liable to entail; he also analyz the various factors liable to cause the chronic stasis, citin the details of a number of cases. In his own experience th patients paid no heed to their chronic constipation, and di not mention that intervals between stools of from two t eight days were the rule. In 2 cases there were symptom of incipient peritonitis and in another an attack of coli In 4 cases the vague pains in the stomach, back and lowe abdomen with dysmenorrhea led to the diagnosis of gynecologic trouble. In 2 others dyspepsia was the main disturbance. Roentgenoscopy may be necessary in case a kin or band is suspected as the cause of the constipation Mothers should be warned that children may be constipate even with a daily passage, and that this tendency to constipation may increase as they grow up, especially in girls. They must be taught to heed the slightest impulse to defecate, and be trained in regular habits in this respect. A few gymnastic exercises, including deep breathing, with a bland diet, will generally regulate bowel functioning in the young. At all ages, the food should contain nothing to irritate the bowel, no alcohol, coffee, sharp condiments, etc., and tobacco should be used sparingly if at all. Mayr advises exercising the abdominal and trunk muscles three times a day, by deep breathing, by rising from the horizontal to the sitting position without the use of the arms, bending the trunk forward and back and sideways during deep breathing, and bending the hip and knee, standing on the other foot. Widerøe adds that half a glass of cold water, fasting in the morning, with or without half a teaspoonful of cooking salt or Carlsbad salts may prove useful. Liquid paraffin is found of great benefit in some cases. It is not absorbed, he says
